Primary blast	Overpressure	Tympanic membrane injury, blast lung, intestinal blast injury
Secondary blast	Penetrating/ fragmentation	All penetrating injuries
Tertiary blast	Blunt	Blunt and crush injuries, traumatic amputation
Quaternary blast	Miscellaneous	Burns, inhalation injury
Quinary blast	Effect of device additions	Radiation sickness, infection

Primary blast lung injury, or blast lung, is the most widely researched blast phenomenon. The exact mechanism of blast lung remains contested but it depends on the propagation of energy from the shockwave into the lung tissue, where it causes disruption. Proposed mechanisms of injury include spalling (disruption of tissues at air–liquid interfaces), implosion (compression and re-expansion of air-filled structures) and rapid acceleration of tissues of different densities. Large animal models have demonstrated that the level of injury is related to the rate of chest wall displacement, rather than the maximal depth of deflection.[23] The severity of injury is dependent on the strength of the blast, the range from detonation and the surrounding environment.

Those working closely with explosives may wear personal armour that assists in decoupling the effect of the primary blast. Current examples of such armour tend to be cumbersome. More common varieties of torso body armour provide protection against penetrating injury but probably do little to mitigate the effects of primary blast.

The pathophysiology of blast lung includes both immediate and delayed responses. There is an immediate bradycardia and apnoea of variable length, which is likely to be a vagally mediated reflex.[24] The lung injury itself is typified by alveolar capillary rupture with subsequent intrapulmonary bleeding and oedema. The extent of this injury is proportional to the blast exposure and may range from microscopic petechial injury to areas of frank haemorrhage.

While rarely seen in isolation, primary blast may leave little external evidence of injury since the skin itself is rarely affected. Clinical features of blast lung include progressive hypoxia, which may not be apparent at the time of injury and is related to the inflammatory response to intrapulmonary haemorrhage and worsening oedema.

Other structural lung injuries are associated with primary blast, although the prediction of these injuries by blast conditions is not consistent and is likely to be complicated by tertiary impact. Pneumothoraces may occur as a result of pleural rupture in the absence of penetrating injury. Injury to the larger vessels may lead to haemothoraces and the formation of alveolar–venous or bronchovenous fistulae. Air embolism due to such fistulae may cause acute hypoxia with cardiovascular collapse and is a leading cause of death in those who do not survive until treatment.

The diagnosis of blast lung is clinical with findings of hypoxia following blast exposure. Typical 'bat-wing' pulmonary infiltrates are seen on the chest radiograph and computed tomography may discriminate these injuries from the more peripheral contusions seen in blunt trauma. Imaging may be useful in detecting associated structural lung injuries.

Treatment of blast lung is largely supportive. Mechanical ventilation may be required but consideration should be given to the possibility of air embolism and pneumothorax that may be exacerbated. Some centres advocate the use of prophylactic bilateral pleural decompression, although there is little evidence to suggest an effect on outcomes. Patients with significant blast lung injury are highly likely to have sustained other blast-related injuries and any management plan should consider their overall condition.

The abdomen may also be subject to primary blast. The incidence of abdominal injury due to air blast has not been extensively examined, although a recent review of multiple incidents, including a variety of blast conditions, showed that abdominal injury is not common – seen in around 3% of incidents.[25]

Damage is dependent on coupling of the blast overpressure and the shockwave to a stress wave that travels through the abdomen. The effect of shockwave dispersal is most marked at tissue–air interfaces. As such, the hollow organs are those most commonly injured. The caecum is probably most sensitive to intestinal blast injury. Conversely, the small bowel and its extensive mesentery may be more susceptible to large shear waves causing mesenteric tearing.

The presentation of primary blast injury to the bowel may be delayed relative to the acute onset of blast lung. Abdominal symptoms may be absent initially with progression to pain and frank peritonitis, should perforation and contamination occur. Given the lack of external injury, indications for operative intervention are largely clinical, as with conventional blunt abdominal trauma. The patient should be assessed anaesthetically with particular consideration to the effect of anaesthesia and ventilation on any concomitant blast lung injury.

The most common operative finding of intestinal blast is subserosal haemorrhage.[25] Tearing of the mucosal surface with bleeding into the lumen of the tract may occur following repeated exposure to relatively lower blast overpressures. As in blunt injury, there is a propensity for mural haematomas to progress to perforation as a result of tissue necrosis. Full-thickness injuries to the bowel with immediate perforation can occur with a greater exposure to blast overpressure.

The surgical management of blast bowel injury is that of any penetrating and blunt trauma, with primary repair or resection as indicated. Surgical judgement is essential regarding the findings of non-perforated but contused bowel. A damage control approach to such injuries may allow for repeat assessment later, but in a physiologically well patient, in whom a relook would not be justified, the surgeon must decide to resect a segment or risk future progression of these lesions to perforation.

The solid organs are more resistant to primary blast. Parenchymal disruption due to the shockwave has been described at very high levels of overpressure, although the experimental data for these injuries are sparse. Injury, with subsequent bleeding, may result from rapid distractions of organ attachments and mesenteries. These blast conditions are more likely to be encountered in enclosed conditions and differentiation of primary from tertiary injuries is difficult.

Secondary blast injury

Secondary blast injury refers to the effect of fragments that are accelerated away from the device following detonation. Sources of fragments include:

- the casing of the device;
- purposefully placed fragments within the device; these may include nails, bolts or ball bearings and are embedded within the device or adherent to the exterior;
- nearby objects including glass and stones;
- biological material including bone may be expelled, particularly following a suicide bomb or antipersonnel mine attack.

Figure 34.5 Large anterior fragmentation injury.

Shrapnel is often used to describe explosive fragments, although the term is more strictly applied to a specific form of artillery shell.

The energy of a primary blast wave disperses quickly in proportion to the distance from the blast; it is subject to the inverse cube law. As such, only those within a reasonably small radius of the blast are affected. Conversely, the velocity and wounding potential of an energised fragment are subject to the inverse square law. Secondary blast injuries may occur at long range from the detonation. Fragments may be accelerated up to very high velocities. As with ballistics, injuries are dependent on the range and energy of the fragment.

In contrast to bullet wounds, the variability of fragments produces a wide range of wounds and no two wounds will be the same (***Figure 34.5***). The irregular surfaces of fragments cause complex patterns of yaw and tumble. Both permanent and temporary wound cavities may be unpredictable and irregular.

The management of fragment wounds is similar to ballistic and conventional penetrating trauma. Wounds should be adequately debrided. Fragment wounds should be considered dirty and principles of septic surgery applied. Where possible, serial debridement and delayed primary closure should be attempted.

The fragments should be removed at the time of surgery if easily accessible. Other indications for early removal include fragments within joint spaces or adjacent to structures with danger of erosion and further injuries. Late indications for fragment removal include ongoing sepsis, pain or lack of function.

Tertiary blast injury

Tertiary blast injury is the result of gross movement of personnel, objects or infrastructure by blast wind. Tertiary injury is

analogous to conventional blunt trauma and may cause a wide variety of injuries to all organ systems. Traumatic amputation is typically included within this category, although primary blast and the shattering or 'brisance' effect on bone may play a part.

Quaternary and quinary injury

Quaternary blast injury refers to a miscellaneous group of injuries that do not fall within other categories. These include burns, inhalational injuries and late-onset respiratory problems. Quinary injury refers to injury caused by the intentional addition of either biologically or radioactively active material to an explosive device.

Environmental effects

As already alluded to, the shockwave of blast overpressure is modified by an enclosed or partially enclosed space. Environmental variations may make marked differences to injury rates and clinical presentations following blast. Higher rates of blast lung and TM rupture are seen following enclosed blast (in which both the casualty and blast are enclosed). In contrast, secondary blast injuries may be lower in number as more people are protected from energised fragments. Tertiary injury is difficult to predict based on blast characteristics but a higher proportion of blunt injuries have been seen following enclosed blast.

A distinct pattern of injury has been described following underbody blast against military vehicles. Underbody blast casualties have a greater range of injuries and are overall more severely injured.[26] In addition to blunt injury sustained from displacement within the vehicle, the effect of blast is manifested by propagation of the shockwave through a solid, with both upwards deformation of the floor and a rapid upwards acceleration of the whole vehicle and subsequent deceleration following impact with the ground. The solid blast injury burden includes severe foot and ankle[27] and pelvic injuries.[28] Mortality from underbody blast is most commonly caused by head injury and non-compressible torso haemorrhage, including aortic disruption and liver laceration.[29]

Complex dismounted blast injury

In contrast, the dismounted IED casualty may sustain a characteristic pattern of injuries, including lower limb amputation, pelvic fracture and genital, perineal and rectal injuries.[30,31] The most common cause of death in such casualties is from haemorrhage.[26] Initial management is therefore focused upon control of bleeding with tourniquets and swift proximal vascular control. This group may in the future benefit from the judicious use of resuscitative endovascular balloon occlusion of the aorta (REBOA) as a bridge to definitive control.[14,32] The role of REBOA in civilian trauma remains greatly contested and its use in military and austere settings may be complicated by long timelines entailing a prohibitively high burden of ischaemic injury.

Following control of bleeding and DCR, management principles for complex dismounted blast injury include the identification and repair of specific injuries, with serial debridement and delayed reconstruction of soft tissues.

Orthopaedic considerations include external fixation of pelvic injuries and the retention of maximal limb length for rehabilitation. High rates of rectal injuries require careful rectal examination with proctoscopy and early consideration of faecal diversion. Genitourinary injuries should be managed with careful catheterisation if possible (and consideration of suprapubic catheters) with exploration of scrotal wounds.[33]

INFECTION

Battlefield wounds are by their very nature grossly contaminated and the treatment and prevention of infection is one of the basic functions of war surgery. Wounds sustained during warfare are high-energy wounds with large areas of devitalised tissue. This is particularly the case for dismounted blast injuries where there is massive disruption of tissue planes with soil and debris forced into the zones of injury (***Figure 34.6***).

Wounding agents are all non-sterile and highly likely to be contaminated by bacteria. Both large-calibre ballistic wounds and blast wounds may contain dirty clothing or contaminated fragments. Multiple steps in casualty evacuation and substantial delays before treatment may allow progression of contamination to clinically significant infection.

Specific organism patterns will depend on endemic flora, but commonly seen bacteria include:

- Gram-positive cocci, including staphylococci, streptococci and enterococci;
- Gram-negative rods, including *Escherichia coli*, *Proteus* and *Klebsiella*;
- *Pseudomonas*, *Enterobacter*, *Acinetobacter* and *Serratia* are common nosocomial pathogens that are usually expected among casualties following long periods of hospitalisation;
- *Salmonella*, *Shigella* and *Vibrio* should be suspected in cases of bacterial dysentery.

Fungal infection, including *Candida*, should be considered in casualties hospitalised for prolonged periods, those who are malnourished or immunosuppressed or those who have received broad-spectrum antibiotics, adrenocortical steroids or parenteral nutrition.

Techniques to reduce the infectious burden are part of every aspect of war surgery. At the point of wounding, sterile dressings should be applied. Antibiotics, if available, should be administered if evacuation and further treatment are likely to be delayed.

Empirical antibiotic therapy should be commenced or continued following movement to a medical facility. The mainstay of treatment is prompt surgical control of the infectious cause with adequate debridement of non-viable tissue and drainage of infective material. Extensive irrigation should be employed to remove dead tissue and foreign bodies. High-pressure wound lavage has been shown to increase bacterial propagation into soft tissue and is not indicated.

With few exceptions (such as facial wounds), closure of contaminated war wounds should not be performed at the time of first operation. The open wound should be left with clean,

Figure 34.6 Blast injuries including bilateral lower limb amputation **(a)**, buttock and thigh soft tissue injury **(b)** and complex hind foot injury **(c)**. The need for extensive debridement is evident from the level of wound contamination and non-viable tissue.

moist dressings. Negative pressure wound therapy should be considered for larger wounds.

Antibiotic therapy should be tailored to specific wounds with the empirical antibiotic choice dependent on the injured body region or cavity. Microbial culture will aid the guidance of therapy for more established infection. Contaminated war wounds should be considered tetanus prone and appropriate tetanus prophylaxis administered.

Clinical experience and judgement are essential in the assessment of war wounds. Adequate exposure, often with extension of the wound, is mandated to ensure debridement of all devitalised tissue. Serial operations may be required. Early consideration should be given to soft-tissue coverage. The skin is often remarkably resilient to injury and conservative debridement of it may facilitate more successful reconstruction.

PART 5 | Elective orthopaedics

CHAPTER 35

History taking and clinical examination in musculoskeletal disease

Learning objectives

To understand how to:

- Take a comprehensive musculoskeletal history
- Perform a structured and systematic musculoskeletal examination
- Use and interpret special tests
- Use findings to understand the impact on a patient's pain and function

INTRODUCTION

The components of the musculoskeletal (MSK) system include the bones, joints, ligaments, muscles and tendons as well as the neurological and vascular structures. A simple system allows a concise yet comprehensive history to be taken and a reliable examination to be performed. This will permit diagnosis of the common, the rare and the clinically urgent MSK problems that are likely to be encountered in clinical practice.

HISTORY

Introduction

- Ensure you have followed appropriate hand hygiene guidance.
- Introduce yourself and check the patient's name and date of birth.
- Request presence of a chaperone as appropriate.
- Explain what you are going to do, obtain verbal consent and ensure that the patient is comfortable.

Take a history

- **Presenting complaint**. Start with an open-ended question. Ask the patient to 'explain what the problem is' in their own words and ask the patient what their hopes and expectations are from the interview.
- **History of the presenting complaint ('the three Ws')**. **W**hen did you first notice the problem? **W**hat were you doing when it started? **W**as the onset sudden or did it develop gradually?
- **Associated symptoms**. Ask about the following: pain; swelling; instability – 'giving way'; mechanical symptoms (e.g. locking, clicking, clunking); loss of power; altered sensation.
- **Functional impairment**. Ask whether the patient is having difficulties performing activities of daily living: upper limb, e.g. personal hygiene, feeding; lower limb, e.g. putting on shoes and socks, standing, walking and climbing stairs.
- **Past medical history (PMH)**. Check for comorbid conditions which may contribute to the presenting problem or affect the patient's fitness for an anaesthetic, e.g. diabetes, asthma, previous heart attack or stroke. Check for any previous problems with anaesthesia.
- **Past surgical history**. Ask about relevant surgical procedures.
- **Drug history**. Ask about all medication and the following in particular: anticoagulants, steroids, aspirin, immunosuppressant therapy, oral contraceptive pill and hormone replacement therapy.
- **Social history**. Tailor questions to the patient's condition: patient's age; hand dominance; employment status; dependants; alcohol consumption; smoking; hobbies; home help; accommodation – own house, residential or nursing home; use of walking aids; mental test score assessment.
- **Family history**. This may reveal a history of MSK disease.

Summary box 35.1

Taking a history

- Introduce yourself and put the patient at ease
- Explain what you are doing and ensure that the patient agrees
- Start with an open question to understand the presenting complaint
- Check for history of the presenting complaint and associated symptoms
- Ask about functional impairment
- Check past medical history and relevant surgical and family history
- Check drug and social history

MUSCULOSKELETAL EXAMINATION

General principles

Apley described a useful and systematic approach to clinical examination. This approach is divided into three parts:

1 look;
2 feel;
3 move.

Look

The inspection begins as soon as you enter the examination room. Look for any walking aids. Remember to look at the whole patient and not just at the joint of interest. For example:

- look at the hands for rheumatoid arthritis;
- look at the eyes for Horner's syndrome;
- look for any obvious upper or lower limb or spinal deformity.

Gait

The gait cycle is all of the activity between the initial contact of the foot with the ground and the succeeding initial contact of the same limb. There are two main stages: the stance phase (60%) and the swing phase (40%). Ask the patient to stand, and inspect from the front, side and back. Then, ask the patient to walk using any walking aids. Some of the types of limp that might be present are described in ***Table 35.1***.

Focused inspection

Adequately expose the joint above and below. Expose the opposite limb for comparison. Make sure that the patient is comfortable. It may be easier for you and the patient if they remain standing for the first part of the examination. When a couch is used, make sure that it is in the centre of the room (not against the wall) so that you can work on both sides of the patient. Remember that all joints are covered by an envelope of soft tissues and skin. Look at the skin for:

- surgical scars (arthroscopy scars may be difficult to see);
- bruising (may indicate recent injury or a bleeding disorder);
- erythema (e.g. cellulitis);
- ulcers (e.g. arterial, vascular or neuropathic);
- rashes;
- sinuses (e.g. secondary to osteomyelitis);
- hair loss and the presence or absence of sweating;
- pigmentations or raised lesion (e.g. café-au-lait spots or neurofibromas).

Look at the soft tissues for:

- swelling (e.g. may indicate a joint effusion);
- lumps (consider which tissue layer they are arising from);
- muscle wasting (e.g. may be secondary to disuse atrophy, neuropathy);
- muscle fasciculation (lower motor neurone pathology).

Look at the bones for:

- abnormal limb alignment – comparison with the other side may be helpful;
- deformity.

Feel

Ask the patient if they have any areas of tenderness. Ensure that you do not cause the patient pain – watch their face as you feel. It may be easier (especially with children) to feel the normal side first.

TABLE 35.1 Types of limp.

Cause	Pathogenesis	Presentation
Long	Osteoarthritis (in other leg)	Head dips. Cadence dash/dash
Incoordinated	Cerebral palsy	Head movement lacks coordination. No regular cadence
Muscle weakness	Osteoarthritis hip	Head moves from side to side (windscreen wiper)
Pain	Osteoarthritis hip	Head dips. Cadence dot/dash
Stiff	Arthrodesis hip	Head rocks to and fro
Limp	**Pathology**	
Antalgic	Hip joint arthritis	
Trendelenburg	Weakness of hip abductors	
High-stepping gait	Foot drop secondary to common peroneal nerve palsy	
Spastic	Cerebral palsy	
Ataxic	Cerebellar pathology	

Alan Graham Apley, 1914–1996, Director of Orthopaedic Surgery, St Thomas' Hospital, London, UK. As a consultant also at Rowley Bristow Orthopaedic Hospital, he conducted the most popular orthopaedic postgraduate course for the FRCS examination in Pyrford, UK, which became internationally known as the 'Pyrford Orthopaedic Course'.
Johann Friedrich Horner, 1831–1886, Professor of Ophthalmology, Zurich, Switzerland, described this syndrome in 1869.
Friedrich Trendelenburg, 1844–1924, Professor of Surgery successively at Rostock (1875–1882), Bonn (1882–1895) and Leipzig (1895–1911), Germany. The Trendelenburg position was first described in 1885.

Skin

The aim of sensory testing is to establish a pattern of sensory loss. Look for a dermatomal (may indicate spinal root or peripheral nerve pathology) or glove-and-stocking distribution (may indicate a neuropathy, e.g. diabetes). Perform a screening test by lightly stroking both limbs. Record whether the patient feels a difference. If none is noticed there is no need to spend more time on the neurological examination. If there is a difference, then a full neurological examination should now be performed.

Soft tissues

- **Tenderness**. Try to determine the actual anatomical structure from which the pain arises (e.g. subcutaneous fat, bursae, nerves, arteries).
- **Lumps and effusions**. Determine the characteristics of any lump or effusion using *Table 35.2* as a guide.
- **Pulses**. Palpate the distal pulses (or capillary return) of the limb. Recording distal neurovascular status both before and after surgery is important. Absence of distal pulses is an absolute contraindication to elective surgery in that limb. Acute loss of circulation to a limb is a surgical emergency.

Bone

Palpate the contours of the joint and assess for tenderness. For superficial joints, such as the knee, the joint line can be felt and checked for lumps and tenderness.

Move

There are three stages to assessing movement. The words used to describe a particular movement are shown in *Table 35.3*.

- **Active**. Ask the patient to move the joint within the limits of their pain.
- **Passive**. Move the limb or joint yourself. Record the range of movement in 'degrees' (a goniometer may be helpful). Comparison of active and passive range allows the three causes of loss of range of movement to be distinguished. In limitation caused by pain or stiffness the ranges are the same but one is painful. In weakness passive range is greater than active.

TABLE 35.2 Swelling: an acronym for history and examination of a lump.

Start	Did it appear after trauma or gradually on its own?
Where	Anatomical site and layer (skin, fat, muscle); does it move in relation to these?
External features	Size, surface and definition of margins
Lymph nodes	Are the local ones enlarged?
Liquid	Is it fluctuant? Can it be transilluminated?
Internal features	Is it hard? Is it tender?
Noise	Is there a thrill? Is there a bruit?
General	Examination of the whole patient for general lumps

TABLE 35.3 Terminology used to describe the direction of movement.

Flexion	Forward or anterior movement of the trunk or limb
Lateral flexion	Bending of the forward-facing head and trunk to either side
Extension	Backward or posterior movement
Abduction	A movement away from the midline of the body
Adduction	A movement towards the midline of the body
Internal rotation	Rotation towards the midline of the body
External rotation	Rotation away from the midline
Supination	Movement of the forearm so that the palm faces anteriorly
Pronation	Movement of the forearm so that the palm faces posteriorly
Circumduction	A combination of flexion, abduction, extension and adduction without rotation
Inversion	Movement of the foot that directs the sole of the foot medially
Eversion	Movement of the foot that directs the sole of the foot laterally
Retraction	Backwards movement of the head, jaw or shoulders

- **Stability**. Stability has a static and a dynamic component: static tests assess the integrity of the ligaments and joint (bone) surfaces; dynamic tests assess the integrity and functions of the muscles and tendons. Ask the patient to move the joint actively through its range of motion while you try to stop the movement. Record power using the Medical Research Council (MRC) grading system as illustrated in *Table 35.4*. Consider the muscles that drive each movement, the peripheral nerves that supply them and the nerve root values (*Table 35.5*).

In the following sections, in addition to the approach of 'look, feel, move', we have included details of special tests for each joint as well as neurological examination of the limb. The peripheral nerve examination comprises sensory and motor testing, reflexes, tone and coordination and proprioception.

TABLE 35.4 The Medical Research Council grading system of muscle power.

Grade	Description
0	No movement
1	Flicker of movement
2	Active movement with gravity elimination
3	Active movement against gravity
4	Active movement against resistance but power less than full
5	Normal power

TABLE 35.5 Peripheral nerves.

Root level	Sensation	Motor	Reflex
C5	Lateral upper arm	Deltoid	Biceps
C6	Lateral forearm	Wrist extension	Brachioradialis
C7	Middle finger	Triceps	Triceps
C8	Little finger	Finger flexors	–
T1	Medial forearm	Interossei	–
L1	Anterior thigh	Psoas	–
L2	Anterior thigh/groin	Quadriceps	–
L3	Anterior and lateral thigh	Quadriceps	–
L4	Medial leg and foot	Tibialis anterior	Knee jerk
L5	Lateral leg and first dorsal web space	Extensor hallucis longus	–
S1	Lateral and plantar foot	Gastrocnemius/perineals	Achilles
S2–S4	Perianal	Bladder and foot intrinsics	–

Assessment of joint hypermobility

Increased movement and flexibility of a joint can often cause joint pain and symptoms of instability. A formal assessment of joint mobility can help document the degree of mobility. The Beighton score alone cannot be used to diagnose hypermobility in terms of its underlying causes; however, it acts as a standardised clinical assessment across both upper and lower limbs and the spine.

The Beighton score is calculated as follows (***Figure 35.1***):

- 1 point if, while standing forward bending, the patient can place their palms on the ground with legs straight;
- 1 point for each elbow that bends backwards;
- 1 point for each knee that bends backwards;
- 1 point for each thumb that touches the forearm when bent backwards;
- 1 point for each little finger that bends backwards beyond 90°;
- total score out of 9.

Summary box 35.2

MSK examination

- Hand hygiene and chaperone presence
- Introduce yourself and put the patient at ease
- Assess the gait
- Look
- Feel
- Move
- Special tests

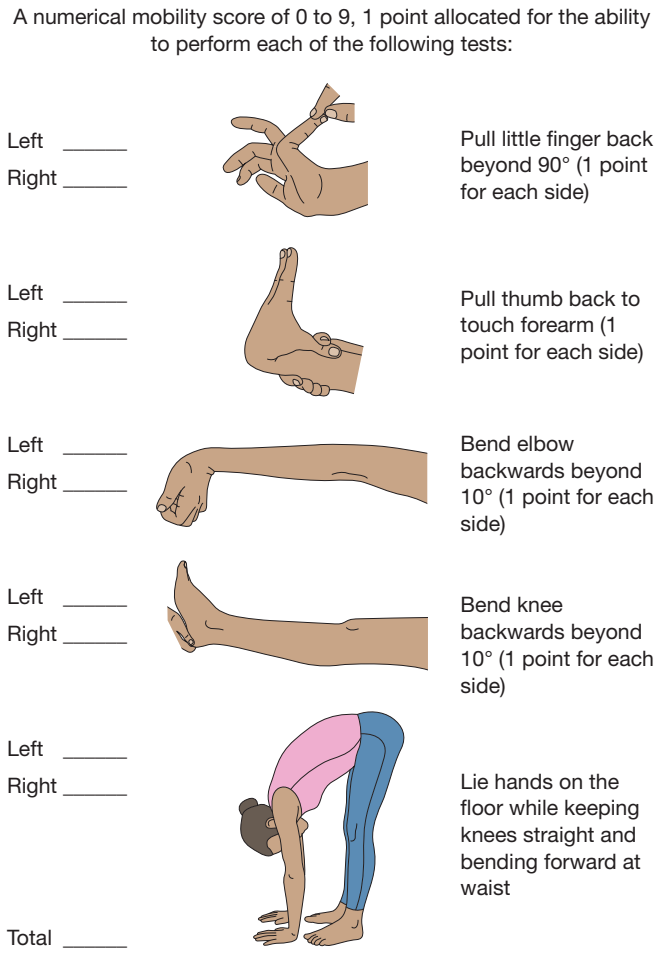

Figure 35.1 Beighton score (a screening technique for hypermobility).

Peter H Beighton, b. 1934, British medical geneticist. With Francis T Horan published 'Orthopedic aspects of the Ehlers-Danlos syndrome' in 1969.

CLINICAL EXAMINATION OF THE SPINE

The spinal column consists of 33 vertebrae with 23 intervertebral discs. This is supported by numerous ligaments and paraspinal muscles.

When observed from the front (coronal plane) with the patient standing and the hips and knees fully extended, the head should be centred over the sacrum. A 'plumb line' dropped from the spinous process of C7 should fall through the gluteal crease (*Figure 35.2*). If it falls to either side of the cleft, lateral tilt of the spine is present. The ear, shoulder and greater trochanter of the hip should lie in the same vertical plane. When the patient is observed from the side, assess the four physiological sagittal plane curves (cervical and lumbar lordosis, and thoracic and sacral kyphosis) (*Figure 35.3*).

Figure 35.2 Plumb line.

Cervical spine

Look

Ensure that the shoulders, back muscles and scapulae can be seen. Look for muscle wasting and asymmetry of the neck creases and check that the shoulders are level and that there is a normal cervical lordosis (range 20–40°).

Feel

Stand behind the patient and support the patient's chin.

- **Soft tissues**. Feel for spasm of the paraspinal muscles.
- **Bone**. Palpate the spinous processes (tenderness and alignment); the spinous processes of C7 (vertebra prominens) and T1 are usually large and are easily palpable at the base of the neck.

Move

Motion occurs in three planes: flexion/extension, lateral bending and rotation (*Figure 35.4*).

- **Flexion (45°)/extension (55°)**. Ask the patient to bend their neck forwards – place the chin on the chest. Measure the distance from the chin to the sternum. Ask the patient to extend their neck by looking up at the ceiling.

Figure 35.3 (a) Standing sagittal profile showing cervical and lumbar lordosis, with thoracic kyphosis. (b, c) Normal alignment whole spine from front and behind patient.

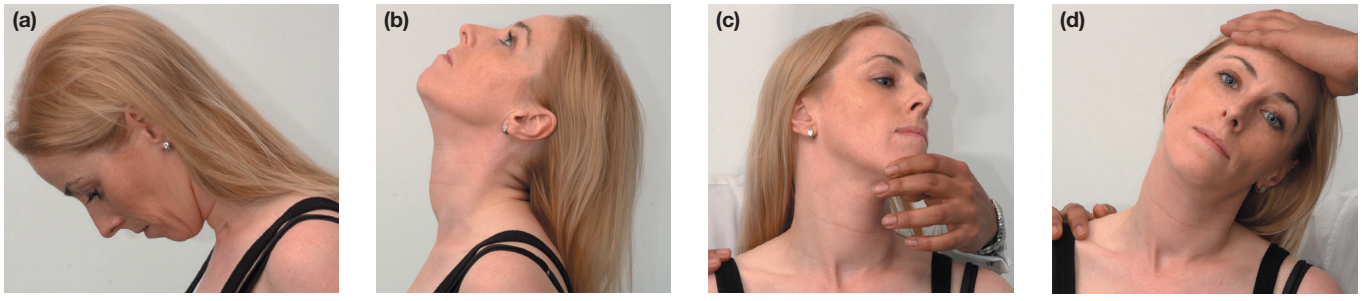

Figure 35.4 Cervical spine flexion/extension (a, b), rotation (c) and bending (d).

- **Right/left rotation (70°)**. Ask the patient to look over each shoulder while not moving the chest wall.
- **Right/left lateral bending (40°)**. Ask the patient to lay their ear on their ipsilateral shoulder.

Neurological

Focus your examination on the C5 to T1 nerve roots. These supply the upper extremities (*Figure 35.5*).

Figure 35.5 Spurling's test for cervical spine nerve root entrapment. The examiner turns the patient's head to the affected side while extending and applying downward pressure to the top of the patient's head.

Thoracic spine

Pathology commonly presents with pain and deformity. The thoracic spine is normally convex with a gentle kyphosis (normal range 20–45°).

Look

Ensure that the front and the back from the neck to the gluteal cleft can be visualised. Note skin markings (e.g. café-au-lait spots, hairy patches). These may suggest occult neurology or bony pathology.

- **Front**. Check for asymmetry of the shoulder and ribcage suggesting scoliosis.
- **Back**. Look for a difference in the height of the iliac crests (pelvic tilt). Assess for coronal plane deformity, such as scoliosis (lateral curvature of the thoracic spine with rotation). A rib hump suggesting a structural scoliosis may be visible.
- **Side**. Assess for sagittal plane deformity, such as an increased kyphosis.

Feel

Palpate, with one hand supporting the patient's pelvis.

Move

Range of motion is limited in the thoracic spine:

- **Forward bending test** (*Figure 35.6*). Ask the patient to bend forwards to touch their toes:
  - *structural scoliosis*: a rib hump will increase in size (bulge posteriorly on the thoracic convex side) as the patient bends forwards; this is diagnostic of idiopathic thoracic scoliosis (rotatory deformity);
  - *functional scoliosis*: the spine straightens as the patient bends forwards and no rib hump is visible; this flexible deformity is secondary to other abnormalities such as abnormal leg lengths and muscle spasm in the lumbar region.
- **Lateral bending**. This can be used to assess the flexibility of a scoliosis. Radiographs can be taken in this position to supplement the assessment.

Lumbar spine

Examination should include the pelvis, hips, lower limbs, gait and peripheral vascular system as well as the lumbar region. Irritation of nerves in the lumbar spine can mimic problems in the lower limb. Always consider referred pain.

Look

- **Back**. Check the skin at the base of the spine for hairy tufts and dimples (underlying spina bifida). Prominence of the spinal muscles on one side may be the result of muscle spasm secondary to pain.
- **Side**. The lumbar spine has a smooth concavity known as the lumbar lordosis (normal range is 40–60°). Muscle spasm is a cause of loss of the normal lordosis.

Roy Glenwood Spurling, 1894–1968, American neurosurgeon, first described the Spurling test with William Beecher Scoville.

Figure 35.6 (a–c) Forward bending test.

Feel

Feel for any 'step-off' in the spinous processes. This may indicate forward slippage of one of the vertebrae on another.

Move

Movement occurs in flexion, extension, lateral bending and rotation (*Figure 35.7*). Record the motion in each plane in degrees. Remember that a significant portion of lumbar flexion is achieved through the hip joint.

- **Forward flexion**. This is a measure of lumbar flexibility. The skin of the lumbar spine stretches as the patient bends forwards. To measure flexion, place the tip of your thumb over the T12/L1 junction and the tip of your index finger of the same hand over the lumbosacral junction. Ask the patient to bend forwards and touch the toes (normal range 40–60°). Measure the distance by which your thumb and the tip of your index finger separate.
- **Lateral bending**. Ask the patient to slide their right hand down the outside of their right leg and then their left hand down the outside of their left leg. Note the distance that each hand moves down that side of the thigh.
- **Rotation**. Stand behind the patient and hold their pelvis still with both hands. Ask the patient to twist around and look over their shoulder. Note the angle that the shoulder girdle forms with the pelvis (range 3–18°).

Special tests

- **Lasègue's straight leg raise test** (*Figure 35.8*). This test increases tension along the sciatic nerve (L5 and S1 nerve roots). With the patient supine, elevate the leg with the knee bent to check pain-free movement of the hip. Then, straighten the knee and note the angle at which the hamstrings allow the hip to flex. Finally, allow the hip to extend until tension is removed from the hamstring muscles and then the ankle is dorsiflexed firmly (but without excessive force), which in turn pulls on the sciatic nerve. If the patient experiences pain running down the leg, then the test is positive.

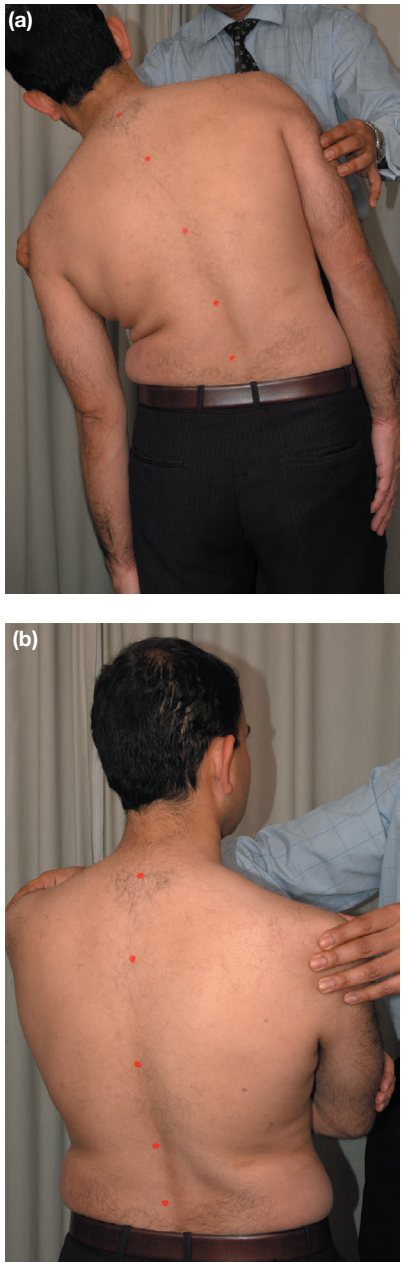

Figure 35.7 Lumbar examination; lateral bending (a) and rotation (b).

Charles Ernest Lasègue, 1816–1863, Professor of Medicine, University of Paris, and Physician, La Salpêtrière, Paris, France. This test was described by Lasègue's student, who named it after his teacher.

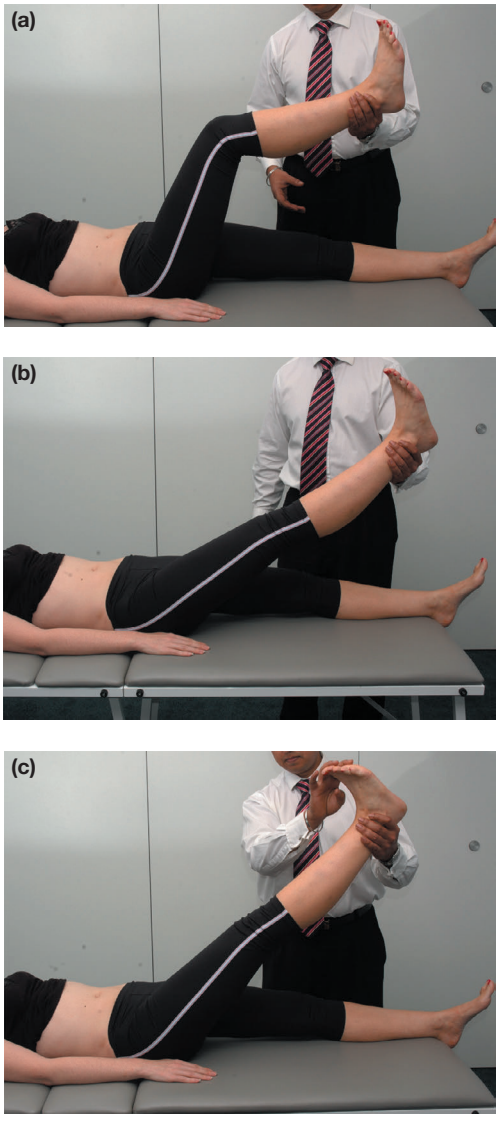

Figure 35.8 (a–c) Lasègue's straight leg test.

- **Contralateral stretch test**. Elevate the asymptomatic leg; if pain is reproduced in the other leg the test is considered positive.

CLINICAL EXAMINATION OF THE HAND AND WRIST

The hand and wrist should be thought of as one functional unit. The muscles may be divided into extrinsic (the muscle bellies in the forearm) and intrinsic (origins and insertions within the hand alone). The 'flexors' (volar side) flex the wrist and fingers and the 'extensors' (dorsal surface) extend the digits and fingers.

Summary box 35.3

Spine examination

- Inspection of the standing patient
  - From the front and back (coronal plane)
  - From the side (sagittal plane)
- Palpation
  - Palpation of the posterior bony elements and the paraspinal muscles
- Move
  - Assess flexion, extension, lateral rotation and lateral bending
- Neurological
  - Assess sensation, tone, power, reflexes, proprioception and coordination
- Special tests
  - Spurling's test
  - Forward bending test
  - Lasègue's straight leg test
  - Contralateral stretch test

Look

Inspect the posture of both hands. A nerve lesion will produce a specific resting position (e.g. an ulnar nerve lesion will produce clawing of the little and ring fingers).

- **Skin**. Assess for scars, discoloration (café-au-lait spots, erythema) and loss of hair. The nails may reveal systemic disease (e.g. psoriatic pitting). Look for tight bands in the palm (Dupuytren's contracture). Loss of sweating is seen in complex regional pain syndrome.
- **Soft tissue**. Centrally located swellings at the wrist may indicate a ganglion arising from the wrist joint itself; de Quervain's tenosynovitis may present with a swelling around the radial styloid.
- **Muscle wasting**. Check for thenar, hypothenar (*Figure 35.9*) and intrinsic muscle wasting. To assess thenar eminence wasting, place the hands side by side with the thumbs upwards and look down and compare the thenar regions. Patterns of muscle wasting are shown in *Table 35.6*.
- **Bones**. Look for bony deformity (dinner fork deformity, Colles' fracture). Typical bony deformities are described in *Table 35.7*.

TABLE 35.6 Patterns of muscle wasting in the hand.

Thenar wasting	Median nerve palsy (C8)
Hypothenar wasting	Ulnar nerve palsy (T1)
Intrinsic wasting	Ulnar nerve palsy (T1)

Baron Guillaume Dupuytren, 1777–1835, surgeon, Hôtel Dieu, Paris, France, described the condition in 1831.
Friedrich Joseph de Quervain, 1868–1940, Professor of Surgery, Berne, Switzerland, described this form of tenosynovitis in 1895.
Abraham Colles, 1773–1843, President of the Royal College of Surgeons of Ireland (1802), Professor of Anatomy, Physiology and Surgery (1804) and described distal radial fracture in 1814.

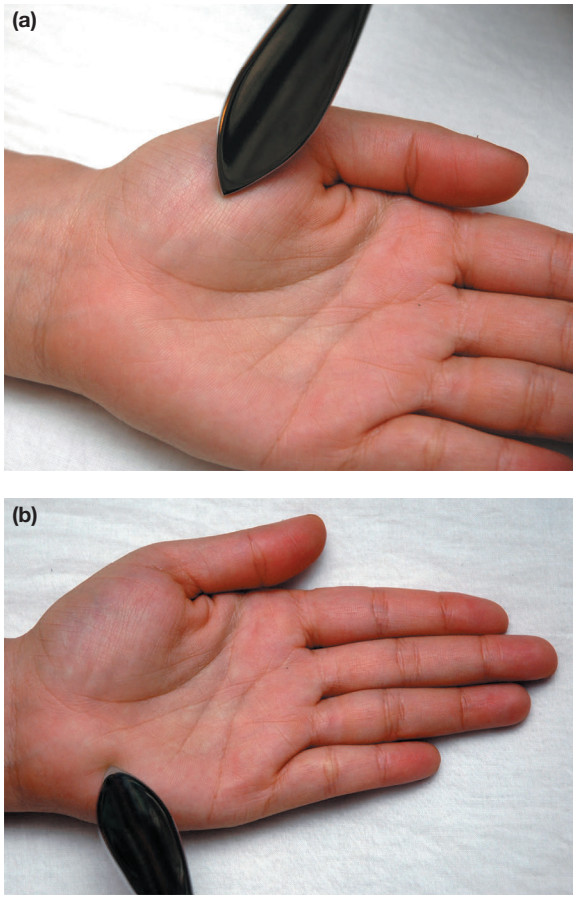

Figure 35.9 Thenar (a) and hypothenar (b) wasting.

Feel

- **Skin**. If there is any question of abnormal sensation on a simple stroke test comparing both sides, proceed to the two-point discrimination test using the sharp ends of a paper clip. Record the minimum distance between the tips of the paper clip at which the patient is able to recognise two points. ***Table 35.8*** describes the anatomical regions supplied by the median, ulnar and radial nerves.
  - *Pen sliding test*. To assess the absence or presence of sweating, slide a pen along the radial border of the index finger. If the pen slides smoothly, this may indicate loss of sweating.
- **Soft tissue**. Feel for muscle bulk and tendon thickening. Feel bony prominences, radial styloid, ulnar styloid and the anatomical snuff box. Feel for sensation using two-point discrimination of the medial nerve (radial aspect of the index finger), radial nerve (in the anatomical snuff box) and ulnar nerve (ulnar aspect of the little finger).

TABLE 35.7 Bony deformities of the hand.

Anatomical site	Name	Association
DIPJ	Heberden's nodes	Osteoarthritis
PIPJ	Bouchard's node	Osteoarthritis
Hyperextension of the MCPJ, flexion of the PIPJ and hyperextension of the DIPJ	Boutonnière deformity	Rheumatoid arthritis
Hyperextension of the MCPJ and PIPJ and flexion of the DIPJ	Swan neck deformity	Rheumatoid arthritis
Flexion of the MCPJ with hyperextension of the interphalangeal joint	Z deformity of the thumb	Rheumatoid arthritis
Subluxation of the MCPJ	Ulnar drift	Rheumatoid arthritis

DIPJ, distal interphalangeal joint; MCPJ, metacarpophalangeal joint; PIPJ, proximal interphalangeal joint.

  - *Blood vessels*: check the radial and ulnar artery pulses; assess the capillary refill time, which is normally less than 2 seconds; Allen's test should also be performed before surgery (***Table 35.9 and Figure 35.10***).
  - *Nerves*: compressive neuropathies are most commonly seen affecting the median nerve (see Tinel's [***Figure 35.11a***] and Phalen's [***Figure 35.11b***] tests in ***Table 35.9***).
  - *Palmar fascia*: feel for palmar thickening and skin pits; long finger-like structures (cords), most commonly affecting the ring and little fingers, are suggestive of Dupuytren's disease.
- **Bones**. Palpate from the radial to the ulnar side of the wrist joint. In the trauma setting, palpate the anatomical snuff box (***Figure 35.12***): a fracture of the scaphoid may cause tenderness (see ***Chapter 32***). The scaphoid tubercle, pisiform and the hook of hamate are all palpable on the volar aspect of the wrist.

TABLE 35.8 Sensory distribution of the nerve supply to the hand.

Nerve	Sensory distribution
Ulnar	Little finger and ulnar half of the ring finger
Median	Thumb, index, middle and radial half of the ring finger
Radial	Base of the thumb on the dorsum of the hand

William Heberden (Senior), 1710–1801, physician, practised first in Cambridge and later in London, UK.
Charles Jacques Bouchard, 1837–1915, physician, Dean of the Faculty of Medicine, Paris, France.
Boutonnière is French for 'buttonhole'.
Edgar van Nuys Allen, 1900–1961, Professor of Medicine, The Mayo Clinic, Rochester, MN, USA.
Jules Tinel, 1879–1952, Physician, Hôpital Beaujon, Paris, France.
George S Phalen, contemporary orthopaedic surgeon and Chief of Hand Surgery, The Cleveland Clinic, Cleveland, OH, USA. He helped to establish the American Society for Surgery of the Hand.

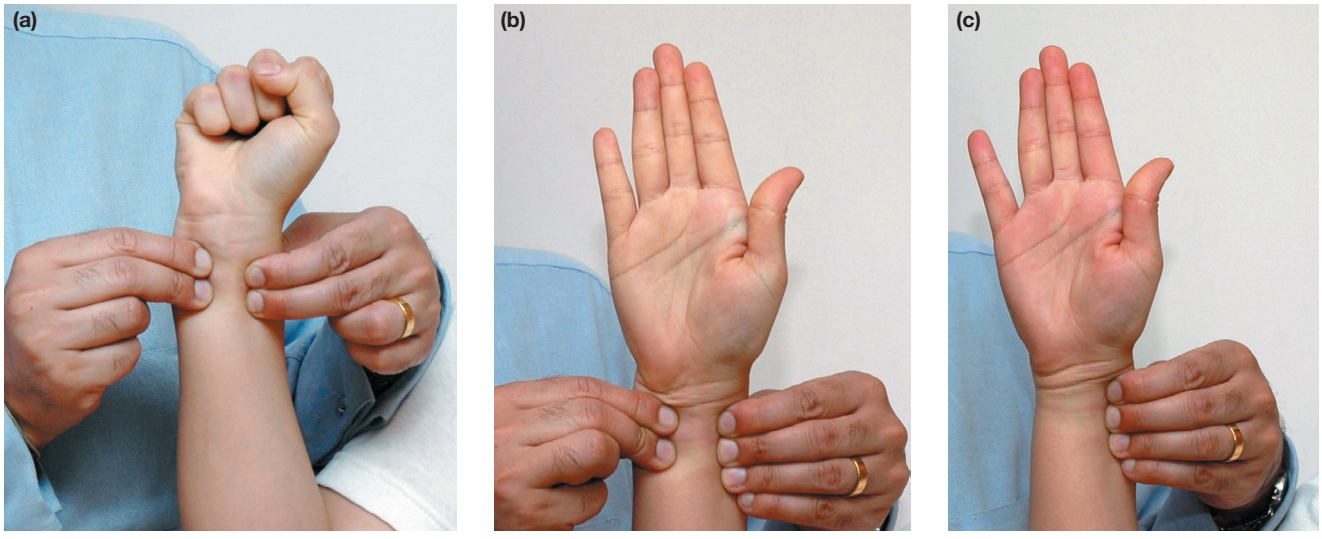

Figure 35.10 (a–c) Performing Allen's test.

TABLE 35.9 Special hand tests.

Test	Technique	Significance
Allen's test	Elevate the hand and apply digital pressure on the radial and ulnar arteries to occlude them. Ask the patient to make a fist several times. The tips of the fingers should go pale. Release each artery in turn and observe the return of colour	Tests the adequacy of the blood supply to the hand from the radial and ulnar arteries and the arcade between them
Tinel's test	Tap over the nerve of interest. Tingling may indicate nerve compression	Identifies compression of a peripheral nerve
Phalen's test	Place the wrist in maximum flexion with the elbows extended	Compression of the medial nerve causes paraesthesia
Froment's sign	Ask the patient to grip a sheet of paper between the index finger and thumb of both hands. Grip the paper yourself similarly. Ask the patient to resist as you attempt to pull the paper away	A positive test indicated by flexion of the thumb interphalangeal joint suggests weakness of the adductor pollicis muscle supplied by the ulnar nerve. Recruitment of the median nerve-innervated flexor pollicis brevis explains the thumb posture

Move

The wrist can be moved into flexion and extension, and ulnar and radial deviation.

- **Wrist**. Extension is tested by asking the patient to push the hands together into a 'prayer' position (*Figure 35.13a*). If there is loss of extension, the palms will not meet and/or one forearm will be dropped. Palmar flexion is tested in a similar fashion but with the hands pointing down and the back of the hands in contact (*Figure 35.13b*). Ulnar and radial deviation are tested by taking the patient's hand in your own and moving the hand into these directions.
- **Hand**. A general screening assessment is to ask the patient to roll up their fingers from full extension to full flexion. This will reveal a trigger finger.

Extensors and flexors

Asking the patient to grip two of your fingers in their fist tests the power of the extensors of the wrist (radial nerve) because they are needed to brace the wrist. It also tests the power of the flexors in the forearm (median nerve). Asking the patient then to extend and spread their fingers apart against resistance tests the intrinsic muscles of the hand (mainly the ulnar nerve).

Finger flexors

- **Superficialis tendon test**. The flexor digitorum profundus (FDP) usually has one muscle belly from which tendons to all of the fingers arise. The FDP can be immobilised by holding all of the fingers (except the one being examined) in extension; this allows the superficialis tendon to be tested in isolation. If the test finger is able to flex, despite profundus being immobilised, then the superficialis tendon to that finger is working. Repeat the test for the other fingers and examine FDP (*Figure 35.14*).

Thumb and thenar eminence

- **Abductor pollicis brevis, opponens pollicis and flexor pollicis brevis** can be tested together by opposing the thumb to the little finger.

Jules Froment, 1878–1946, Professor of Clinical Medicine, Lyons, France.

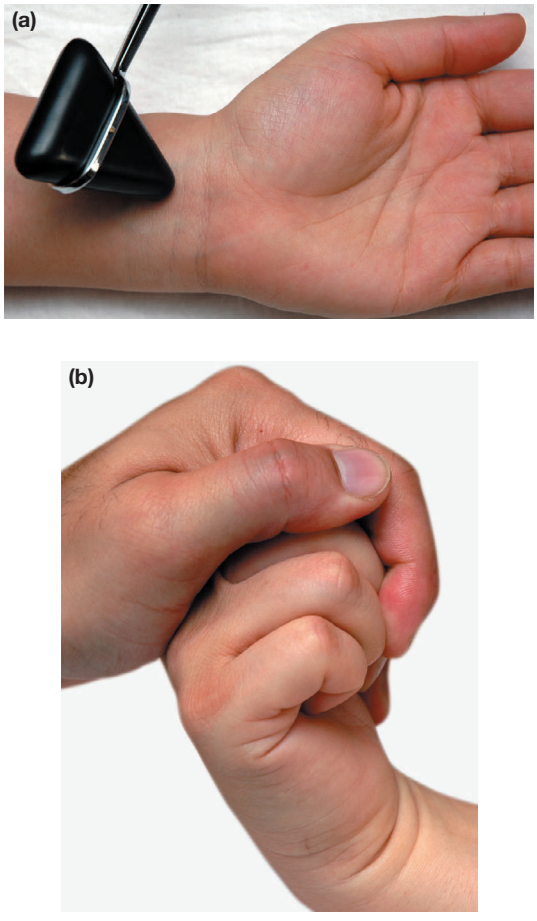

Figure 35.11 (a) Tinel's test; (b) Phalen's test.

Figure 35.12 Palpating the anatomical snuff box between the tendons of extensor pollicis longus and abductor pollicis brevis.

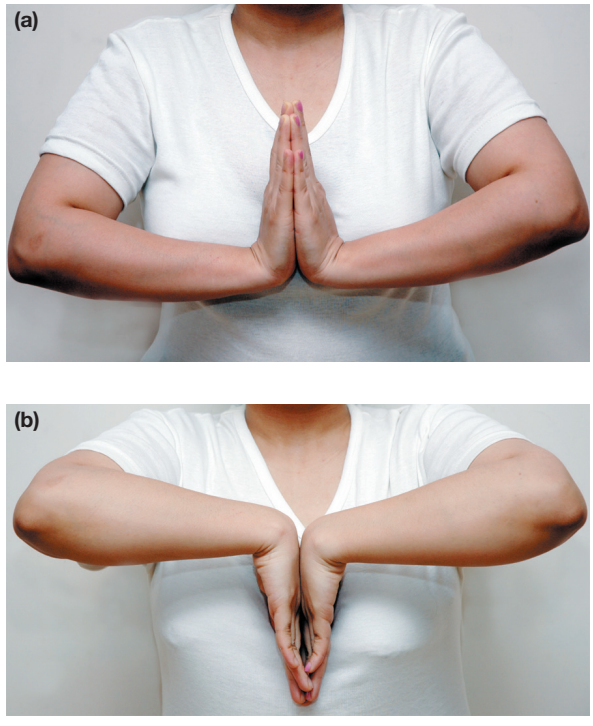

Figure 35.13 Testing the range of (a) wrist extension; (b) wrist flexion.

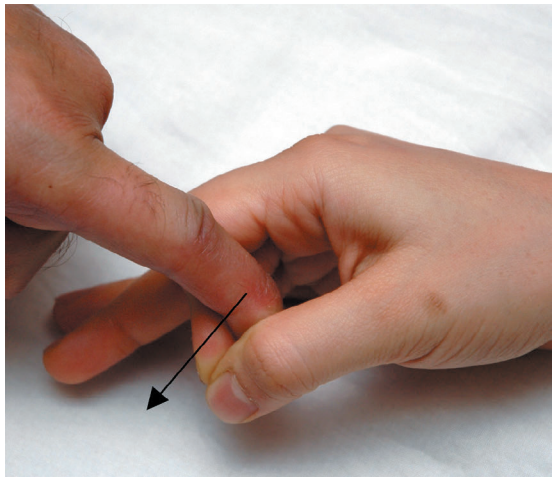

Figure 35.15 Test for flexor pollicis longus supplied by the anterior interosseus nerve.

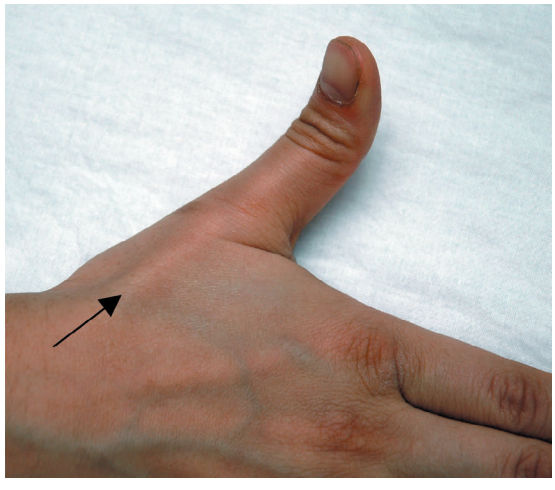

Figure 35.16 Testing the integrity of extensor pollicis longus.

- **Flexor pollicis longus**. The muscle is supplied by the anterior interosseus nerve (branch of the median nerve) and can be tested by asking the patient to bring the tips of the thumb and index finger together (the 'OK' sign; *Figure 35.15*).
- **Extensor pollicis longus**. The integrity of the tendon is tested by asking the patient to lift the thumb off a table with the palm flat on the table (*Figure 35.16*).
- **Adductor pollicis**. Test using Froment's sign (see *Table 35.9 and Figure 35.17*).
- **Abductor pollicis brevis**. This muscle is supplied by the median nerve. With the hand lying flat on a table with the palm facing upwards, ask the patient to raise the thumb towards the ceiling. Ask the patient to resist as you push the thumb back towards the palm (*Figure 35.18*).

Summary box 35.4

Hand and wrist examination

- Inspection of the standing patient
  - Dorsum and palm – asymmetry, deformity, muscle wasting
  - Inspection of the supine patient
  - Skin, scars, soft tissues
  - Palpation of bony structures and joints of the hand
- Movements
  - Wrist – flexion and extension, ulnar and radial deviation
  - Hand – thumb movements, metatarsophalangeal joints and small joints of the hand
- Special tests
  - Allen's test
  - Tinel's and Phalen's tests for the median nerve
  - Froment's sign
  - Finkelstein's test

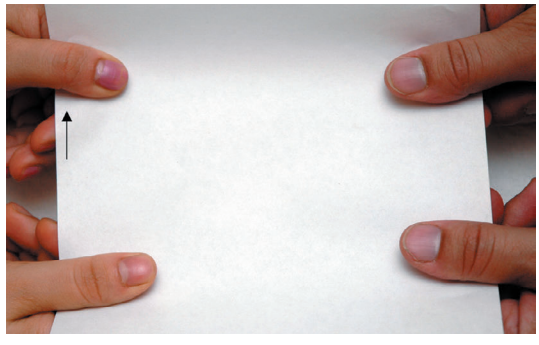

Figure 35.17 Froment's sign; the arrow illustrates the flexed posture of the thumb interphalangeal joint, indicating weakness of the ulnar nerve-innervated adductor pollicis muscle.

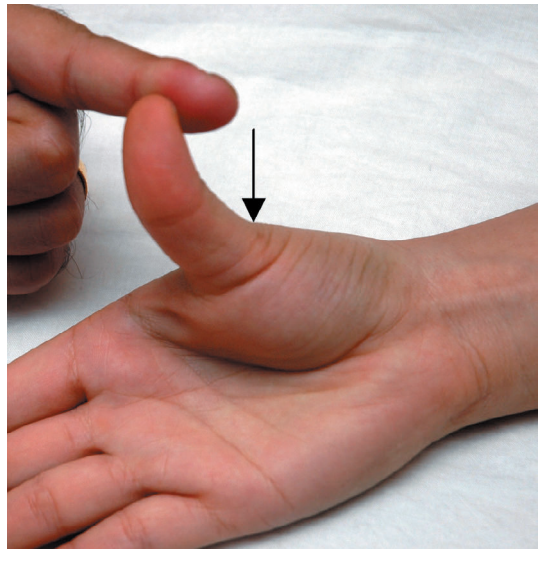

Figure 35.18 Testing the power of the abductor pollicis brevis supplied by the median nerve.

Harry Finkelstein, 1883–1975, American surgeon, one of the cofounders of the Hospital for Joint Diseases, New York, NY, USA. In 1932, along with E.J Haboush invented a stabilising apparatus and operative technique for bone lengthening, anticipating by decades the current widely utilised Ilizarov technique.

CLINICAL EXAMINATION OF THE ELBOW

The elbow is a hinge joint formed by the articulation of the ulna and radius with the humerus.

Look

- **Skin**. Check the extensor surface for signs of psoriasis.
- **Soft tissues**. Look for any swellings, e.g. olecranon bursa, rheumatoid nodules, gouty tophi.
- **Muscle wasting**. Examine the biceps and triceps muscle bulk. Note that compression of the ulnar nerve at the elbow leads to wasting distally in the hypothenar eminence and intrinsic muscles of the hand – assess the hand for the presence of clawing and wasting.
- **Bone**. With the elbow in extension, look at the axis between the upper arm and forearm. There is a physiological valgus ('carrying angle') of 9–14° (2–3° greater in women) (***Figure 35.19***). This angle allows the elbow to be tucked into the waist depression above the iliac crest:
  - *cubitus varus* (gun-stock deformity): the carrying angle is reversed, secondary to a malunited supracondylar fracture;
  - *cubitus valgus*: the carrying angle is increased, caused by malunion of a distal humeral fracture;
  - *hyperextension*: there is normally a physiological hyperextension of the elbow (5°).

Figure 35.19 Carrying angle of the elbow illustrating the normal cubitus valgus.

Feel

- **Soft tissues**. An effusion may be detected by performing a cross-fluctuation test. The ulnar nerve can be rolled under your fingers placed between the medial epicondyle and the olecranon. Test the distal sensation in the hand (especially in the distribution of the ulnar nerve) and assess the vascular status.
- **Bones**. The three palpation landmarks are the medial and lateral epicondyles and the apex of the olecranon. These form an equilateral triangle when the elbow is flexed to 90°. The radial head is palpated with the examiner's thumb while the other hand pronates and supinates the forearm. On the medial side, palpate the medial epicondyle. Posteriorly, palpate the olecranon fossa.

Move

- **Flexion–extension**. The normal range is from –5° (slight hyperextension) to 150°. Ask the patient to bend the elbow from the fully straight position (***Figure 35.20***).
- **Pronation and supination**. With the elbows at 90° and the palms facing upwards (full supination), ask the patient to turn the forearm so that the dorsum of the hand faces upwards (full pronation) (***Figure 35.21***). The normal values are 70° pronation and 90° supination.

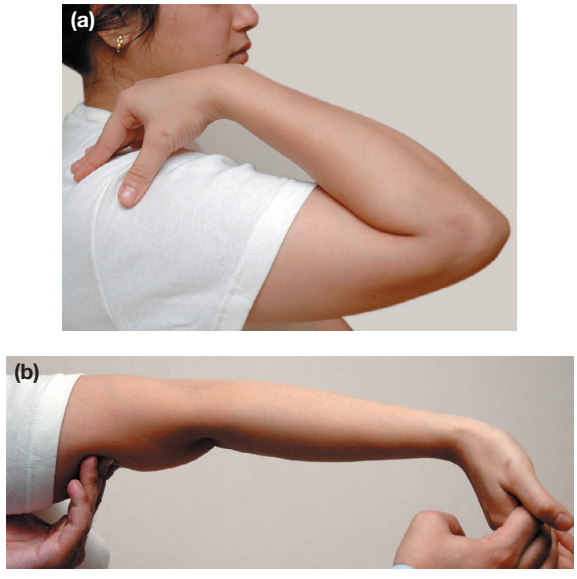

Figure 35.20 **(a)** Elbow flexion; **(b)** elbow extension.

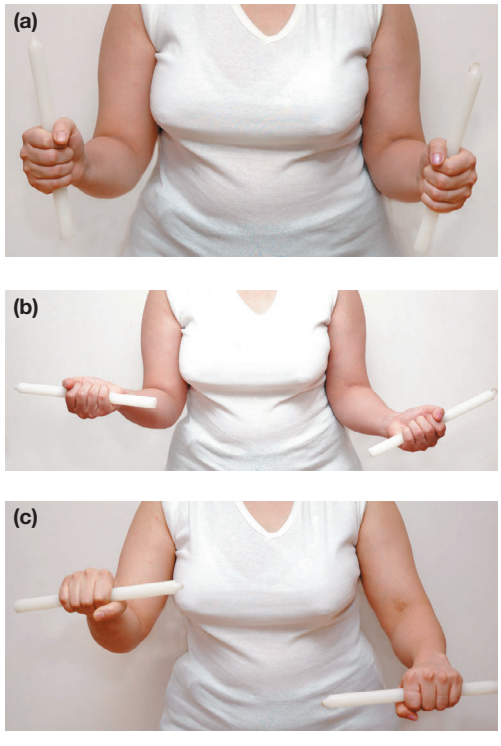

Figure 35.21 Testing forearm rotation: **(a)** mid-prone position; **(b)** full supination; **(c)** full pronation.

Special tests and diagnoses

Tennis elbow and golfer's elbow

Both conditions are inflammatory processes of the tendons that attach the large muscle mass of the forearm to the lateral or medial epicondyle.

- **Medial epicondylitis** (synonym golfer's elbow). The medial epicondyle is the common origin of the forearm flexors and the pronator muscle. Palpate the medial epicondyle for tenderness. The diagnostic test is resisted wrist flexion, which reproduces the pain over the medial epicondyle.
- **Lateral epicondylitis** (synonym tennis elbow). The lateral epicondyle is the common origin of the forearm extensors. Palpate for tenderness – usually just distal (5–10 mm) to the epicondyle near the origin of the extensor carpi radialis brevis muscle. Wrist extension against resistance with the elbow extended should provoke the patient's symptoms.

Summary box 35.5

Elbow examination

- Inspection of the standing patient
  - Front – asymmetry, carrying angle, deformity
  - Back – olecranon fossa
- Inspection of the supine patient
  - Skin, scars, soft tissues, deformity
  - Palpation of bony structures
- Movements
  - Flexion and extension, pronation and supination
- Special tests
  - Tennis and golfer's elbow

CLINICAL EXAMINATION OF THE SHOULDER

Pain arising from the shoulder joint may be felt anterolaterally. Referred pain may present from the cervical spine, heart, mediastinum and the diaphragm.

Look

Assess the attitude of the limb.

- **Skin**. Check for surgical scars. An anterior scar is used for the deltopectoral approach. At the side, the deltoid splitting approach and lateral arthroscopic portals may be seen. Posteriorly, arthroscopic portal sites can be seen.
- **Soft tissues**. Wasting of the deltoid muscle is commonly seen after shoulder dislocation when there is a temporary loss of function of the axillary nerve that supplies it. The rotator cuff comprises four muscles: supraspinatus, infraspinatus, subscapularis and teres minor. Wasting of these muscles may occur following a rotator cuff problem.
- **Bone**. Look for any obvious deformity or prominence. A fracture of the middle third clavicle is the most common cause. A dislocation may be suspected by a loss of normal shoulder contour. The more common anterior dislocation often presents with an anterior bulge and a squared-off shoulder.

Feel

Generalised pain in the shoulder may arise from the neck or the shoulder joint itself. More localised pain is often indicative of acromioclavicular joint pathology.

- **Skin**. Test sensation in the upper part of the lateral aspect of the arm ('regimental badge area') (*Figure 35.22*). Loss may indicate damage to the axillary nerve (following shoulder dislocation).
- **Bones**. Palpate the acromioclavicular and sternoclavicular joints and the clavicle.

Figure 35.22 The area of skin supplied by the axillary nerve – the 'regimental badge area'.

Move

Differentiate between movements of the shoulder joint and scapulothoracic movement of the scapula on the chest wall. Patients with a painful shoulder will commonly move from the scapulothoracic joint. Stabilise the scapula by placing the thumb over the coracoid process and the fingers of the same hand over the spine of the scapula. Start in the 'neutral position' with the arms by the sides, elbows extended and the palms facing forwards. Note any pain throughout the range of movement (*Figure 35.23*).

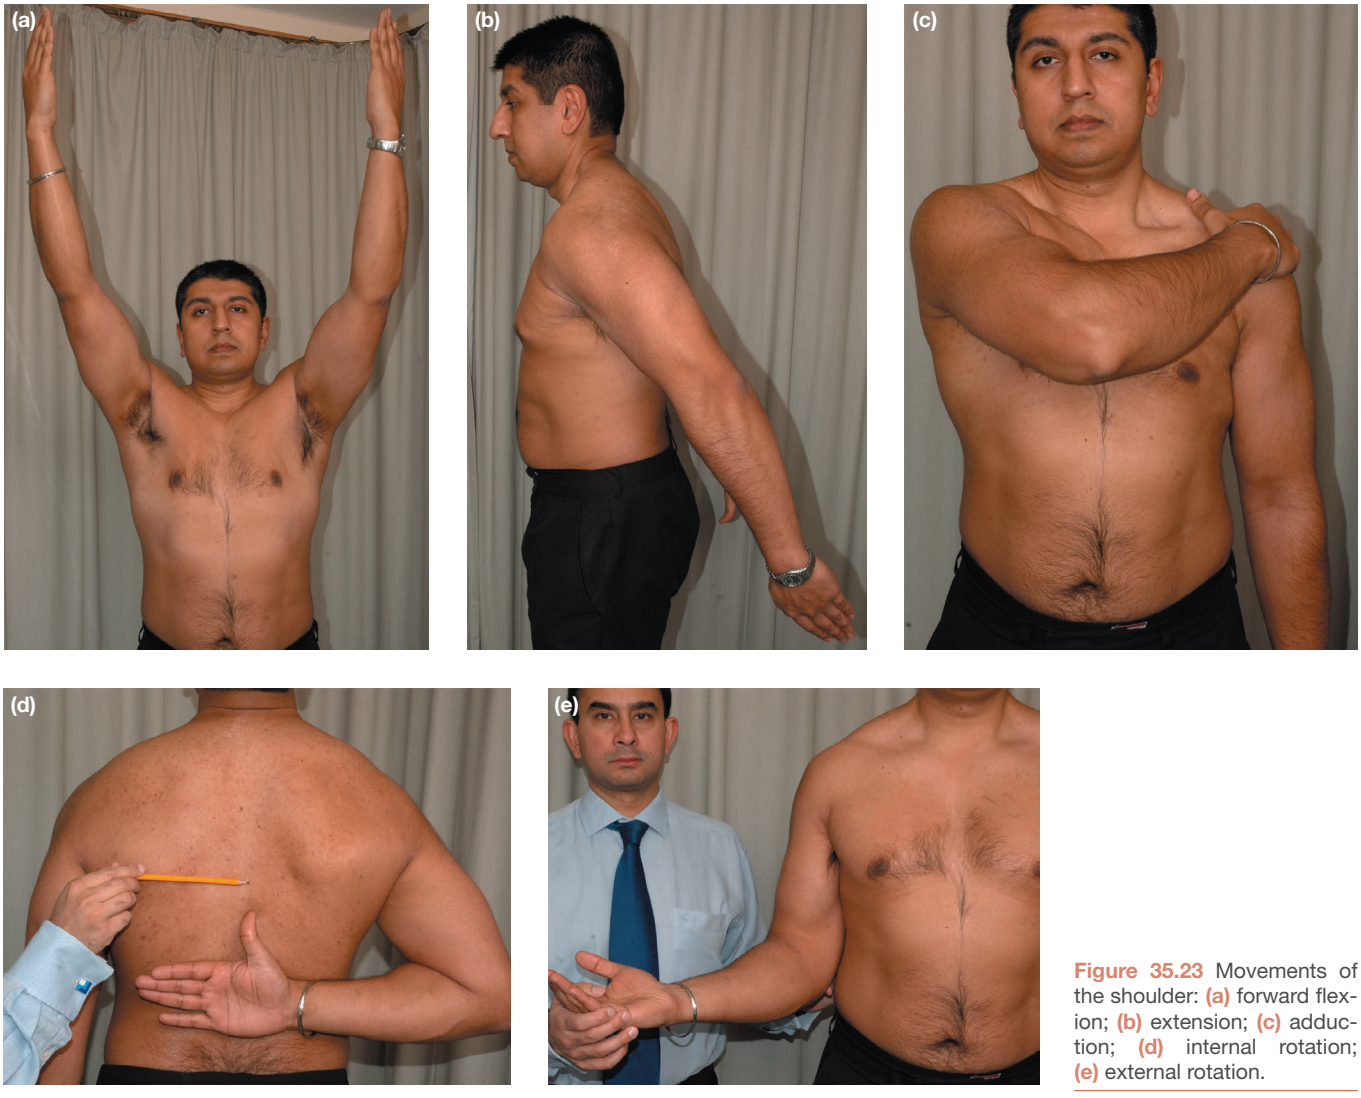

Figure 35.23 Movements of the shoulder: (a) forward flexion; (b) extension; (c) adduction; (d) internal rotation; (e) external rotation.

- **Forward flexion**. Ask the patient to raise their hands in front to touch the ceiling while keeping the elbows extended (0–180°).
- **Extension**. Ask the patient to extend both arms behind (0–30°).
- **Abduction**. Shoulder abduction involves the glenohumeral joint and scapulothoracic movement. The first 60° of movement is mainly at the glenohumeral joint. Beyond this the scapula begins to rotate on the thorax and final movements are almost entirely scapulothoracic. Raise the arms sideways until the fingers point to the ceiling (180°).
- **Adduction**. Ask the patient to touch their other shoulder tip.
- **Internal rotation**. Ask the patient to touch their back with the dorsum of the hand and to raise their hand up the back as high as possible (normal range is thoracic spine level T7–9).
- **External rotation**. With the arms by the sides, bend the elbows to 90° and rotate the forearms to the mid-prone position. Ask the patient to separate their hands as much as possible (0–40°).

Special tests and diagnoses

Impingement syndrome

This is impairment of rotator cuff function within the subacromial bursa. It may lead to inflammation (tendinitis) or a partial- or full-thickness tear. Impingement is characterised by pain and weakness on abduction and internal rotation.

- **Painful arc test** (*Figure 35.24*). Ask the patient to abduct their arms from their sides. The presence of pain from 60° to 120° is positive.
- **Jobe's test (empty can)** (*Figure 35.25*). Ask the patient to abduct the arm to 90° elevation in the scapular plane with full internal rotation (empty can position). Ask the patient to resist downward pressure. The presence of pain is a positive test.

Christopher Jobe, contemporary, American orthopedic surgeon, specialising in shoulder and knee surgery, diagnostic musculoskeletal ultrasound and sports injuries.

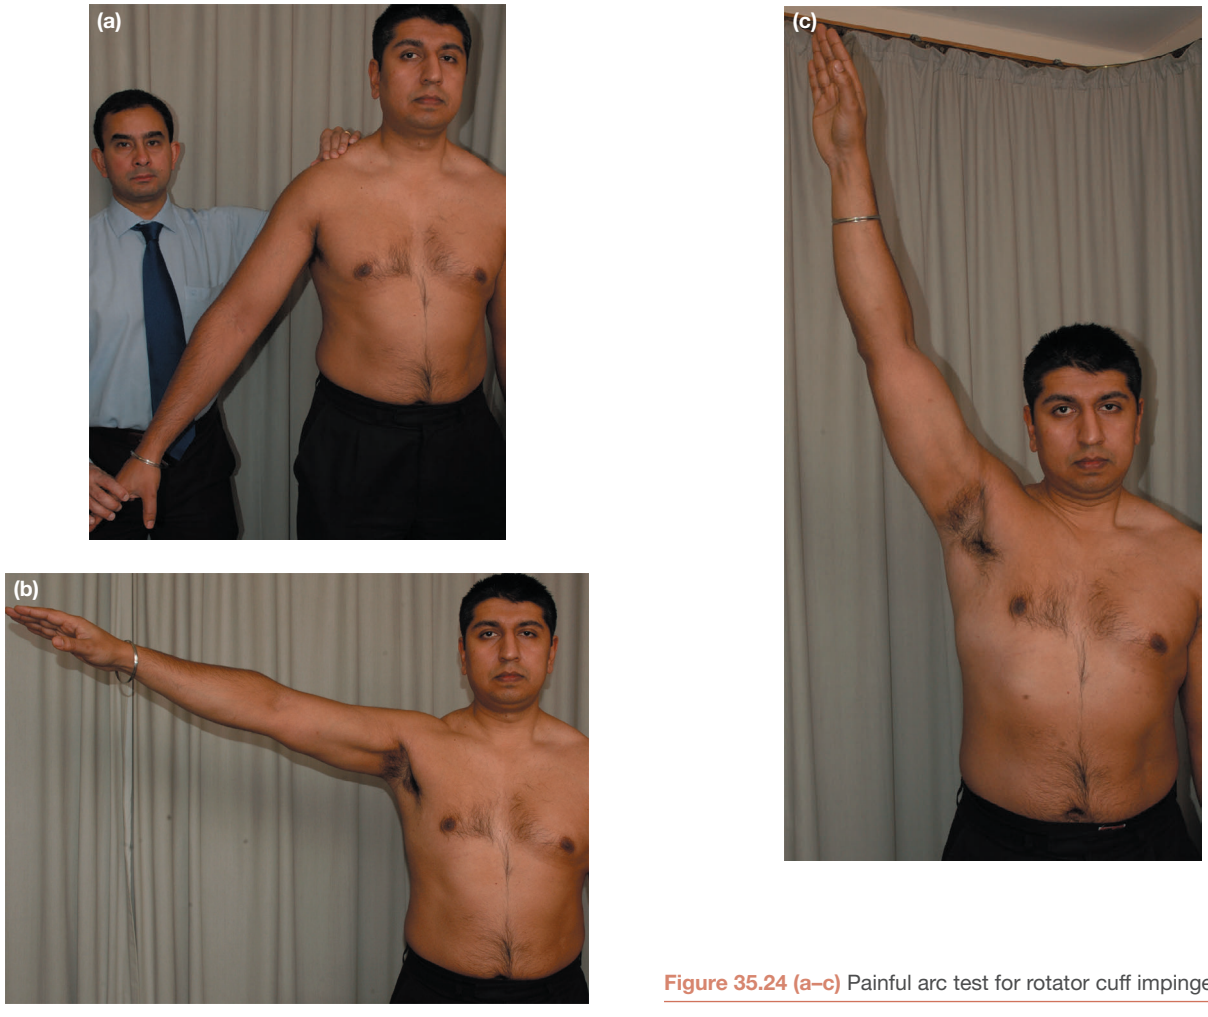

Figure 35.24 (a–c) Painful arc test for rotator cuff impingement.

Figure 35.25 Jobe's test for rotator cuff impingement.

Figure 35.26 Anterior apprehension test for anterior shoulder instability.

Shoulder instability

Instability may be defined as a shoulder that slips in and out of joint (dislocation) more than once or twice, or frequently slips partially out of joint and then returns on its own. Instability can be anterior, posterior, inferior or multidirectional.

- **Apprehension test** (*Figure 35.26*). With the patient supine or standing, flex the elbow to 90° and abduct the shoulder to 90°. Now externally rotate the shoulder. Apprehension indicates anterior instability.

Summary box 35.6

Shoulder examination

- Inspection of the standing patient
  - Front – asymmetry, deformity
  - Side – muscle wasting
  - Back – muscle wasting, scapula
- Inspection of the supine patient
  - Skin, scars, soft tissues, deformity
  - Palpation of shoulder girdle (sternum to scapula)
- Movements
  - Flexion and extension, abduction and adduction, internal and external rotation
- Special tests
  - Impingement syndrome – painful arc, Jobe's test, Hawkins' test (see also *Chapter 38*)
  - Shoulder instability – apprehension, relocation test, sulcus sign
  - Rotator cuff assessment
  - Acromioclavicular joint pathology
  - Frozen shoulder versus glenohumeral osteoarthritis

CLINICAL EXAMINATION OF THE HIP JOINT

The hip is a synovium-lined ball-and-socket joint. Typical clinical diseases of the hip that may be encountered in children and adults are shown in *Table 35.10*. A patient complaining of hip pain should undergo a careful examination of the spine, abdomen, pelvis, groin and thigh. In addition, consider a gynaecological examination in women.

Look

With the patient standing, look at the front, side and back of the hip. Look around the room for walking aids and heel raises in the shoes.

- **Skin**. Look for scars and sinuses.
- **Soft tissues**. Muscle wasting may be present as a consequence of hip arthritis or primary muscle or neurological disease.
- **Bone**. Look at the posture of the limb and assess for adduction deformity; fixed adduction may be present in severe osteoarthritis and cerebral palsy, and makes the leg appear short because the pelvis is tilted (apparent shortening).

TABLE 35.10 Common clinical diseases of the hip in children and adults.

Children	Adults
• Developmental dysplasia of the hip • Transient synovitis of the hip • Perthes' disease • Septic arthritis and osteomyelitis • Slipped capital femoral epiphysis • Juvenile idiopathic arthritis	• Primary osteoarthritis • Secondary osteoarthritis • Inflammatory arthritis • Avascular necrosis • Femoroacetabular impingement • Labral tears • Referred pain

Feel

- **Soft tissues**. Tenderness overlying the greater trochanter may suggest trochanteric bursitis or an abductor enthesopathy.
- **Bone**. Bony landmarks can be palpated; these include the anterior superior iliac spine (ASIS), iliac crest and the greater trochanter of the femur.

Other areas for palpation include the inguinal ligament, which may have a local hernia or lymphadenopathy. The femoral artery can be palpated as it passes under the inguinal ligament at its midpoint halfway between the ASIS and the pubic tubercle.

Move

The hip joint can be moved into flexion, extension, abduction and adduction, and internal and external rotation (*Figure 35.27*). True hip movement ends when the pelvis begins to move. To detect true hip movement, simultaneously place a finger/hand on the ASIS contralateral to the hip being examined. Remember to compare both sides.

Passive movement

Hip flexion (120–0°) when lying supine

The patient is asked to lie on their back and then roll themselves into a ball, flexing the hips and the spine fully. A comparison of the flexion of the two hips can be made in this position. The patient is then asked to hold onto the knee of the 'bad' leg with both hands (thereby fixing the pelvis in flexion) and the other leg is allowed to extend down onto the couch. A note is made of any fixed flexion deformity (inability of the thigh to come down onto the couch). This 'good' hip is then returned to full flexion and the patient grasps that knee while dropping the other, 'bad', hip into extension. This modified Thomas's test is the most comfortable and accurate way of measuring flexion and extension of the hip, minimising movement of the painful hip (*Figure 35.28*).

Richard J Hawkins, contemporary, Canadian orthopaedic surgeon, based in Colorado and a founding member and Past President of the American Shoulder and Elbow Surgeons.
Georg Clemens Perthes, 1869–1927, Professor of Surgery, Tübingen, Germany, described osteochondritis of the femoral capital epiphysis in 1910.
Hugh Owen Thomas, 1834–1891, general practitioner, Liverpool, UK. He is regarded as the founder of orthopaedic surgery although never holding a hospital appointment, preferring to treat patients in their own homes. He introduced the Thomas splint in 1875.

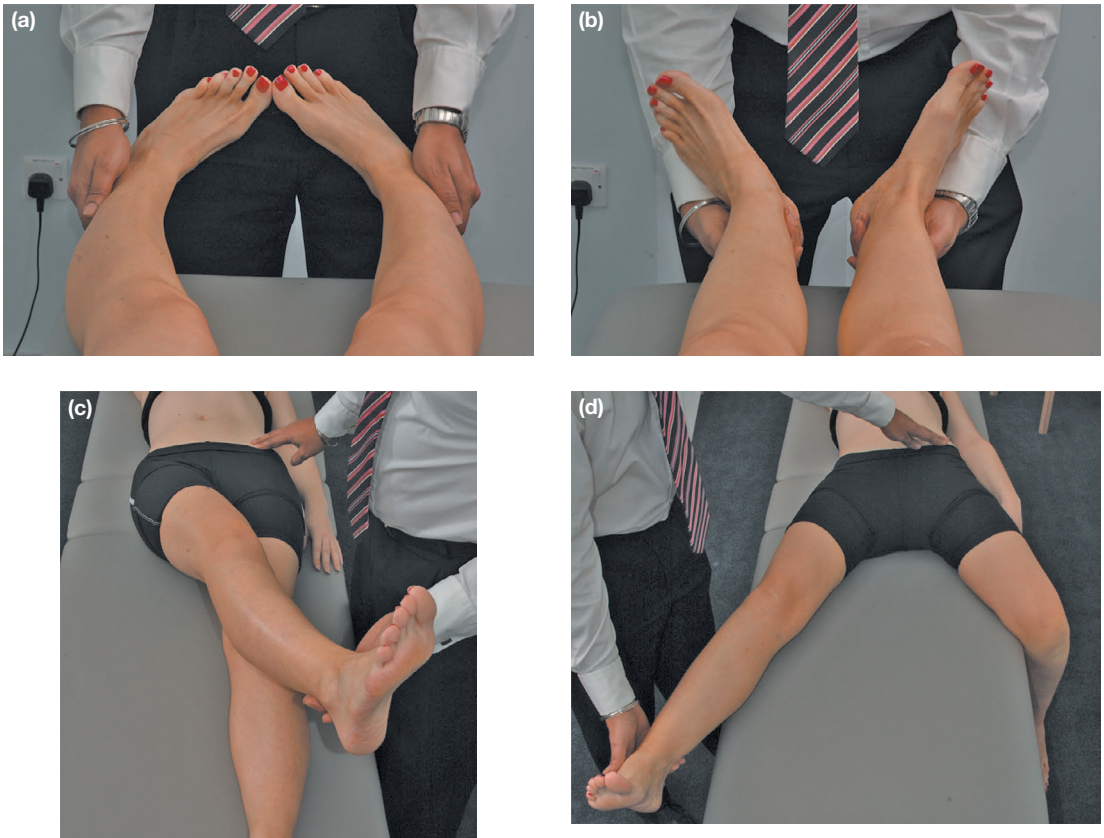

Figure 35.27 Hip movements: (a) internal rotation; (b) external rotation; (c) adduction; (d) abduction.

Figure 35.28 Modified Thomas's test for assessing a fixed flexion deformity. A fixed flexion deformity of the right hip is indicated by an inability to fully straighten the right leg (arrow).

Hip extension (0–10°) when lying in a prone position

Hip extension can be measured by asking the patient to roll onto their front and extend the hip.

Rotation

- **Internal rotation (45°)**. With the hip flexed to 90° and the knee in 90° of flexion, hold the front of the knee with one hand and the foot with the other. Internally rotate the hip (the foot goes outwards), then externally rotate the hip (the foot goes in). The angle that the tibia makes with the vertical indicates the range of movement. Pain at the extremes of movement suggests inflammation in the hip.
- **Abduction (40°)**. The hip should be abducted by moving the leg away from the midline with the other hand on the patient's pelvis to detect any tilt in the pelvis.

Special tests

- **Trendelenburg test** (*Figure 35.29*). Face the patient and ask them to place their hands on the palm of your hands for support. Then ask them to stand first on one leg, then the other. Increased pressure from the opposite hand as they take weight through the weak hip indicates a positive Trendelenburg test.
- **Leg length discrepancy (LLD)**. The inequality may be in the hip joint, femur, tibia, ankle or foot or a combination of these. The pathology may be from the bone being too short or too long. When assessing LLD, square the pelvis. If that is not possible then place both legs in the same position. For example, if there is an adduction deformity present in the affected leg, place the good leg in the same degree of adduction. LLD can be caused by a real difference in the leg lengths (the bones are different lengths) or by a deformity that makes the leg appear short because the pelvis must be tilted to get the leg onto the ground. The first is called 'real' LLD, measured ASIS to medial malleolus. The second is called 'apparent' LLD, measured midline, e.g. xiphisternum to medial malleolus. Each differs in cause and therefore treatment. The LLD apparent to the

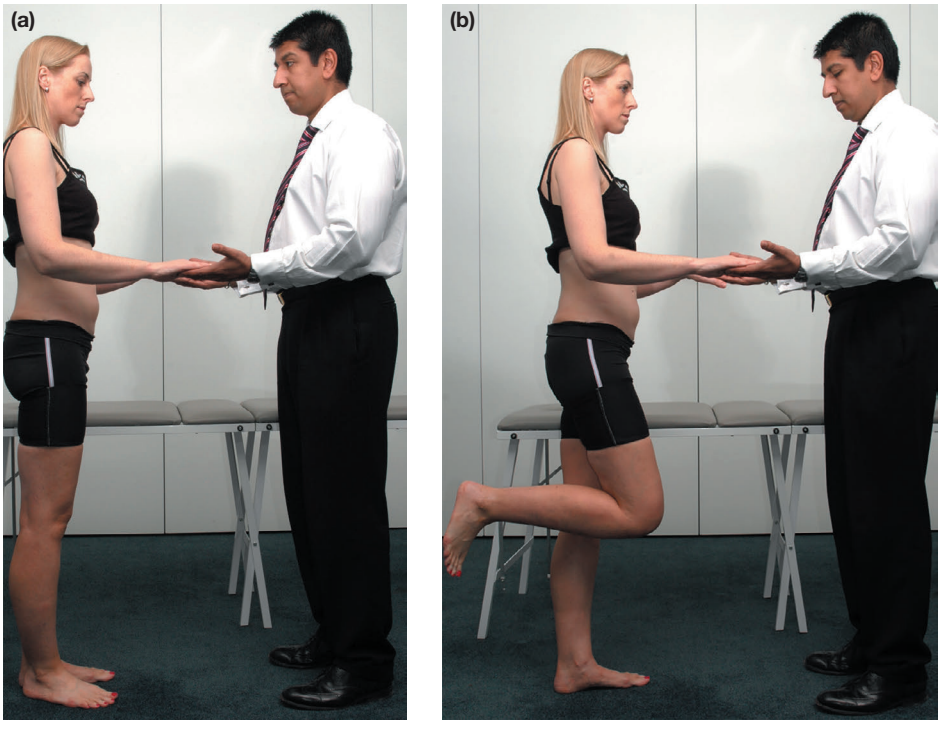

Figure 35.29 (a, b) Trendelenburg test.

patient can also be measured using wooden blocks placed under the patient's 'short' leg until the patient feels level.

- **Gait**. Hip disease can present with an altered gait pattern. The common types of abnormal gait are described in *Table 35.11* (see also *Summary box 35.8*).
- **Impingement**. Two commonly performed tests relate to femoroacetabular impingement. The FADDIR test, performed with hip flexion at 90° and subsequent adduction and internal rotation (F-ADD-IR) can reproduce the hip pain in impingement. The FABER test combines hip flexion, abduction and external rotation (F-AB-ER) and can reproduce hip pain in impingement but also pain from other locations, e.g. sacroiliac.

Snapping hip

Snapping hip is a condition in which the patient feels a snapping sensation or hears a popping sound in their hip when they walk, get up from a chair or swing their leg around. The snapping sensation occurs when a muscle or tendon (the strong tissue that connects muscle to bone) moves over a bony protrusion in the hip region, e.g. psoas and iliotibial band. Although snapping hip is usually painless and harmless, the sensation can be annoying. In some cases, snapping hip leads to bursitis, a painful swelling of the fluid-filled sacs that cushion the hip joint.

Summary box 35.7

Common causes of LLD in the hip

- Osteoarthritis
- Hip fracture
- Hip dislocation
- Hip dysplasia
- Avascular necrosis
- Fixed flexion deformity

TABLE 35.11 Common limps observed in hip disease.

Gait pattern	Description
Weak: Trendelenburg	May lead to pelvic sway or tilt. The patient swings the body over the weak hip to stay in balance when it is weight-bearing
Painful: antalgic	The rhythm is dot–dash, with a short period spent on the painful limb
Unbalanced: broad-based	May be caused by ataxia, e.g. cerebellar pathology. The rhythm also tends to be disordered
Loss of muscle control: high-stepping	May be due to loss of proprioception or a drop foot. This leads to difficulty in clearing the toes during the swing phase: the patient compensates by externally rotating the leg and flexing the hip and knee
Deformity: in-toeing	Can be caused by persistent femoral anteversion. The foot may catch on the back of the calf of the weight-bearing leg, tripping the patient

CLINICAL EXAMINATION OF THE KNEE

The knee is a synovial hinged joint. There are three compartments: medial, lateral and patellofemoral. The quadriceps, quadriceps tendon, patella, patellar tendon and tibial tuberosity constitute the extensor mechanism of the knee.

The anterior cruciate ligament (ACL) provides primary restraint to anterior displacement of the tibia. The posterior cruciate ligament (PCL) provides posterior restraint of the tibia. The medial collateral ligament (MCL) resists valgus and

Summary box 35.8

Hip examination

- Inspection of the standing patient
  - Front – pelvic tilt, rotational deformity
  - Side – lumbar lordosis
  - Back – pelvic tilt, scoliosis, gluteal wasting
  - Gait – Trendelenburg, antalgic
- Inspection of the supine patient
  - Skin, scars, soft tissues, deformity
- Palpation of the anterior joint line, adductor origin, greater trochanter, ischial tuberosity
- Movements
  - Flexion and extension
  - Abduction and adduction
  - Internal and external rotation
- Special tests
  - Thomas's test
  - Trendelenburg test
  - Leg length assessment – real/apparent
  - Impingement tests
  - Snapping hip tests

Figure 35.30 (a) Knee flexion; **(b)** extension.

external rotation forces whereas the lateral collateral ligament (LCL) resists varus forces.

Look

Look at the front, sides and back of both knees and for any walking or mobility aids or external appliances.

- **Skin**. Check for scars.
- **Soft tissues**. Look for wasting of the quadriceps and swelling in front of and behind the knee.
- **Bone**. Look for overall alignment (varus or valgus deformity). Measure the intermalleolar distance if a valgus deformity is present. With varus deformity, measure the distance between the medial aspects of the knees. From the side of the knee, look for fixed flexion or recurvatum (hyperextension).

Gait

Look for antalgic gait (osteoarthritis) and varus thrust (collapse of the knee into more varus as weight is taken on that leg).

Feel

- **Soft tissue**. Feel the tendons for quadriceps and patellar tendon rupture.
- **Fluid displacement or stroke test**. First empty the medial side of the knee by stroking any fluid up from the medial side into the suprapatellar pouch. Then place your hand on the superior aspect of the suprapatellar pouch and move it inferiorly, attempting to displace any fluid into the knee joint. Maintain your hand at the level of the superior pole of the patella. Now look to see whether the normal gutters on either side of the knee are less noticeable because of fluid distension. Stroke the back of your hand over each gutter in turn. Look at the opposite gutter to see if there is cross-filling.
- **Patellar tap test**. This test is used when a large effusion is present. Place one hand on either side of the patella and, with the other hand, push down on the patella. With an effusion, fluctuance is present as the patella moves towards the joint.
- **Bone**. Feel the tibial tuberosity, inferior pole of the patella, patellar facets, origin and insertion of the knee ligaments and joint line (medial and lateral). Remember to palpate for any popliteal swellings. Note the height of the patella.

Move

The knee moves principally in flexion (0–135°) and extension (from 0 to –10°) (***Figure 35.30***). Assess hyperextension by placing one of your hands on the anterior aspect of the distal femur. Now lift the distal tibia with the other hand. Measure the angle or the height that the heel can be lifted off the couch before the knee starts to move.

Perform a lag test to assess the integrity of the extensor mechanism. The patient is asked to lift the whole leg up off the bed (10°) with the knee straight. They are then asked to bend the knee and then try to straighten it again with the leg still held in the air. If they are unable to re-straighten the knee they have a positive lag. This indicates significant weakness of the quadriceps mechanism.

In the presence of an apparent fixed flexion deformity of the knee (seen in osteoarthritis), decide whether this is arising

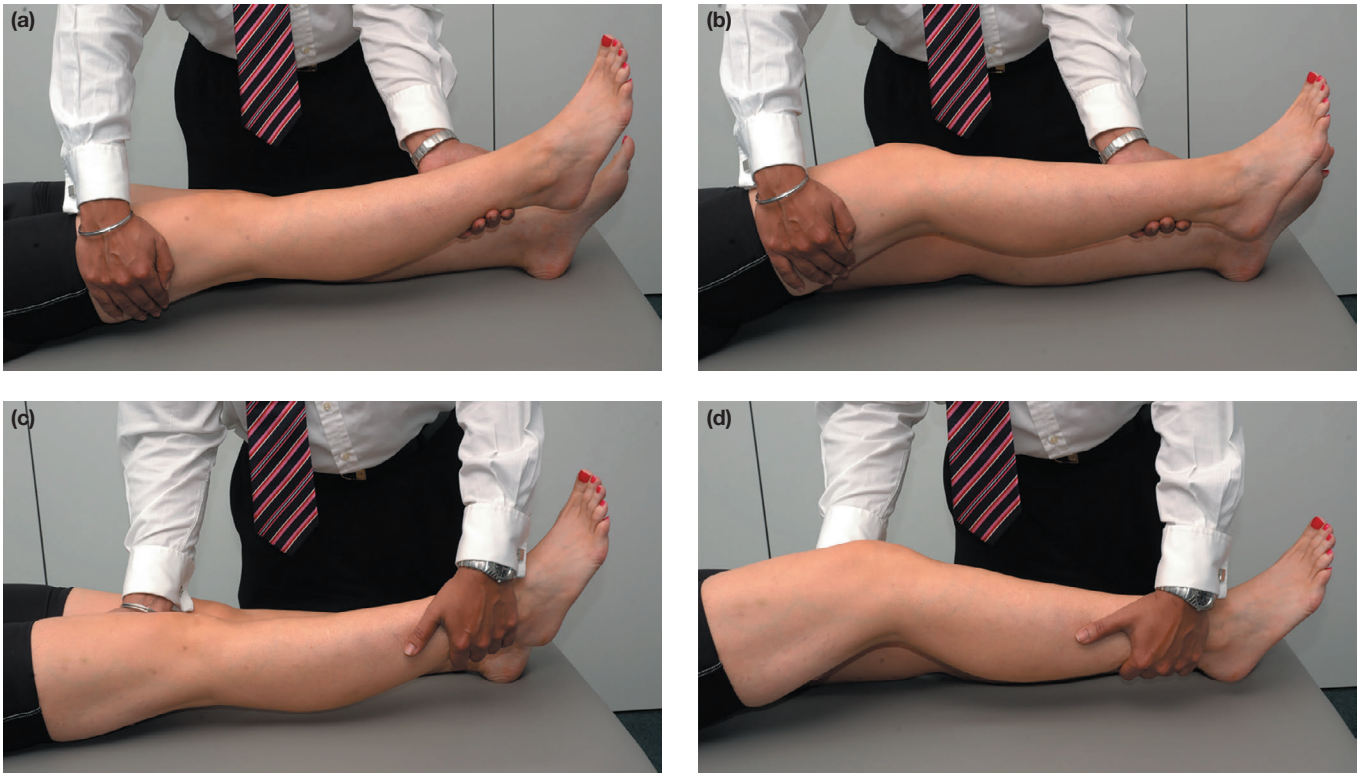

Figure 35.31 Assessing the medial (a, b) and lateral (c, d) collateral ligaments.

from the knee or the hip joint. To differentiate, sit the patient up with the knees hanging over the edge of the couch; this obliterates the effect of any hip flexion deformity. Passively try to extend the knee fully. With a flexion deformity of the knee, this is not possible.

Special tests

Collateral ligaments

To assess the ligaments, place the leg under your arm. Flex the knee to 30° (not more) to relax the posterior capsule (the MCL and LCL are taut in full extension and lax in flexion). Stress each ligament in turn by applying a valgus or varus force. With your index fingers simultaneously palpate over the collateral ligaments. Assess for signs of instability (excessive opening of the joint). The quality of the end point should be noted (is it firm or spongy?). Compare both sides (*Figure 35.31*).

- **Medial collateral ligament**. A lax MCL or deficient lateral compartment may cause knee instability when applying a valgus stress. It is important to note that the valgus stress test should be applied with the knee in 30° of flexion. Valgus instability in full extension (0°) should alert you to a possible posterior structure injury (e.g. posterior capsule, PCL).
- **Lateral collateral ligament**. A lax LCL or deficient medial compartment may cause knee instability when applying a varus stress in 10° of flexion. Instability in full extension (0°) suggests injury to the posterior structures. In a suspected lateral injury, evaluation of the peroneal nerve must be performed.

Figure 35.32 Lachman's test: flex the knee to 15–30° and pull the proximal tibia forwards.

Anterior cruciate ligament

The most sensitive test for evaluation of the ACL is the Lachman test.

- **The Lachman test** (*Figure 35.32*). Flex the knee to 15–30° and pull the proximal tibia gently forwards. Excessive laxity may indicate rupture of the ACL. Anterior translation of the tibia associated with a soft or no end point is a positive test. The test may be negative in chronic ruptures because the ACL stump can scar to the PCL.

John W Lachman, 1919–2007, Professor and Chairman of the Orthopedic Department at Temple University in Philadelphia, PA, USA.

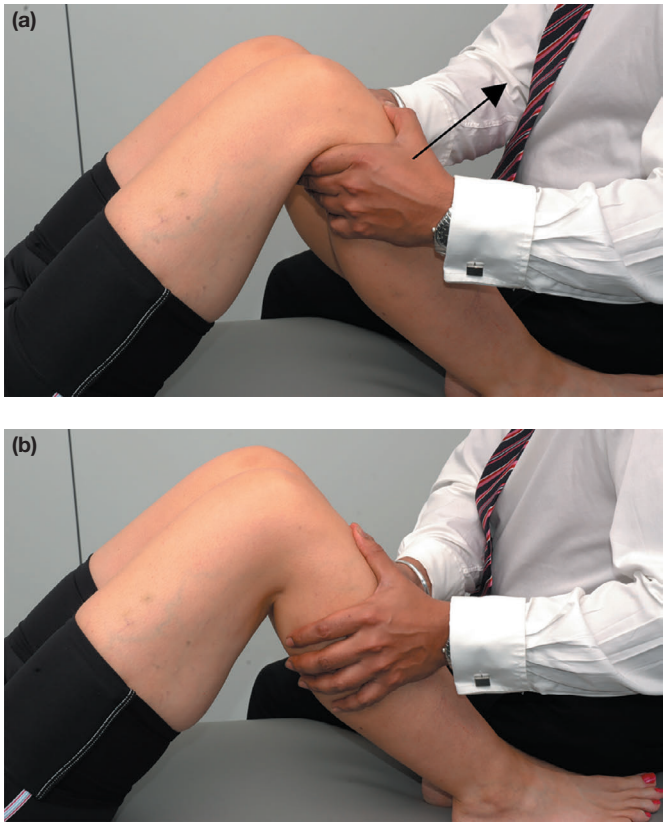

Figure 35.33 **(a)** Anterior draw test for anterior cruciate ligament stability; **(b)** posterior draw test for posterior cruciate ligament stability.

- **Anterior draw test** (*Figure 35.33a*). Flex both knees to 90° and look for a posterior sag (compare the height of the tibial tuberosities looking from the side). This may indicate an injury to the PCL. Stabilise the feet by sitting on them. Now place your hands around the proximal and posterior aspect of the tibia. With your index fingers, push up the hamstrings to encourage them to relax. Now draw the tibia gently forwards and measure any laxity, comparing it with the other knee. The degree of laxity can be graded: grade I (0–5 mm), grade II (5–10 mm) and grade III (>10 mm).

Posterior cruciate ligament

The PCL is the primary restraint to posterior tibial translation between 30° and 90° of knee flexion. At 90° knee flexion, the PCL controls the majority of posterior translation of the tibia. Look for a posterior sag with the knees flexed to 90°. The posterior draw test is the most reliable clinical test for a PCL injury.

- **Posterior draw test** (*Figure 35.33b*). Perform the test with the knee flexed to 90°. Push the anterior aspect of the proximal tibia posteriorly and compare any laxity with the other side. If more than 10 mm of posterior tibial translation is noted at 30° and/or 90° of knee flexion, a combined PCL and posterolateral corner injury may be present. An evaluation of the competency of the posterolateral corner is necessary.

Menisci

The presence of palpable joint line tenderness is the most sensitive clinical examination test for a meniscal tear. Flex the knee to 90° and palpate the joint line using your thumb and index finger. Note any areas of tenderness. Tests for meniscal damage are not very reliable but, combined with a history of mechanical symptoms, locking, catching and pain, may be helpful. With posterior medial meniscal tears patients suffer pain on high flexion or squatting. The well-known test for meniscal tears is McMurray's test. The patient lies supine with their knee flexed to 45° and hip flexed to 45°. The examiner braces the lower leg: one hand holds the ankle; the other hand holds the knee. For assessment of the medial meniscus, palpate the medial joint line with the knee flexed. A 'click' may be felt, suggesting meniscus relocation. A valgus stress is applied to the flexed knee. Externally rotate the leg (toes point outward), and slowly extend the knee while it is still in valgus.

Patellofemoral joint

The patella normally enters the trochlea from a lateral position and becomes centralised with increasing knee flexion, travelling in a 'J' pattern.

- **Patellar tracking** (*Figure 35.34*). Sit the patient and ask them to let their legs hang off the end of the couch with the knees flexed to 90°. Ask the patient to extend the knee slowly to full extension. Towards the end of extension, look for lateral subluxation of the patella ('J' sign). This indicates maltracking.
- **Patellar apprehension** (Fairbank's) test (for instability). Attempt to displace the patella laterally with the knee in extension. Patients with instability contract their quadriceps muscle or complain of pain. With the patient supine and the quadriceps relaxed, flex the knee to 30° while trying to push the patella laterally. With instability the patient may react with apprehension. In addition, the quadriceps muscle may contract in an attempt to realign the patella.

Patellar tendon

The patellar tendon serves as the distal limit of the extensor mechanism. Rupture usually occurs at the osseotendinous junction. This results in an inability to actively perform and maintain full knee extension. A rupture presents with diffuse swelling in the anterior knee. A high-riding patella (patella alta) is present secondary to the unopposed pull of the quadriceps muscle. A defect in the tendon is usually palpable. When the rupture extends through the medial and lateral retinacula, active extension is lost.

Thomas Porter McMurray, 1887–1949, Professor of Orthopaedic Surgery, Liverpool University, Liverpool, UK.
Sir Harold Arthur Thomas Fairbank, 1876–1961, orthopaedic surgeon, King's College Hospital, London, UK.

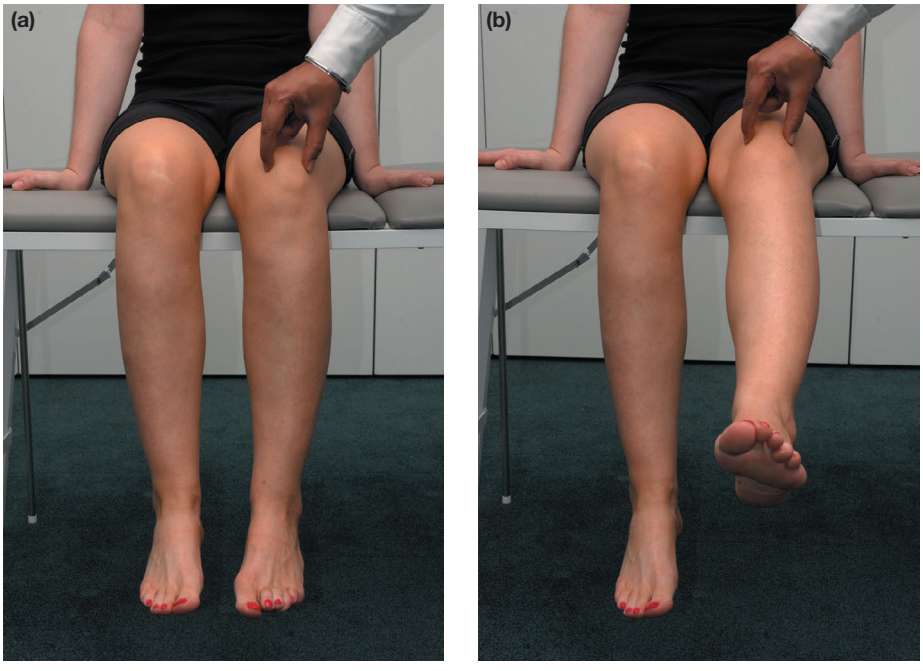

Figure 35.34 (a, b) Patellar tracking.

Summary box 35.9

Knee examination

- Inspection of the standing patient
  - Front – alignment (varus/valgus/rotational deformity), muscle bulk
  - Side – fixed flexion deformity
  - Back – popliteal swellings, hamstrings
  - Gait – antalgic, high-stepping gait (foot drop), varus thrust
- Inspection of the supine patient
  - Skin, scars, soft tissues, deformity
  - Palpation of the extensor mechanism, medial and lateral joint lines and collateral ligaments, hamstrings, tibial tuberosity, fibular head
- Movements
  - Flexion and extension
- Special tests
  - Patellar apprehension test and extensor mechanism
  - Cruciate ligaments
  - Collateral ligaments
  - Menisci

CLINICAL EXAMINATION OF THE FOOT AND ANKLE

The foot can be divided into three parts: the hindfoot (calcaneus, talus), the midfoot (navicular, cuboids, cuneiforms) and the forefoot (metatarsals and phalanges).

Look

Ask the patient to stand and assess the overall limb alignment. Assess pelvic obliquity, LLD (and its level), valgus/varus deformities of the knee and rotational alignment. Check for contractures of the hips and knees. Now focus your attention on the foot itself:

- **Foot shape**. Assess the overall shape of the forefoot from the front. From the side, look for the normal medial arch (*Figure 35.35a*). The hindfoot is best appreciated from behind. Now look at the vertical relationship between the Achilles tendon and the calcaneus (normal heel valgus of 5–7°). Look from behind and count the number of toes that can be seen. The 'too many toes' sign demonstrates increased forefoot abduction (pes planus [flat foot]) and a splayed forefoot. Foot shapes that may be encountered include neutral foot (no overall deformity), skew foot (hindfoot valgus and forefoot adduction), metatarsus adductus (neutral hindfoot and adduction of the metatarsus), pes planus (collapse of the medial arch) and pes cavus or high arch (increased medial arch) (*Figure 35.35b*). The possible causes of pes planus and pes cavus are shown in *Summary boxes 35.10 and 35.11*, respectively.
- **Skin**. A bunion or red swelling on the medial aspect of the metatarsophalangeal joint (MTPJ) is common. This is an area of inflamed skin with an underlying subcutaneous bursa and a joint osteophyte. Systemic manifestations include gouty tophi and thin fat pads under the metatarsal heads as seen in rheumatoid arthritis. Corns are callosities which form where toes rub against the inside of shoes. Remember to assess the appearance of the nails.
- **Soft tissues**. Swelling may indicate soft-tissue or joint pathology. Muscle wasting is most commonly seen on the dorsum of the foot and in the clefts between the metatarsals. If this is present, a full neurological examination of the upper and lower limbs should be performed, including the spine.
- **Bones**. Look for any bony prominences or exostoses. Common forefoot deformities are shown in *Table 35.12*.

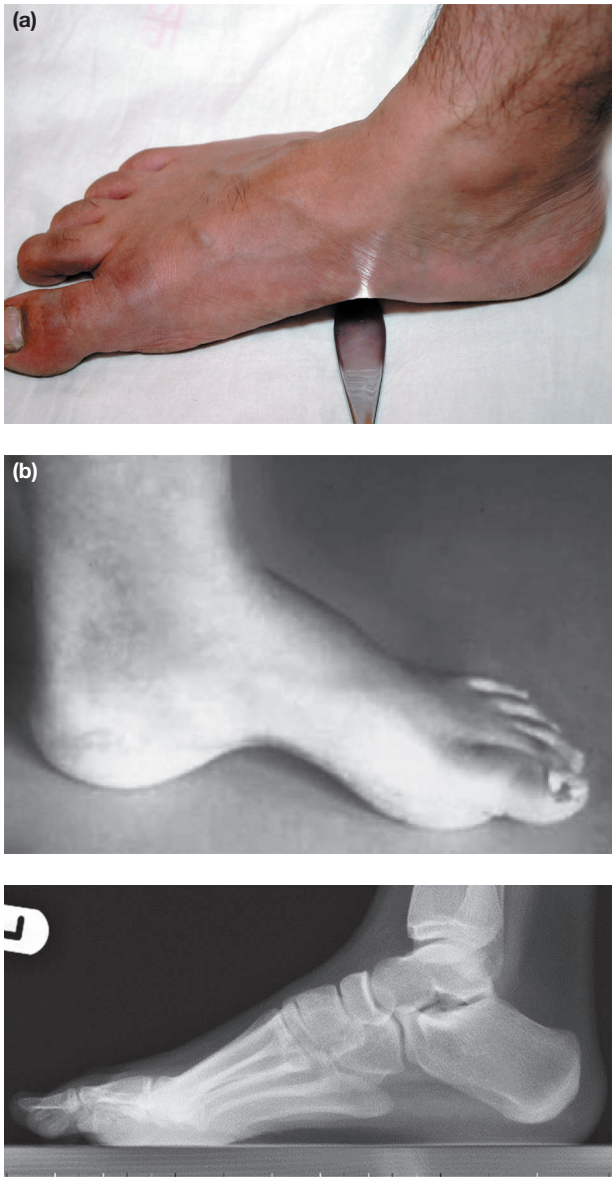

Figure 35.35 (a) Normal medial longitudinal arch of the foot. (b) Clinical and radiological appearance of pes cavus.

Summary box 35.10

Causes of pes planus

- Normal variant
- Hyperlaxity syndrome, e.g. Marfan's syndrome
- Tarsal coalition – rigid and painful flat foot (see *Figure 35.40a*)
- Tibial posterior dysfunction

Summary box 35.11

Causes of pes cavus (*Figure 35.35b*)

- Spinal anomalies, e.g. spina bifida
- Hereditary sensorimotor neuropathies, such as Charcot–Marie–Tooth disease
- Charcot foot (e.g. neuropathic foot)
- Post-compartment syndrome (e.g. Volkmann's ischaemic contracture)

Gait

Look for a high-stepping gait (foot drop), painful (antalgic) gait (ankle and foot joint pain) and a short propulsive phase (forefoot pain).

Footwear

Inspect the footwear. This may reveal areas of abnormal weight-bearing. With normal wear of the sole, a corner is typically worn off the posterolateral aspect of the heel (heel strike). In addition, there may be a circular wear pattern under the ball of the big toe (toe-off phase).

- **External appearance**. Look at the materials used, the metal supports and heel raise, depth and width.
- **Internal appearance**. Look at the insoles, arch supports and heel cups.

Feel

- **Skin**. Reduced sensation in a glove-and-stocking distribution is seen with diabetes.

TABLE 35.12 Common forefoot deformities.

Deformity	Metatarsophalangeal joint	Proximal interphalangeal joint	Distal interphalangeal joint
Claw toe	Hyperextension	Flexion	Flexion
Hammer toe	Normal	Flexion	Flexion
Mallet toe	Normal	Normal	Flexion
Hallux valgus or varus	Valgus or varus position	Normal	–

Antoine Bernard-Jean Marfan, 1858–1942, physician, Hôpital des Infants-Malades, Paris, France, described this syndrome in 1896.
Jean Martin Charcot, 1825–1893, physician, La Salpêtrière, Paris, France.
Pierre Marie, 1853–1940, neurologist, Hospice de Bicêtre, Paris, France, later became Professor of Pathological Anatomy in the Faculty of Medicine, and finally, in 1918, Professor of Neurology.
Howard Henry Tooth, 1856–1925, physician, St Bartholomew's Hospital and the National Hospital for Nervous Diseases, London, UK, described peroneal muscular atrophy in 1886, independently of Charcot and Marie.
Richard von Volkmann, 1830–1889, Professor of Surgery, Halle, Germany.

Figure 35.36 (a) Palpation of the posterior tibial pulse. (b) Palpation of the dorsalis pedis pulse.

- **Soft tissues**. The posterior tibial and the dorsal pedis pulses should be identified (*Figure 35.36*). Palpate the tibialis anterior tendon and the long extensor tendons on the dorsum of the foot. From the back, palpate the Achilles tendon. Palpate the peroneal tendons from the lateral side and the tibialis posterior tendon from the medial side. The sinus tarsi can be assessed. This is an anatomical space bounded by the talus and calcaneus and is recognisable as a soft-tissue depression anterior to the lateral malleolus. It is filled with fat and the extensor digitorum brevis muscle. Sinus tarsi syndrome may occur. This may be caused by injury to the interosseous talocalcaneal ligament or the subtalar joint. There is pain and tenderness over the sinus tarsi with subjective hindfoot instability. The pain is characteristically relieved by local anaesthetic injection.
- **Bones**. Feel for deformity, bony prominences and loose bodies:
  - *ankle joint*: the medial and lateral malleoli, anterior and posterior joint line, lateral gutter and ligament complex, the syndesmosis (front of the ankle), medial gutter and medial ligament complex;
  - *subtalar joint*: palpate each facet;
  - *midtarsal joints*: the talonavicular and calcaneocuboid joints;
  - *tarsometatarsal joints* (TMTJ): note that the second TMTJ is several millimetres proximal to the others; movement is minimal in the second ray, limited in the third ray, moderate in the fourth and fifth rays and very variable in the first ray.
- **Specific structures to palpate:**
  - *calcaneus* (heel bone): the most common cause of pain is plantar fasciitis; this may present with numbness, burning and electric shock sensations, which are worse in the morning and improve as the day goes on; identify the exact point of tenderness;
  - *tendons*: examine for contracture of the Achilles tendon insertion and the peroneal or tibialis posterior tendons;
  - *head of talus*: invert and evert the patient's foot;
  - *sustentaculum tali*: palpate one fingerbreadth below the medial malleolus; this important structure serves as an attachment for the spring ligament;
  - *cuneiforms* (medial, middle and lateral), MTPJs, web spaces and all the forefoot bones.

Move

The movements of the foot and ankle are linked via the ankle, subtalar and midfoot joints. Remember the acronyms PAED – pronation, abduction, eversion and dorsiflexion – and SAPI – supination, adduction, plantarflexion and inversion. These are the two common general foot deformities.

Ankle (*Figure 35.37*)

- **Dorsiflexion**. Test dorsiflexion with the knee both flexed and extended. If restriction is greater with the knee extended than flexed, the contracture is principally in the gastrocnemius. Restriction that is equal in all knee positions is caused by a contracture principally of the soleus.
- **Plantarflexion**. Ask the patient to touch the floor with their foot (15°). Weakness suggests injury to the Achilles tendon or pathology affecting the S1 nerve root.

Subtalar joint (*Figures 35.38 and 35.39*)

Hold the talar neck and ask the patient to move their heel from side to side. Repeat using a hand on the heel to move the joint and apply a varus and valgus stress while feeling for movements of the talus. Holding the talus as opposed to the tibia isolates the subtalar from ankle motion. (Normal range is 5° in each direction.)

- **Inversion**. Ask the patient to move their foot in towards them.
- **Eversion**. Ask the patient to move their foot out to the side.

Midtarsal joint

Hold the heel with one hand and move the forefoot medially (adduction = 20°) and laterally (abduction = 10°) with the other hand.

Tarsometatarsal joint

Hold the midfoot and manipulate each metatarsal up and down to estimate the passive range of movement.

Figure 35.37 (a) Ankle dorsiflexion and (b) ankle plantarflexion.

Metatarsophalangeal joint

Test extension (70–90°) by asking the patient to lift the toes to the ceiling and test flexion (45°) by pointing the toes to the floor. Normal toe-off requires 35–40° of dorsiflexion.

Special tests

Achilles tendon

Feel the gastrocnemius and soleus bellies and the whole length of the tendon for gaps (rupture), tenderness or swelling. Also identify the posterolateral (Haglund's) prominence of the calcaneus and palpate the retro-Achilles bursa.

The test for integrity of the tendon is the Thompson or Simmonds test. Do not be misled by the patient's ability to stand on tiptoes – some people can do this using their long toe flexors alone. Lie the patient prone and allow their calves to rest on your forearms. Squeeze each calf in turn and watch for movement at the ankle joint. Lack of movement may indicate a rupture.

Figure 35.38 Testing subtalar joint motion.

Subtalar joint flexibility

Ask the patient to stand on their toes and observe the heel from behind; the heel moves normally from valgus to varus, indicating flexibility. The Coleman block test is used to assess the flexibility of the subtalar joint. Ask the patient to stand on a 2-cm block with the great toe over the medial edge, resting on the floor. Now look from behind. If the hindfoot varus remains, the subtalar joint is fixed. If it corrects to valgus, the joint is mobile (*Figure 35.39*).

Flat foot flexibility

Use the windlass and Jack's tests to distinguish a flexible from a fixed flat foot (*Figure 35.40*).

- **Windlass test**. Ask the patient to stand on their toes and observe the arch of the foot on the medial aspect. As soon as the patient stands on their toes, the arch forms. Failure of this indicates a fixed flat foot.

Patrik Haglund, 1870–1937, Swedish orthopaedic surgeon.
Theodore Campbell Thompson, 1902–1986, American orthopedic surgeon, made many contributions to orthopaedic surgery, especially in the field of post-polio deformities.
Franklin Adin Simmonds, 1911–1983, orthopaedic surgeon, Rowley Bristow Hospital, Pyrford, UK.
Sherman S Coleman, 1922–2004, Chief Surgeon, Intermountain Unit of the Shriners Hospital, and Chairman, Division of Orthopedics, University of Utah, Salt Lake City, UT, USA.
Ewan A Jack, 1909–1953, Scottish orthopaedic surgeon.

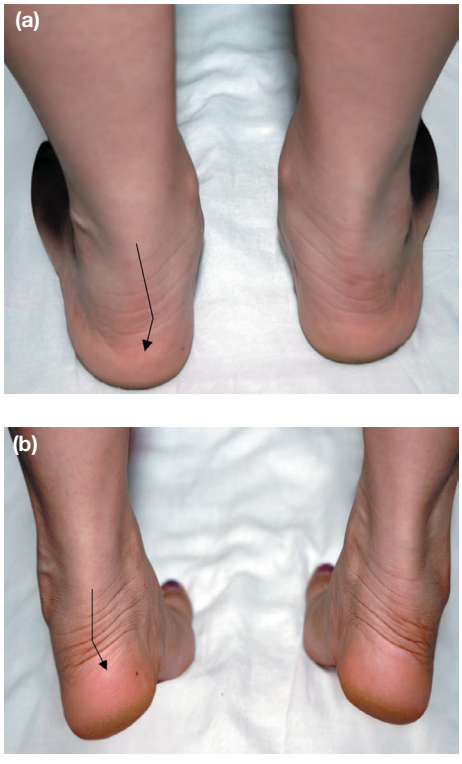

Figure 35.39 (a, b) Testing subtalar joint flexibility.

- **Jack's test**. With the patient standing, lift up the great toe. The arch should form in the flexible flat foot.

Ankle stability

Trauma to the ankle is a common cause of instability. Accurate assessment may be difficult in the acute setting because of pain.

- **Anterior draw test**. With the foot resting over the bed, hold the heel with one hand and the front of the tibia with the other. Move the heel forwards on the fixed tibia. Compare with the other side. Instability of the syndesmosis may be palpable (*Figure 35.41*).
- **Squeeze test for distal tibiofibular stability**. Compress the proximal calf. Pain at the ankle may indicate separation of the distal fibula from the tibia.
- **Tilt test**. Hold the talus at the neck rather than the heel so that you can be sure that any tilt is in the ankle and not the subtalar joint.

Tarsometatarsal joint stability

Stability can be assessed by pushing each joint up and down. Standing lateral radiographs may be used in addition.

Tibialis anterior

Ask the patient to walk on their heels with their feet inverted; the tibialis anterior tendon can be seen. With the patient's feet resting over the edge of the couch, ask the patient to actively dorsiflex and invert their foot to reach your hand. Palpate the tibialis anterior muscle.

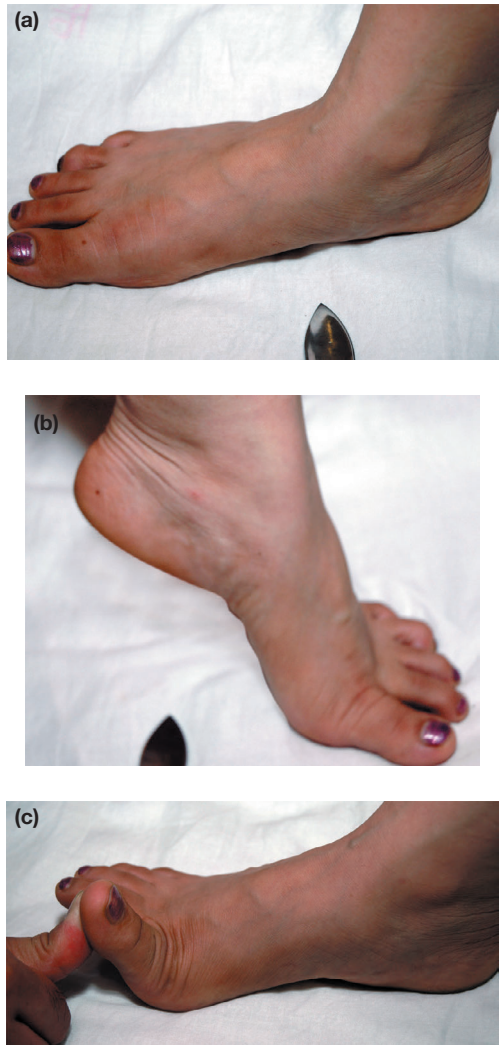

Figure 35.40 (a) Flat foot appearance with a reduced medial longitudinal arch; (b) windlass test; (c) Jack's test.

Figure 35.41 Anterior draw test.

Tibialis posterior

Pathology of the tibialis posterior typically presents with posteromedial ankle pain, swelling and gradual onset of a flat foot. When assessing the tendon, look for swelling along its course, a flat foot with heel valgus, the 'too many toes' sign and prominence of the talar head. Palpate for tenderness, swelling or gaps in the tendon.

- **To test integrity**, ask the patient to perform a single-foot tiptoe test on both sides. The inability to lift the affected heel off the ground is suggestive of a tibialis posterior tendon injury or insufficiency.
- **To test strength**, position the foot in the plantarflexed and inverted position. Ask the patient to hold this position while you push against their foot.

Dorsiflexors

Tendinitis of the long toe dorsiflexors usually presents in athletes. Pain affects gait in the early contact phase. Palpate for swelling, gaps or any tenderness. Ask the patient to move the foot into dorsiflexion and to hold this position while you push the foot down.

Inability to dorsiflex the foot is referred to as foot drop. Causes include stroke, spinal injury, spinal stenosis or disc prolapse, peripheral nerve injury (e.g. sciatic, common and deep peroneal) or a peripheral neuropathy.

Peroneal tendons

Peroneal tendon pathology presents with swelling and/or pain of the lateral hindfoot or midfoot. There may be a history of the ankle 'giving way'. Presentations of peroneal tendon pathology include:

- **'peroneal spasm'**: may be seen in tarsal coalition; here, the muscles are usually contracted secondary to the hindfoot valgus;
- **peroneal tendon dislocation**: attempt to dislocate the tendons by dorsiflexing and everting the foot.

The peroneus longus may be palpated just before it crosses under the foot to insert onto the base of the first metatarsal. Ask the patient to plantar flex the first metatarsal. Test strength and integrity by active and resisted eversion while you palpate the tendons for swelling, tenderness or gaps.

Morton's neuroma

This condition represents thickening of the tissue that surrounds the digital nerve leading to the toes as the nerve passes under the ligament connecting the metatarsals in the forefoot. It is most frequent between the third and fourth toes. A neuroma presents with burning pain in the ball of the foot that radiates to the involved toes. The condition is difficult to diagnose and requires a high index of suspicion. Palpate in the web space between the symptomatic toes for a mass. Compression of the metatarsals may elicit a 'click' between the bones (Mulder's click).

Summary box 35.12

Ankle and foot examination

- Inspection of the standing patient
  - Front – alignment, foot shape and deformity
  - Side – medial arch
  - Back – heel position
  - Gait – antalgic, high-stepping gait (foot drop)
- Inspection of the supine patient
  - Skin, scars, soft tissues, bony deformity
  - Palpation of the ankle, subtalar, midfoot and forefoot joints
- Movements
  - Dorsiflexion, plantarflexion, inversion, eversion
- Special tests
  - Flexibility of the subtalar joint and a flat foot
  - Joint stability, Morton's neuroma
  - Tendons – tibialis posterior and anterior, Achilles tendon, peroneals and dorsiflexors

PART 5 | Elective orthopaedics

CHAPTER 36

Sports medicine and sports injuries

Learning objectives

- To review some common sports injuries
- To understand the basics of history, physical examination and imaging for common injuries
- To assess the patient and offer treatment and rehabilitation plans

INTRODUCTION

In addition to a clinical assessment, an understanding of the biomechanics of injury associated with sporting activity can facilitate diagnosis, treatment and management of the patient according to their competitive level and recovery goals. This chapter aims to provide a brief clinically directed overview of selected common injuries, with the examples associated with a wide variety of sports.

DIAGNOSIS OF SPORTS INJURIES

Within the history, there are some additional questions that need to be asked when treating a patient with a sports injury:

- How was the injury sustained?
- When was the injury sustained?
- What intervention(s) has the patient tried and what rehabilitation have they had?
- How many hours of training is the patient doing and has this changed recently?
- Has the patient had a previous injury?
- What are the patient's competitive goals?

The examination should follow the general system described in *Chapter 35*.

COMMONLY ENCOUNTERED REGIONAL INJURIES

Shoulder

Shoulder instability and rotator cuff tear

Background

Shoulder injuries affect athletes of all ages; however, the distribution of shoulder injuries varies between young and older participants. In athletes younger than 30 years old, especially those participating in contact sports, anterior shoulder dislocations can occur in instances of traumatic or forced shoulder abduction and external rotation. Unfortunately, such dislocations, even if reduced, lead to some degree of stretching of the anterior capsule and tearing of the anteroinferior labrum, which places the patient at risk for further instability events. In older patients who experience falls and sustain the same anterior shoulder dislocations, additional pathologies, including rotator cuff tears, can occur.

History and physical examination

Patients who sustain a shoulder dislocation often describe a violent injury event such as a fall or tackle with the arm in some degree of abduction. Patients will often describe a sensation of their shoulder feeling out of place, especially if the shoulder does not spontaneously reduce. An important component of the history involves the details of the dislocation(s): self-reduction versus emergency department reduction, length of time dislocated prior to reduction, prior dislocations, extremity numbness, general ligamentous laxity and activity profile – all of these details have implications for management. Examination in the acute period should focus on evaluating anterior apprehension or subjective patient discomfort and fear of re-dislocation in the positions of abduction and external rotation of the shoulder, as well as rotator cuff strength and neurovascular integrity, especially of the axillary nerve (see *Further reading*).[1,2]

Imaging

Radiographs, including at least true anteroposterior (AP) or Grashey, scapular Y, axillary or Velpeau views, should be obtained in all circumstances and evaluated to confirm glenohumeral reduction while ruling out associated fractures, such as Hill–Sachs deformities or glenoid rim fractures.

Rudolph Grashey, 1876–1950, Professor of Roentgenology, University of Cologne, Cologne, Germany.
Alfred-Armand-Louis-Marie Velpeau, 1795–1867, French anatomist and surgeon.
Harold Arthur Hill, 1901–1973, radiologist, San Francisco, CA, USA.
Maurice David Sachs, 1909–1987, radiologist, San Francisco, CA, USA.

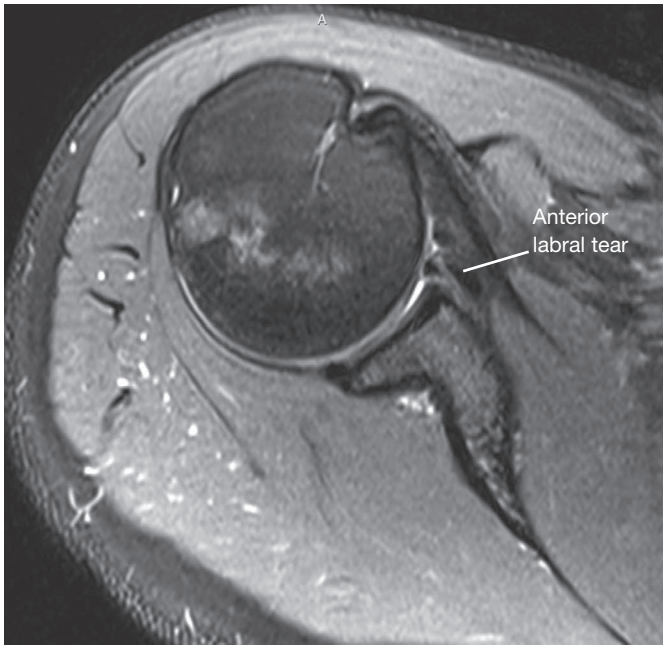

Figure 36.1 Axial fluid-sensitive magnetic resonance image of the shoulder demonstrating an anterior labral tear.

Specific views, including the West Point axillary and the Stryker notch views, can be helpful for evaluating glenoid rim or Bankart fractures or Hill–Sachs lesions, respectively. In cases of recurrent instability where glenoid bone loss is suspected, computed tomography (CT) with or without three-dimensional reconstruction can be helpful in further determining the extent of bone loss. In most instances of anterior instability, magnetic resonance imaging (MRI) is recommended (***Figure 36.1***) to evaluate for concomitant soft-tissue injuries, including rotator cuff tears, humeral avulsions of the glenohumeral ligament (HAGL), glenolabral articular disruptions (GLAD) or anterior labrum periosteal sleeve avulsion (ALPSA).

Treatment

After reduction of an acute anterior glenohumeral dislocation, patients are typically placed in a sling for the first few days.[2] It is important to begin early gentle range of motion of the shoulder through pendulum exercises but also to continue to move the elbow, wrist and digits actively to maintain range of motion in those distal joints. The initial period is then progressed to increased passive and then active and active-assisted range of motion of the shoulder. Once range of motion has returned to near normal, rotator cuff and scapular strengthening is progressed. Surgery is considered for even first-time dislocators based upon stratification of several factors, including younger age, activity profile and pathology present on imaging. Furthermore, depending upon the pathology present, the surgical options exist on a continuum from arthroscopic capsulolabral repair to open capsulolabral repair and capsular shift to glenoid bony augmentation procedures.[3,4] Regardless of the treatment method chosen, athletes are cleared to return to sport once their range of motion and strength have returned to normal levels.

Older athletes who acutely tear their rotator cuff in the setting of shoulder dislocations can be considered for acute rotator cuff repair.[5] The treatment of rotator cuff tears has evolved over several years and current techniques of arthroscopic repair with a knotless, linked, double-row construct (***Figure 36.2***) have demonstrated excellent patient-reported outcomes with low re-tear rates.

Differential diagnosis

- Proximal humerus fracture.
- Greater tuberosity fracture.
- Acromioclavicular joint separation.

Summary box 36.1

Shoulder instability

- Dislocations occur in instances of traumatic or forced shoulder abduction and external rotation
- Details of the reduction, time dislocated, history of prior dislocations, general ligamentous laxity and activity profile have implications for management
- Radiographs to confirm glenohumeral reduction include true AP or Grashey, scapular Y, axillary or Velpeau views
- A sling should be used for a few days following an acute anterior glenohumeral dislocation
- Surgery is considered based upon stratification of several factors, including younger age, activity profile and pathology present on imaging

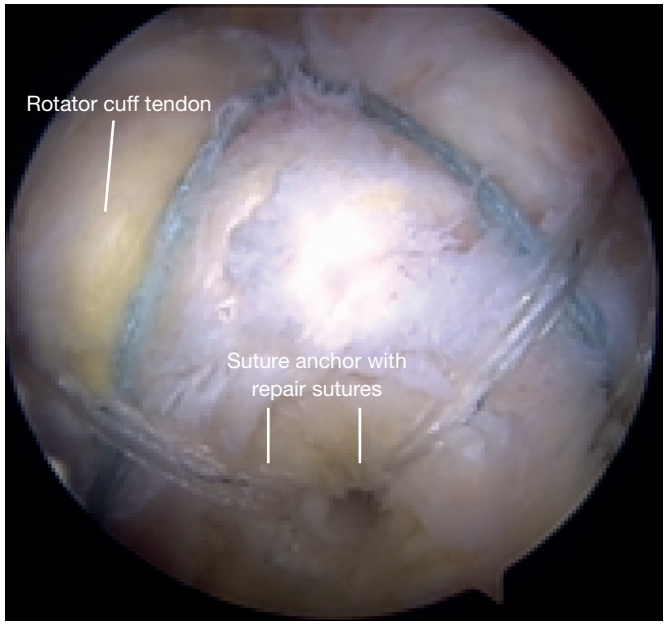

Figure 36.2 Shoulder arthroscopic image of a rotator cuff repair viewed from the subacromial space through a lateral portal with a 30° arthroscope.

William Schamel Stryker, 1916–2015, orthopedic surgeon and Captain in the United States Navy.
Arthur Sydney Blundell Bankart, 1879–1951, orthopaedic surgeon, The Middlesex Hospital, London, UK.

Elbow

Ulnar collateral ligament tear

Background

The anterior band of the ulnar collateral ligament (UCL) is the primary stabiliser to valgus stress at the elbow. Anatomically this ligament courses from the medial epicondyle of the humerus to the sublime tubercle of the ulna. Although it can be injured acutely through mechanisms of elbow dislocations, pathology is most frequently encountered in repetitive throwing athletes, such as baseball pitchers and javelin throwers. In the late cocking and early acceleration phases of throwing the ligament is under its maximum stress and at this stage is at the highest risk of rupture and chronic attenuation.

History and physical examination

Throwers who sustain ruptures of their UCL commonly present with two sets of complaints. Rarely, the thrower will recall an acute episode when they heard a pop in the throwing cycle followed by medial elbow pain and pain worse with throwing. The vast majority of throwers complain of medial elbow pain and tightness coupled with decreased velocity that comes on more insidiously. Examination focuses on provocative manoeuvres that are specific for the UCL, including valgus stress and the moving valgus stress tests or milking manoeuvre (***Figure 36.3***), in which the examiner provides a valgus stress through elbow range of motion.[6] Pain at the medial elbow during these manoeuvres is specific for UCL pathology. The examiner should also focus on both ulnar nerve sensory and motor symptoms in the hand in addition to ulnar nerve subluxation as these pathologies can affect the proposed treatment algorithm.

Imaging

Radiographs of the elbow include a series of AP, lateral, internal and external oblique views. These can help rule out other commonly encountered phenomena seen in overhead throwing athletes, including medial epicondyle fractures, posteromedial impingement and capitellar osteochondral defects. When UCL pathology is suspected, dynamic ultrasound is a helpful imaging modality to help characterise the location of the UCL pathology. Moreover, it permits easy examination of the contralateral elbow, which can help to quantify incongruities in medial elbow joint space gapping, an indirect gauge of tear severity. MRI is commonly obtained to precisely define the location of the UCL tear as well as to better evaluate the articular cartilage and the flexor pronator mass, which can also commonly be affected.

Treatment

Conservative management of UCL injuries is considered first-line treatment and typically entails a period of several months of cessation of throwing followed by structured rehabilitation that includes strengthening of secondary stabilising muscles about the elbow and a gradual return of throwing.[6] The use of biological injections, including platelet-rich plasma, has been proposed for partial-thickness ligament tears in some centres, but more clinical evidence is required. Although ligament repair with an internal brace has recently been demonstrated to have efficacy in certain types of tears, the gold standard for surgical treatment is UCL reconstruction or Tommy John surgery. The surgery involves an autograft tendon harvest, commonly utilising the ipsilateral palmaris longus tendon, and reconstruction of the ligament through bone tunnels in both the humerus and ulna.[6] This surgery can be coupled with *in situ* decompression or transposition of the ulnar nerve, if indicated. Ulnar reconstruction surgery is indicated for the highest level of throwers who wish to continue playing their respective sport, with return to sport taking anywhere from 12 to 18 months.

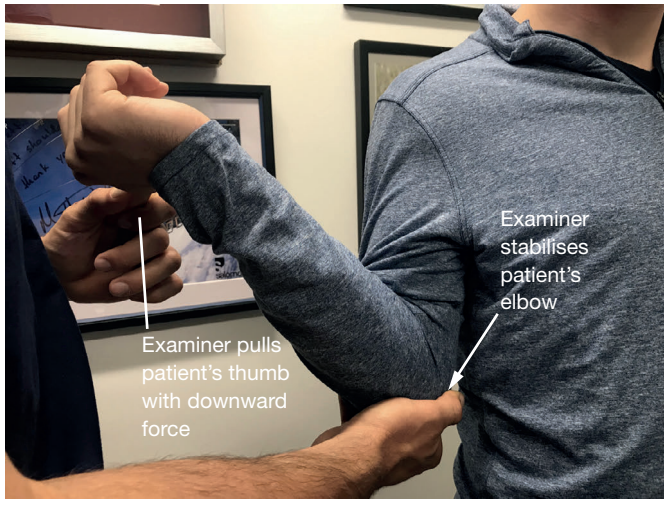

Figure 36.3 Demonstration of the milking manoeuvre. This is considered a positive test when this provocative manoeuvre elicits pain in the medial elbow, indicating ulnar collateral ligament injury.

Differential diagnosis

- Flexor pronator mass sprain.
- Ulnohumeral arthritis.
- Ulnar nerve compression or subluxation.
- Loose body.

Summary box 36.2

UCL tears

- Injury seen among repetitive throwing athletes
- Onset can be acute ('pop') or insidious with medial elbow pain, tightness and decreased throwing velocity
- Dynamic ultrasound or MRI can be used to characterise the location of the UCL pathology
- First-line treatment is conservative management with cessation of throwing followed by structured rehabilitation
- Surgical options include UCL reconstruction (gold standard) or ligament repair with an internal brace

Tommy John surgery, named after Thomas Edward John Jr, the first major league baseball pitcher who received an ulnar collateral ligament reconstruction in 1974.

Figure 36.4 Example of the C-sign for intra-articular hip pathology when asking a patient to demonstrate where they feel their pain.

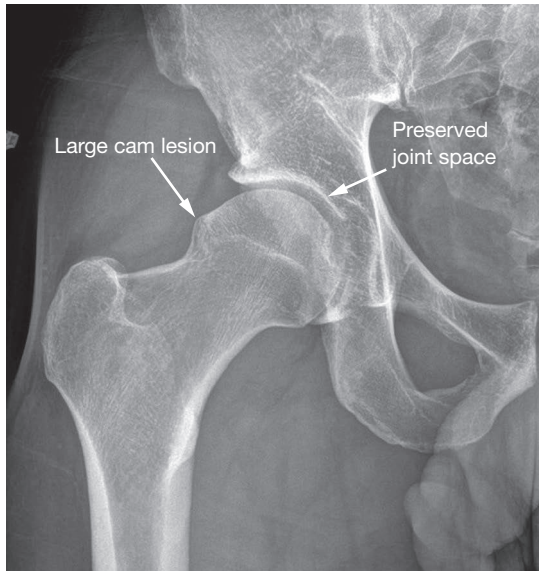

Figure 36.5 Anteroposterior right hip radiograph demonstrating a large cam lesion in the setting of the preserved hip joint space.

Hip

Femoroacetabular impingement and dysplasia

Background

Intra-articular hip derangements most commonly manifest as anterolateral groin pain in a characteristic distribution, referred to as a 'C-sign' (***Figure 36.4***). In a young patient, two common sources of groin pain with intra-articular origin are femoroacetabular impingement (FAI) and dysplasia. These conditions are considered in some detail in ***Chapter 39*** but are described here as they can present as a sports-related injury.

History and physical examination

Young patients with a history of groin pain or repetitive 'groin or hip flexor sprains' should be evaluated for dysplasia or FAI. Physical examination focuses on hip range of motion, strength, palpation and provocative manoeuvres. Some important manoeuvres include the FADIR examination, which stands for hip Flexion, ADduction and Internal Rotation, which is specific for impingement pathologies, but the FABER (Flexion, ABduction and External Rotation) manoeuvre as well as resisted hip flexion (Stinchfield testing) can also identify true intra-articular pathologies.[7]

Imaging

Initial imaging includes radiographs of the pelvis and the affected hip. Anteroposterior pelvis and false profile views can help determine lateral or anterior coverage of the acetabulum, respectively, while 45° Dunn lateral radiographs of the hip are the optimal projection for detecting the presence of a cam lesion (***Figure 36.5***). Three-dimensional imaging, including CT and MRI, is helpful for better defining the bony morphology and soft-tissue (i.e. labral) integrity, respectively.

Treatment

Once the correct diagnosis is determined both pathologies can initially be treated conservatively using anti-inflammatory drugs, physical therapy and at times intra-articular injection, for example corticosteroid. Should these modalities fail, both FAI and dysplasia have their own specific surgical interventions: arthroscopy (***Figure 36.6***) and osteotomy, respectively (see ***Chapter 39***). Importantly, the aforementioned interventions are only a consideration prior to the development of joint space narrowing and osteoarthritis in an effort to preserve the hip joint.[7]

Differential diagnosis

- Adductor strain.
- Hip osteoarthritis.
- Athletic pubalgia.
- Lumbar radiculopathy.

Summary box 36.3

Femoroacetabular impingement and dysplasia

- Intra-articular hip derangements can manifest with anterolateral groin pain in a characteristic distribution ('C-sign')
- Consider pathologies in young patients with a history of groin pain or repetitive 'groin or hip flexor sprains'
- Initial imaging includes radiographs of the pelvis and the affected hip
- Three-dimensional imaging includes CT (bony morphology) and MRI (soft-tissue integrity)
- Conservative treatment involves using anti-inflammatory drugs, physical therapy and/or intra-articular injection
- Surgical interventions are arthroscopy (FAI) and osteotomy (dysplasia) prior to the development of joint space narrowing and osteoarthritis

Denis M Dunn, 1916–2001, British orthopaedic surgeon.

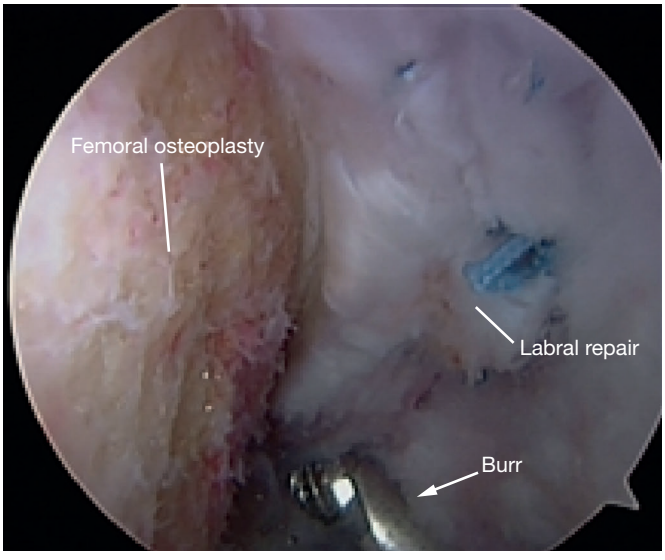

Figure 36.6 Hip arthroscopic image viewed through the mid-anterior portal with a 70° arthroscope.

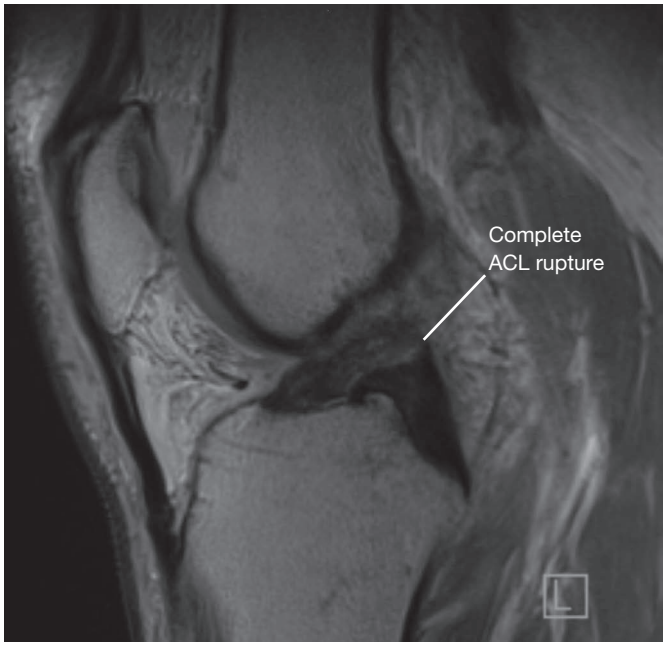

Figure 36.7 Sagittal proton density magnetic resonance image of the knee demonstrating a complete proximal anterior cruciate ligament (ACL) rupture.

Knee anterior cruciate ligament rupture with meniscus tear

Background

Acute knee injuries are extremely common in most sports that require jumping, twisting and contact. Sports with physical impact or tackling, such as rugby or American football, can result in contact knee injuries that often lead to varus or valgus stresses to the knee, resulting in collateral ligament injuries (i.e. lateral collateral ligament or medial collateral ligament) in addition to concomitant cruciate ligament, meniscus or articular cartilage injuries. More frequently, however, acute non-contact injuries of the knee lead to injury to the anterior cruciate ligament (ACL). The most common mechanism of these injuries is a deceleration when the knee falls into valgus and the tibia externally rotates, leading to a subluxation of the knee. These injuries are often associated with either medial or lateral meniscus injuries.

History and physical examination

Patients with an acute ACL injury will often report hearing or feeling a pop in their knee followed by a notable effusion and/or haemarthrosis. Once the effusion resolves, they may report a paucity of knee pain, often leading the patient to believe that the injury has healed itself. However, patients usually present to a physician after attempting subsequent cutting and pivoting activities, which can lead to recurrent instability. Given that the ACL's primary function is to restrict anterior translation of the tibia on the femur, the most commonly utilised tests to evaluate the competency of the ACL are the anterior drawer and Lachman tests (see *Chapter 35*).

Imaging

The initial evaluation of an acute knee injury with effusion and/or haemarthrosis necessitates radiographic evaluation. AP, lateral and merchant views are the minimum recommended. These radiographs can be useful for identifying any concomitant injuries, including fractures. A Segond fracture located on the anterolateral tibia is pathognomonic for an ACL injury. If an ACL injury is suspected by physical examination, an MRI is performed to better evaluate the intra-articular structures and to aid in surgical planning. A systematic evaluation of the MRI is necessary to ensure that no additional pathology is missed (*Figure 36.7*). 'Kissing lesions' of bony oedema seen on fluid-sensitive sequences on the posterolateral tibia and lateral femoral condyle are also pathognomonic for ACL rupture and represent the pivot shift knee subluxation seen in the setting of ACL rupture.

Treatment

ACL injuries can be managed conservatively through activity modification and bracing. Should these modalities fail, surgery is an excellent option for restoration of knee stability and to decrease the potential for further meniscal or articular cartilage degeneration. ACL repair has recently become a resurging option for proximal-type tears when the ACL can be restored back to its anatomic footprint on the femur. The bridge-enhanced ACL repair (BEAR) technique using a collagen scaffold is currently under clinical trial and may emerge as an option in the future. The gold standard for ACL, however, is reconstruction. In younger patients, large multicentre cohort studies have indicated that autograft reconstruction offers the best durability and lowest chance for re-rupture. Options for autograft reconstruction include bone–patellar tendon–bone, hamstring and quadriceps–tendon autografts. For older and

John W Lachman, 1919–2007, Professor and Chairman of the Orthopedic Department at Temple University in Philadelphia, PA, USA.
Paul Ferdinand Segond, 1851–1912, French surgeon who was a founder of obstetrics and also an expert of the knee, Paris, France.

low-demand patients with symptomatic instability, allograft tendon reconstruction provides an additional graft option.

Meniscal tears are frequently encountered in the setting of ACL rupture.[8] Common tear patterns encountered include radial tears, root tears and bucket-handle tears where the torn portion of the meniscus can flip like a bucket handle into the centre of the joint. Previously, meniscus tears were treated with partial excision to remove any mechanical disruptions and associated pain, but in recent years the joint preservation functions of the menisci as well as their contribution to stability of the knee have been better appreciated, leading to efforts to preserve as much meniscal tissue as possible, especially in younger patients. Various methods of meniscus repair are currently utilised to restore the meniscus anatomy, including all-inside devices, inside-out, outside-in and root repair techniques, the details of which are beyond the scope of this chapter. Biological strategies, to augment the repair, are being evaluated in some centres.

Differential diagnosis

- Patellar dislocation.
- Posterior cruciate ligament rupture.
- Medial collateral ligament knee rupture.
- Posterolateral corner knee ligament injury.
- Patellar tendon rupture.

Summary box 36.4

ACL ruptures

- Mechanism is commonly a non-contact pivoting injury or a direct impact to the lateral knee
- Patients often hear or feel a pop in their knee followed by a notable effusion and may experience instability when returning to cutting and pivoting activities
- Radiographic evaluation includes AP, lateral and merchant views
- MRI is performed to better evaluate the intra-articular structures, aid in surgical planning and ensure that no additional pathology is missed
- ACL injuries can be managed conservatively through activity modification and bracing
- Surgical options include ACL reconstruction (gold standard) and repair in certain select scenarios

Ankle

Low ankle sprains

Background

Ankle sprains are a common injury that can prevent athletes from competing. These injuries are prevalent in sports that involve cutting actions or uneven surfaces while running, such as basketball, rugby, soccer, football and trail running. The ankle primarily resists inversion through the lateral collateral ligament complex, which is composed of the anterior talofibular ligament (ATFL), posterior talofibular ligament (PTFL) and calcaneofibular ligament (CFL). The ATFL is the most frequently injured ligament in the complex; it attaches at the most distal aspect of the fibula and spans anteromedially to the lateral aspect of the talus to prevent inversion during plantarflexion. The CFL is the next most injured ligament; it attaches proximal and posterior to the ATFL origin on the fibula and traverses posteromedially to the lateral aspect of the calcaneus. The position and orientation of the CFL results in resistance against inversion of the ankle while dorsiflexed. The PTFL is the strongest ligament in the complex and is rarely involved in ankle sprains.

History and physical examination

Patients with ankle sprains can often recall the injury and will report the feeling of the ankle inverting. Post injury, many patients will have swelling and bruising on the lateral aspect of their ankle, which can travel to a dependent position on their foot. Examiners should perform all examination manoeuvres on the contralateral and ipsilateral sides to assist in comparisons. The patient may exhibit tenderness to palpation at the lateral collateral ligament complex. The anterior drawer test can be used to evaluate for ATFL injuries. In this test, the ankle is placed into mild plantarflexion while a posterior force is applied to the distal tibia and an anterior translation force is applied to the calcaneus. This test is positive when there is excessive anterior translation of the talus on the tibia compared to the contralateral side. The talar tilt examination evaluates both the CFL and the ATFL. This test is performed with mild plantarflexion of the foot, followed by stabilisation of the distal tibia with one hand while the other hand places varus stress on the talus. Excessive tilt during this manoeuvre is indicative of ATFL injury, whereas CFL injury is indicated by excessive tilt when placing the foot in slight dorsiflexion with varus stress on the talus being applied.

Imaging

Radiographs of the ankle are indicated if the patient fulfils any of the Ottawa ankle rules (***Table 36.1***). Foot radiographs are obtained if the patient has tenderness at the base of the fifth metatarsal or at the navicular bone or if they are unable to bear weight on the foot. Typically, radiographs include weight-bearing AP, mortise and lateral views along with a talar tilt view. These can help rule out other pathologies that may be contributing to ankle pain, such as various types of fractures or osteochondral lesions of the talus. If the examiner is concerned about a high ankle sprain, an external rotation radiograph can be obtained. MRI is not a standard modality utilised in the evaluation of ankle sprains but should be obtained for patients with chronic ankle pain or instability to evaluate for osteochondral lesions of the talus, tendon injury, anterolateral impingement or tibiofibular syndesmosis injury.

TABLE 36.1 Ottawa ankle rules.

- Bone tenderness along the distal 6 cm of the posterior margin or at the tip of the lateral malleolus
- Bone tenderness along the distal 6 cm of the posterior margin or at the tip of the medial malleolus
- Inability to bear weight at the time of the accident or at the time of examination

Treatment

Ankle sprains are often treated conservatively with rest, ice, compression and elevation. Athletes should limit

weight-bearing initially, with care being directed towards pain control, reducing swelling and proprioceptive exercises. Strengthening of the peroneal muscles and stretching can occur once the patient is able to tolerate bearing weight on the ankle. Consider supportive braces to further stabilise the ankle from inversion and eversion. Surgery is indicated in patients with persistent pain and recurrent ankle sprains. This can be achieved through anatomical reconstruction by imbrication of the attenuated ATFL with or without reinforcement using the inferior extensor retinaculum.[9] Several non-anatomical lateral ankle ligament reconstruction techniques have also been described for use in chronic ankle instability. The prognosis following an ankle sprain depends on the severity of the injury, but many patients are back participating in sports after a few weeks.

Differential diagnosis

- Anterolateral ankle impingement.
- Peroneal tendon disruption.
- Fracture of the lateral talar process.
- Syndesmotic sprain.
- Osteochondral lesion of the talus.
- Malleolar fracture.
- Lateral process of the calcaneus fracture.

Summary box 36.5

Low ankle sprains

- Common injury among athletes in sports that involve cutting actions or running on uneven surfaces
- Patients may report the feeling of the ankle inverting and present with subsequent swelling and bruising on the lateral aspect of their ankle
- Radiographs of the ankle are indicated if the patient fulfils any of the Ottawa ankle rules
- Foot radiographs are obtained if the patient has tenderness at the base of the fifth metatarsal or at the navicular bone or if they are unable to bear weight on the foot
- Ankle sprains are often treated conservatively with rest, ice, compression and elevation
- Surgery is indicated in patients with persistent pain and recurrent ankle sprains

INJURIES ASSOCIATED WITH INDIVIDUAL SPORTS

Golf

The shoulder and the back are the common sites of overuse injuries. Golfer's elbow or medial epicondylitis is due to a common flexor origin tendinosis that also commonly occurs in weightlifters and rodeo athletes.

Tennis

Tennis elbow or lateral epicondylitis is angiofibrous dysplasia of the common extensor origin. Treatment consists of bracing, activity modification, injection (with some centres using platelet-rich plasma) and surgery if conservative measures fail.

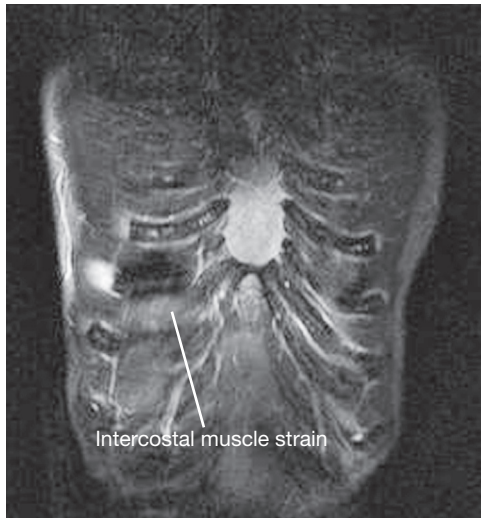

Figure 36.8 Coronal magnetic resonance imaging scan of the chest showing an intercostal muscle injury in a rower.

Partial ruptures of the calf muscles, especially the medial head of the gastrocnemius, are also found in tennis players (called tennis leg), and in patients who take part in other sports requiring sudden extreme acceleration.

Rowing

The common injuries that are encountered in rowing but that are rare in other athletics include rib stress fractures and intercostal muscle tears (***Figure 36.8***), which occur from the repetitive engagement of the latissimus dorsi muscles. Forearm tendon issues such as intersection syndrome (a tendinosis where the first and second extensor tendon compartments of the forearm cross) are also a commonly encountered problem in rowing athletes.

American football

This contact sport produces a variety of unique injuries, the main ones of which are closed head injuries, fractures, hip dislocations, twisting injuries to the knees and ankles leading to ligament tears, and turf toe.

Rugby

This is a high-intensity contact sport. Patients present with neck injuries including fractures of the cervical spine; acromioclavicular joint and finger injuries including dislocation of the phalanges; and tendon injuries such as jersey finger, in which there is injury to the flexor digitorum profundus tendon.

Javelin

Javelin throwers experience various injuries to the kinetic chain given the violent and abrupt throwing approach. Injuries due to abnormal stresses on the elbow are similar to those seen in baseball. This causes abnormalities of the hip, shoulder, UCL and phalanges.

Swimming

Shoulder injuries are more common in swimmers, especially in those performing the crawl or the butterfly stroke because of multidirectional instability, which can provide a competitive advantage for swimming but can become pathological.

Ballet dancing

Ballet dancers have problems with posterior impingement of the ankle and tendinopathy of the flexor hallucis longus tendon when working *en pointe* (tiptoe). Stress fractures are also found in female dancers as a result of repetitive training and can be more frequent in the female athlete triad (osteoporosis, disordered eating and amenorrhoea) (***Figure 36.9***).

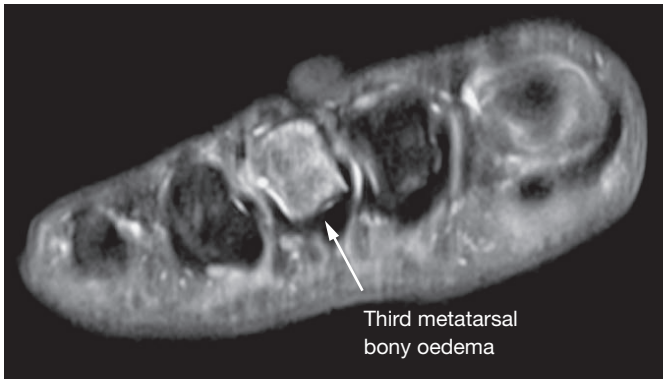

Figure 36.9 Magnetic resonance imaging short T1 inversion recovery axial sequence showing a stress injury to a metatarsal.

Snowboarding and skiing

Participants in both snowboarding and skiing have the full range of injuries associated with these high-speed sports. The rigid high boots used by skiers protect the ankle but increase the loads transmitted up the limb, risking fracture of the tibia and ligament disruption of the knee (especially the anterior cruciate). Novice snowboarders tend to get wrist fractures, while all levels of snowboarder can injure the acromioclavicular joint.

Marathon running

Most common problems include electrolyte abnormalities during events and iliotibial band syndrome and stress fractures in the feet and shins chronically.

SUMMARY

Athletic activities commonly result in a variety of injuries. For providers who take care of athletes, a basic knowledge of both common injuries and treatment algorithms as well as various sport-specific injury patterns is necessary to provide optimal care.

ACKNOWLEDGEMENT

The authors are grateful for and wish to acknowledge the contribution of Dylan Rakowski MD in the preparation of this chapter.

PART 5 | Elective orthopaedics

CHAPTER
37 The spine

Learning objectives

To learn:

- The salient features relating to the history and examination of the spine
- The investigations commonly used in the field of spinal disorders
- The treatment principles for common conditions affecting the spine
- The global issues in spinal surgery

EPIDEMIOLOGY

The lifetime prevalence of low back pain has been reported to be 60–80%. By contrast, the lifetime prevalence of true sciatica is 2–4%. It is generally accepted that 90% of acute low back pain episodes settle, allowing return to work within 6 weeks. However, some 5–7% of the population aged between 45 and 64 years will report back problems as a 'chronic sickness'. Up to 70% of acute episodes of sciatica resolve within 3 months.

Summary box 37.1

Epidemiology

- Low back pain is extremely common
- 90% of acute low back pain episodes settle within 6 weeks
- Sciatica is much less frequent
- 70% of acute sciatic episodes settle within 3 months

CLINICAL ANATOMY

The normal cervical lordosis measures between 35° and 45°. The normal lumbar lordosis is between 40° and 80° (mean 60°) and decreases with age. Most lumbar lordosis occurs between L4 and S1. The normal thoracic kyphosis is between 20° and 50° (mean 35°) and increases with age. When standing, the normal sagittal vertical axis (sagittal plumb line) falls from the odontoid process through the C7/T1 disc space and crosses the spinal column at the T12/L1 disc space, before reaching the posterosuperior corner of the S1 vertebral body. For an energy-efficient posture, cervical and lumbar lordosis will balance thoracic kyphosis.

The spinal canal is formed behind the articulated vertebral body by the posterior elements of the vertebral column and can be divided into a **central** portion and two **lateral** portions. The central portion is occupied by the thecal sac containing the spinal cord, which terminates behind the body of L1. The lateral portions contain the nerve roots.

The spinal nerve roots comprise 8 cervical, 12 thoracic, 5 lumbar, 5 sacral and 1 coccygeal. Dorsal and ventral roots join to form spinal nerves. The ventral root and the dorsal root ganglion lie within the intervertebral foramen. This foramen is bounded superiorly and inferiorly by pedicles, anteriorly by the disc and posteriorly by the facet joint. Degenerative changes in these structures may lead to neural compromise. Laminar overlap within the lumbar spine decreases from L1 to S1 so that, at the L5/S1 level, access to the intervertebral disc requires less bone removal than at a more proximal level.

The blood supply of the spinal cord is derived from the vertebral, deep cervical, intercostal and lumbar arteries. The arteries of the spinal cord include the anterior spinal artery and two posterior spinal arteries, with the anterior spinal artery providing the majority of the vascular supply to the spinal cord. The radicular artery of Adamkiewicz makes a major contribution to the anterior spinal artery, supplying the lower spinal cord. It originates on the left in 80% of people, usually accompanying the ventral root of T9, T10 or T11, but can originate anywhere from T5 to L5. Ligation of this important artery may lead to critical ischaemia of the spinal cord. Ligating segmental vessels over the midpoint of the vertebral body will minimise the risk of injury to this important artery during anterior approaches to the spine.

PATIENT HISTORY

The commonest reasons for referral to a spinal clinic include **pain** and **spinal deformity**. A detailed history of the pain, including site, type, severity, duration, frequency and aggravating factors, should be sought. Has there been any history of

Albert Adamkiewicz, 1850–1921, Professor of Pathology, the University of Kraków (Cracow), Poland, described the arterial supply to the spinal cord in 1882.

trauma? Is the pain present at night? Is there associated pain in the upper limbs (brachialgia) or lower limbs (sciatica)? Is there associated numbness, tingling, weakness or difficulty with gait? Is there a family history of ankylosing spondylitis or rheumatoid arthritis? Are there concurrent medical conditions such as diabetes, peripheral vascular diseases, osteoarthritis of the hip or previous malignancies? Are there systemic symptoms such as unexplained weight loss, chills or fever?

Patients should always be asked about the presence of perineal numbness (saddle area) and difficulties or changes in sensation when passing urine or faeces, as these symptoms may indicate a cauda equina syndrome (CES) (*Table 37.1*).

Patients should be asked whether the pain is interfering with their ability to work. What treatment has the patient already tried and how effective were these treatments (e.g. analgesics, exercise, physiotherapy or spinal injections)? Pending litigation or worker's compensation claims may have a negative prognostic effect on future treatments.

Spinal deformities, e.g. scoliosis and excessive kyphosis (>50°), are generally painless in children but may be symptomatic in adult life. How quickly has the spinal deformity progressed? It is important to assess skeletal maturity and whether the child has gone through a recent growth spurt. Has menstruation commenced in the female or has the voice dropped in the male, indicating the onset of puberty?

TABLE 37.1 Cauda equina syndrome

- Low back pain
- Uni- or bilateral sciatica
- Saddle anaesthesia
- Motor weakness in the lower extremities
- Variable rectal and urinary symptoms

PHYSICAL EXAMINATION

The patient should be undressed and posture should be evaluated in both frontal and sagittal planes. Shoulder or waist asymmetry suggests the presence of scoliosis. The Adams forward bend test will accentuate trunk asymmetry and allow appreciation of rib or loin prominence on the convex side of each curve. The skin should be examined for cutaneous neurofibromata, café-au-lait patches or axillary freckling commonly present in neurofibromatosis. Neurological examination should include abdominal reflexes. Leg lengths should be measured. In the case of kyphosis, the sagittal alignment and forward gaze should be assessed.

Palpation is useful to locate specific areas of tenderness. The normal range of motion in the cervical spine is 45° of flexion, 55° of extension, 70° of rotation and 40° of lateral bend. The normal range of motion in the lumbar spine is 40–60° of flexion, 20–35° of extension, 15–20° of lateral bending and 3–18° of rotation. Schober's test is a simple clinical test to evaluate spinal mobility. A tape measure is used to mark the skin midway between the posterior superior iliac spines and at points 10 cm proximal and 5 cm distal to this mark while the patient is standing. The patient is then asked to bend forwards as far as possible and the distance between the two points is measured with the patient in the flexed position. Normally one would expect to see an increase of at least 5 cm between the two points in the erect and flexed positions. A distance of less than 5 cm between these points may indicate ankylosing spondylitis.

Neurological examination of the upper and lower limbs will focus on tone, power, coordination, reflexes, sensation and gait (*Tables 37.2 and 37.3*). A rectal examination and assessment of perineal sensation should be performed if there is any concern about cauda equina integrity. The superficial abdominal reflex is an upper motor neurone (UMN) reflex. It is performed by stroking one of four abdominal quadrants in succession. The umbilicus should move towards the quadrant that was stroked. The reflex should be symmetrical from side to side. Absent or asymmetrical abdominal reflexes may indicate intraspinal pathology such as syringomyelia or spinal cord injury.

Myelopathy or UMN lesions are reported by spasticity, motor weakness, hyper-reflexia, positive Hoffmann's sign (forced flexion of the distal phalanx of the middle finger results in flexion of the thumb and index finger), upgoing Babinski response and patellar and ankle clonus.

Summary box 37.2

UMN lesions are characterised by:

- Increased tone – spastic
- Hyper-reflexia
- Muscle spasms
- Motor weakness
- Disuse atrophy
- Positive Hoffmann's sign
- Ankle and patellar clonus
- Upgoing plantar response

Typical signs of radiculopathy (lower motor neurone [LMN] lesion) include sensory loss, motor weakness, flaccid paralysis, muscle atrophy, loss of reflexes and muscle fasciculation. The straight leg raise (SLR) test is performed with the patient in the supine position. The leg is elevated with the knee straight to increase tension along the L5 and S1 nerve roots. The test is positive if the leg elevation provokes radicular pain. The crossed SLR test is carried out by elevating the asymptomatic leg; if positive, this produces sciatic symptoms in the opposite leg. A positive test is associated with a herniated disc

William Adams, 1820–1900, described the forward bending test for scoliosis in 1865. His understanding of the nature of the rotational element of scoliosis was given by a postmortem examination he performed on an eminent surgeon and geologist, Gideon Mantell.
Paul Schober, 1865–1943, German physician.
Johann Hoffmann, 1857–1919, Professor of Neurology, Heidelberg, Germany.
Joseph Francis Felix Babinski, 1857–1932, neurologist, Hôpital de la Pitié, Paris, France.

TABLE 37.2 Neurological evaluation of the upper limb.

Neurological level	Motor	Sensation	Reflexes
C5	Deltoid	Lateral arm	Biceps (C5/6)
C6	Wrist extensors	Lateral forearm	Brachioradialis (C5/6)
C7	Triceps	Middle finger	Triceps (C7/8)
C8	Long finger flexors	Medial forearm	No reflex
T1	Interosseus muscles	Medial arm	No reflex

TABLE 37.3 Neurological evaluation of the lower limb.

Neurological level	Motor	Sensation	Reflexes
L2	Hip flexion	Anterior thigh, groin	No reflex
L3	Knee extension	Anterior and lateral thigh	Patellar (L3/4)
L4	Ankle dorsiflexion	Medial leg and foot	Patellar (L3/4)
L5	Extensor hallucis longus	Lateral leg and foot	No reflex
S1	Ankle plantarflexion	Lateral foot and little toe	Achilles (S1/2)

in 97% of patients. Lasègue's sign denotes radicular pain aggravated by ankle dorsiflexion.

The femoral nerve stretch test is performed with the patient in the prone position by extending the hip and flexing the knee. This creates tension on the L2, L3 and L4 nerve roots. The femoral nerve stretch test is considered positive if radicular pain occurs in the anterior thigh region during the test.

The examination should include, where appropriate, examination of the shoulder, hip, knee, sacroiliac joint and vascular system, as dual pathology is common in the ageing community.

In 1979, Waddell and colleagues (see ***Further reading***) developed and validated a series of signs and tests that have proved helpful in identifying individuals who are magnifying or exaggerating symptoms, possibly for secondary gain (*Table 37.4*)

TABLE 37.4 Non-organic physical signs in low back pain.

- **Tenderness**: superficial or non-anatomical
- **Simulation tests**: axial loading or rotation
- **Distraction tests**: variable straight leg raises
- **Regional disturbances**: non-anatomical sensory or motor loss
- **Over-reaction**: grimacing, muscle tremor, etc.

Summary box 37.3

LMN lesions are characterised by:

- Decreased tone – flaccid
- Hyporeflexia
- Denervation fasciculations
- Motor weakness
- Sensory loss
- Severe atrophy
- Downgoing plantar response

Red flags

After taking a history and examining the patient it is important to consider 'red flags' (*Table 37.5*), which allow diagnostic triage into those with serious pathology of the spine, such as CES, fractures, tumours and infection, and those without.

Non-spinal causes of back pain

Pain may arise from the spine, but non-spinal causes of pain must also be considered (*Table 37.6*).

INVESTIGATIONS

The most common diagnostic imaging tests used to evaluate spinal disorders include plain radiographs, computed tomography (CT), magnetic resonance imaging (MRI), CT myelography and isotope bone scanning. These investigations are extremely sensitive, but relatively non-specific. For example, at least one-third of asymptomatic patients have been noted to have 'abnormalities' on MRI scans. All investigations must therefore be carefully correlated with the clinical findings.

Plain radiographs

It is not appropriate to order spine radiographs for every patient presenting with neck or low back pain. Patients with red flag signs or symptoms and those who have not responded to conservative treatment require imaging, with most units in resource-rich countries utilising MRI (no radiation penalty) in this situation. Standing radiographs of the whole spine are important for the assessment of scoliosis. Radiographs cannot diagnose early-stage tumour or infection, because significant bone destruction (between 40% and 60% of bone mass) must occur before a radiographic abnormality is detected.

Charles Ernest Lasègue, 1816–1863, Professor of Medicine, University of Paris, and physician, La Salpêtrière, Paris, France

TABLE 37.5 'Red flags': serious conditions whose signs and symptoms can cause low back pain.

Condition	Signs and symptoms
Cauda equina syndrome	• Severe or progressive bilateral neurological deficit of the legs, such as major motor weakness with knee extension, ankle eversion or foot dorsiflexion
	• Recent-onset urinary retention (caused by bladder distension because the sensation of fullness is lost) and/or urinary incontinence or alteration of function (caused by loss of sensation when passing urine)
	• Recent-onset faecal incontinence (due to loss of sensation of rectal fullness)
	• Perianal or perineal sensory loss (saddle anaesthesia or paraesthesia)
	• Unexpected laxity of the anal sphincter
Spinal fracture	• Sudden onset of severe central spinal pain that is relieved by lying down
	• A history of major trauma (e.g. road traffic collision or fall from a height), minor trauma or just strenuous lifting in people with osteoporosis who take corticosteroids
	• Structural deformity of the spine such as a step from one vertebra to an adjacent vertebra
	• There may be point tenderness over a vertebral body
Cancer	• The person being 50 years of age or more
	• Gradual onset of symptoms
	• Severe unremitting pain that remains when the person is supine, aching night pain that prevents or disturbs sleep, pain aggravated by straining (for example, at stool or when coughing or sneezing) and thoracic pain
	• Localised spinal tenderness
	• No symptomatic improvement after 4–6 weeks of conservative low back pain therapy
	• Unexplained weight loss
	• Past history of cancer; breast, lung, gastrointestinal, prostate, renal and thyroid cancers are more likely to metastasise to the spine
Infection (such as discitis, vertebral osteomyelitis or spinal epidural abscess)	• Fever
	• Tuberculosis or recent urinary tract infection
	• Diabetes
	• History of intravenous drug use
	• HIV infection, use of immunosuppressants or where the person is otherwise immunocompromised

HIV, human immunodeficiency virus.

TABLE 37.6 Non-spinal causes of low back pain: referred pain.

- Respiratory, e.g. mesothelioma
- Vascular, e.g. abdominal aortic aneurysm
- Renal, e.g. pyelonephritis
- Gastrointestinal, e.g. peptic ulcer, pancreatitis
- Urogenital, e.g. testicular, ovarian or prostatic carcinoma

Computed tomography

This investigation is the best test for assessing bone anatomy. Three-dimensional reconstructions are often useful for the assessment of congenital spinal deformity. However, one should remember that a typical CT of the lumbar spine will expose the patient to an effective dose of 5–10 millisieverts (mSv), which would be equivalent to 2.5–5 years of natural background radiation; those who travel on 7-hour flights (0.05 mSv per 7-hour flight) would need to make 100–200 journeys in their lifetime to be exposed to the same effective dose.

Magnetic resonance imaging

This allows detailed visualisation of the spinal cord, thecal sac, epidural space, intervertebral discs, nerve roots, paraspinal soft tissues and bone marrow. It is contraindicated for patients with certain pacemakers and coronary stents, intracranial metal clips, metallic bodies in the eye, spinal cord stimulators and certain drug pumps.

Bone scintigraphy

Isotope bone scans are highly sensitive, but non-specific, tests that are useful for screening the skeletal system for metastatic disease, discitis or vertebral body osteomyelitis, or to assess the relative activity of bone lesions such as osteoid osteoma, osteoblastoma, defects in the pars interarticularis or a pseudarthrosis (incomplete fusion). In the case of multiple myeloma or purely lytic metastases, the bone scan may not show increased activity as these tumours may not stimulate a significant **osteoblastic** response.

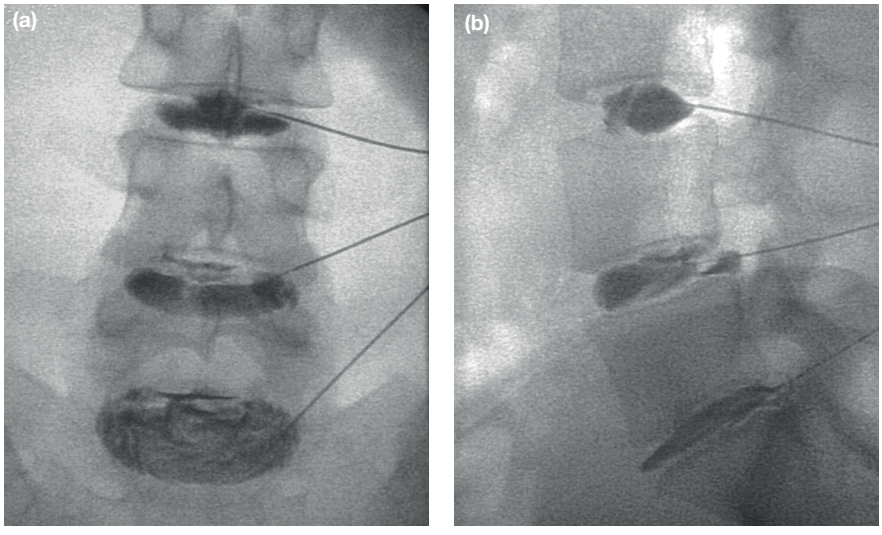

Figure 37.1 Lumbar discography. Antero-posterior **(a)** and lateral **(b)** radiographs following injection of contrast medium into the lower three lumbar discs. Morphology: L3/4 cotton ball, L4/5 fissured, L5/S1 ruptured. Concordant low back pain was reproduced when injecting the L4/5 and L5/S1 discs. No pain was experienced when the L3/4 disc was injected. The patient underwent a postero-lateral fusion L4 to S1.

Bone densitometry

Bone density and osteoporosis can be measured using dual energy x-ray absorptiometry (DEXA) of the hip, wrist and spine.

Provocative discography

This investigation involves the placement of a 24-gauge needle into the centre of the intervertebral disc in a conscious patient. Radio-opaque contrast agent (1–3.5 mL) is then injected into the disc. The contrast pattern will allow the discrimination of different degrees of disc degeneration; cotton ball or lobular would be considered normal whereas irregular, fissured or ruptured would be considered degenerate (*Figure 37.1*). The patient is asked if they are experiencing their 'usual type of back pain'. To diagnose discogenic low back pain one must document evidence of disc degeneration and concordant pain during the injection. Treatment options may include spinal fusion or disc replacement.

Facet joint injections

For patients with facet joint arthropathy, x-ray-guided local anaesthetic and steroid injections may be both diagnostic and therapeutic for 4–6 weeks. Longer term relief may be obtained by facet joint rhizolysis. This percutaneous procedure denervates the facet joint.

Foraminal epidural steroid injections

For patients with radiculopathy due to a prolapsed intervertebral disc or lateral recess stenosis, a targeted foraminal epidural injection of local anaesthetic and steroid may provide important diagnostic information and have a lasting therapeutic effect.

Spinal biopsy

Either CT-guided or open biopsy is often performed to obtain tissue for diagnostic study in cases of suspected tumour and/or infection.

DEGENERATIVE CONDITIONS OF THE SPINE

Cervical radiculopathy

Patients present with neck and arm pain (brachialgia), paraesthesia and motor weakness in the distribution of the compromised nerve root (radiculopathy). This may be caused by disc herniation or degenerative stenosis. Symptoms often respond to conservative treatment, including physiotherapy and medication for neuropathic pain (amitriptyline, gabapentin or pregabalin), or CT-guided foraminal epidural steroid injections of local anaesthetic and steroid. Intractable pain and/or functional neurological deficit are indications for surgical intervention. Surgical options include anterior cervical discectomy and fusion (using a cage packed with bone graft and plate), cervical total disc replacement (*Figure 37.2*) or posterior procedures to enlarge the canal such as laminoplasty and laminoforaminotomy. Randomised controlled trials have compared anterior cervical discectomy and fusion with cervical disc replacement. Similar clinical outcomes have been observed in both groups. However, cervical disc replacements preserve motion in the operated level and may protect against adjacent segment disease in the longer term.

Cervical myelopathy

Degenerative change in the cervical spine leading to spinal cord compression is the commonest cause of cervical myelopathy in patients over 55 years of age. LMN changes occur **at the level** of the lesion, with atrophy of the upper extremity muscles, particularly the intrinsic muscles of the hands. UMN findings are noted **below** the level of the lesion and may involve both upper and lower extremities. If surgery is considered an anterior or posterior decompression may be required.

Thoracic disc herniation

Thoracic disc herniations that require surgical intervention are rare, accounting for less than 2% of all discectomy procedures.

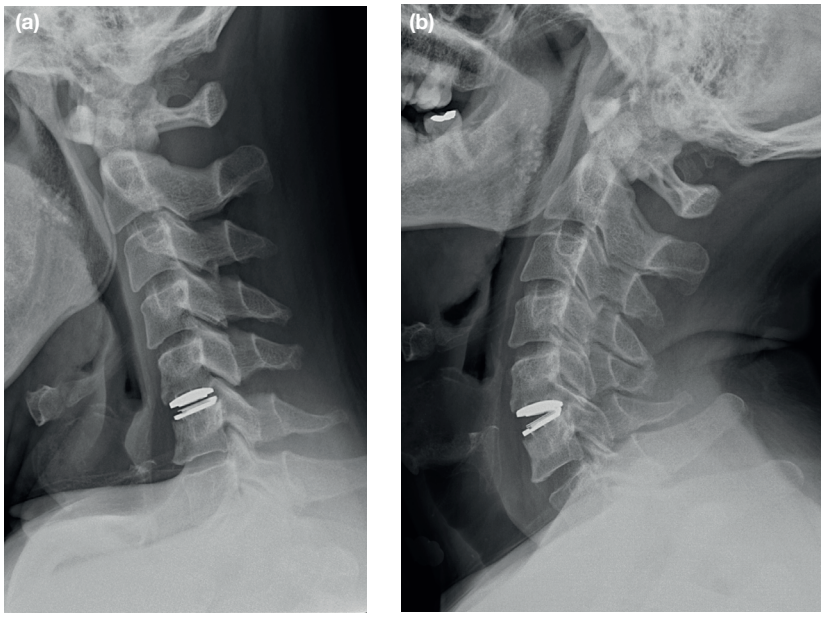

Figure 37.2 Cervical total disc replacement. The patient presented with severe left-sided C6 radiculopathy. Magnetic resonance imaging scan confirmed a left C5/6 disc herniation. The patient underwent a C5/6 discectomy and decompression of the left traversing C6 nerve root, followed by insertion of a cervical disc replacement. Lateral radiographs in flexion **(a)** and extension **(b)** show restored motion to the C5/6 level.

Typically, the patient presents with axial pain, radiculopathy or myelopathy. Conservative treatment including non-steroidal anti-inflammatory drugs, physiotherapy and general fitness improvement should be considered initially. If required, thoracic discectomy may be performed via thoracotomy or, for a soft disc prolapse, via a thoracoscopic approach.

Cauda equina syndrome

CES is a very serious and urgent condition that arises from compression of the cauda equina nerve roots, which supply the perineum and genital regions and bladder, bowel and sexual function. The most frequent cause is a massive central lumbar disc protrusion at L4/5 or L5/S1; other causes include lumbar fractures, postoperative epidural haematoma, spinal stenosis and spinal tumours. Occlusion of the lumbar arteries by dissection or aneurysm of the abdominal aorta can lead to similar dysfunction of the cauda equina without compression.

CES is rare, accounting for only 2–6% of all lumbar disc herniations. However, it is important as timely treatment can prevent catastrophic incontinence; delay in treatment is a major cause of litigation in many countries.

CES presents most commonly in the 20- to 45-year age group, with some or all of the following symptoms: low back pain; unilateral or bilateral sciatica; lower limb motor weakness; and sensory abnormalities, including saddle anaesthesia, bladder dysfunction (initially sensory changes, later painless retention and overflow incontinence in later stages) and sexual and bowel dysfunction. CES may result from acute or chronic compression of the cauda equina nerve roots.

TABLE 37.7 Classification of cauda equina syndrome (CES).

Name	Abbreviation	Definition	Investigation after initial diagnosis	Treatment if MRI positive for compression of CES
CES suspected	CES-S	Large disc herniation or bilateral sciatica but normal S2–5 motor and sensory function	MRI within 24 hours	Discuss risks and benefits of surgery versus conservative treatment
CES early	CES-E	Some perineal sensory change but normal bladder and bowel function	MRI immediate	Urgent decompression
CES incomplete	CES-I	Impaired bladder function or sensation but executive/voluntary control of bladder maintained	MRI immediate	Urgent decompression
CES retention	CES-R	Bladder retention and overflow incontinence	MRI immediate	Urgent decompression on next daytime list if patient presents overnight
CES complete	CES-C	Complete loss of cauda equina function	MRI in working hours	Decompression if improvement considered possible

MRI, magnetic resonance imaging.

Cauda equina nerve roots lack epineurium and perineurium and only have a thin endoneurium root sheath, making them more susceptible to compression forces when compared with peripheral nerves. The syndrome can result in permanent motor deficit and bladder, bowel and sexual dysfunction. It represents a true spinal emergency and requires urgent surgical decompression. The outcome for patients who undergo surgical decompression within 24 hours of the onset of loss of bladder or bowel control is significantly better than that of those who undergo surgery beyond this 24-hour period.

Cauda equina syndrome classification

The key classification of CES (*Table 37.7*) is into cases where there is still executive or voluntary control of the bladder (CES-I) and cases where there is bladder retention and overflow incontinence (CES-R). CES-I cases are considered to be more urgently in need of decompression to prevent deterioration to CES-R. Most surgeons now believe that continued compression causes a continuous deterioration in function and therefore early decompression is of benefit.

Summary box 37.4

Cauda equina syndrome

- Commonest presenting symptoms: perineal numbness, alteration in bladder function and sensation leading to painless urinary retention, overflow incontinence and faecal incontinence
- Urgent investigation with MRI is required for all suspected cases
- Confirmed CES requires surgical decompression within 24 hours to achieve optimum outcomes

Lumbar disc herniation

Symptomatic lumbar disc herniation occurs during the lifetime in approximately 2–4% of the population. Risk factors include family history, male gender, age (30–50 years), heavy lifting or twisting, stressful occupation, lower income and cigarette smoking.

Over 90% of lumbar disc herniations occur at the L4/5 or L5/S1 levels. A posterolateral disc protrusion will affect the **traversing** root, e.g. an L4/5 disc protrusion will affect the L5 nerve root. A far-lateral disc protrusion (extraforaminal) will affect the **exiting** nerve root, e.g. a far-lateral L5/S1 disc protrusion will affect the L5 nerve root. Symptoms typically commence with a period of back pain followed by sciatica. There may be paraesthesia, motor weakness, loss of reflexes and a reduction in SLR.

For simple sciatica, a period of 6–12 weeks of conservative treatment is advised. Up to 70% of patients will settle within this period. A trial of pregabalin (GABA analogue) and/or a transforaminal epidural steroid injection may be helpful. Microdiscectomy is the standard surgical intervention for those in whom conservative treatment has failed. The procedure is carried out in the prone position with radiographic confirmation of the correct level. Loupes with a headlight or use of the operating microscope greatly facilitate the procedure. A 3- to 4-cm incision is made with a unilateral take down of the multifidus. The spinal canal is entered via removal of the ligamentum flavum under the lamina. The thecal sac and traversing nerve root are identified. The dura and nerve root are retracted medially and the offending disc prolapse incised via a transverse annulotomy. The disc fragment is removed and the disc space cleared of any remaining nuclear material with rongeurs and multiple washouts of the disc space. The wound is closed. Patients are generally discharged the next morning.

Spinal stenosis

Spinal stenosis may be defined as any type of narrowing of the spinal canal, nerve root canal or intervertebral foramen. The resultant nerve root compression leads to nerve root ischaemia, presenting with back, buttock or leg pain provoked by exercise. Spinal stenosis may be congenital, as is the case in achondroplasia, or acquired, as is the case for degenerative types (commonly presenting between 50 and 70 years of age). The narrowing is caused by facet joint hypertrophy, disc bulging and ligamentum flavum thickening.

Symptoms of spinal claudication can be distinguished from vascular claudication because they are frequently associated with neurological symptoms, are often worse in extension and pedal pulses are present on clinical examination. Symptoms progress in approximately 20–33% of patients who receive no treatment. The condition may be treated successfully by surgical decompression alone with preservation of the facet joints.

Summary box 37.5

Spinal stenosis

- Extremely common condition in the 50- to 70-year age group
- Classic symptoms: back, buttock, thigh and calf pain
- Provoked by walking and extended posture
- Relieved by flexed posture
- Symptoms progress in up to one-third of untreated patients

Discogenic low back pain

Discogenic low back pain has been defined as a continuum of diagnostic categories (internal disc disruption, degenerative disc disease, segmental instability) reflecting various stages of degenerative pathology affecting the intervertebral disc. Not all degenerate discs are painful. Patients typically present with chronic relapsing episodes of low back pain between the ages of 40 and 60 years.

A recent study has compared rehabilitation with spinal fusion for discogenic pain. Both groups reported reductions in disability, with the authors strongly recommending a course of rehabilitation **before** surgical intervention. For those who fail to improve with conservative measures, provocative lumbar discography (*Figure 37.1*) may help to identify the source of pain, and surgery in the form of a lumbar spinal fusion (*Figure 37.3*) or lumbar disc replacement (*Figure 37.4*) may be considered.

Figure 37.3 Anterior lumbar interbody fusion. **(a)** The PEEK (poly-ethyl-ethyl-ketone) cage has been packed with bone graft prior to insertion; **(b, c)** show the anteroposterior and lateral postoperative radiographs, respectively.

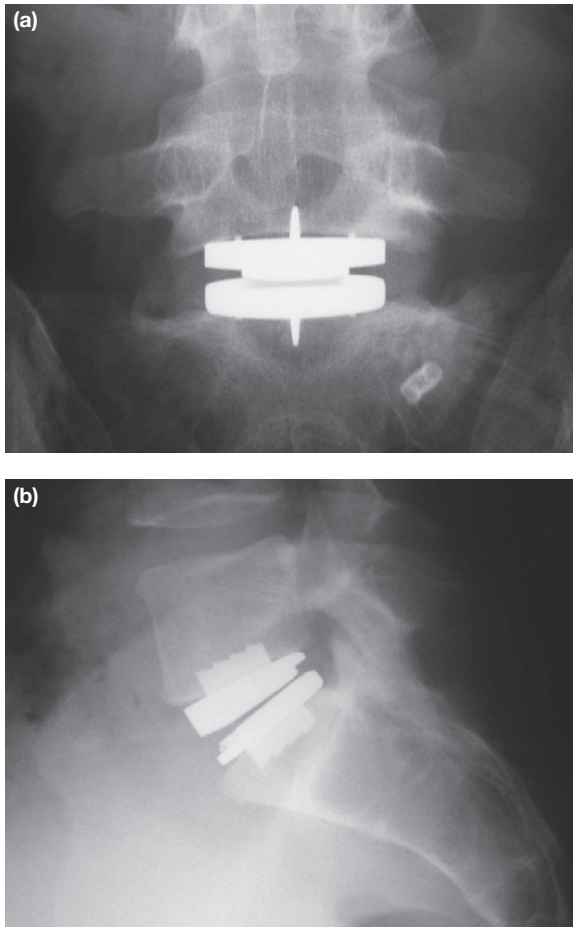

Figure 37.4 Lumbar total disc replacement. **(a)** Anteroposterior radiograph with 30° of cranial inclination. **(b)** Lateral radiograph with the implant appropriately positioned.

SPONDYLOLYSIS AND SPONDYLOLISTHESIS

Spondylolysis

This is a unilateral or bilateral defect in the pars interarticularis without vertebral slippage. The incidence is reported in approximately 6% by the age of 14 years, but is much higher in the young athletic population. The diagnosis is difficult to confirm with plain radiographs. Reverse gantry CT, MRI and single photon emission computed tomography (SPECT) are useful investigations for this condition. Treatment involves rest, non-steroidal anti-inflammatory medication, activity modification and a lumbosacral orthosis. For patients who remain symptomatic despite an adequate trial of non-operative care, surgery in the form of a direct repair of the pseudarthrosis by a Buck's fusion may be indicated.

J E Buck, surgeon, Brook General Hospital, London, UK, described the direct repair of the defect in spondylolisthesis in 1970.

Summary box 37.6

Spondylolysis

- Incidence in general population 6% by 14 years
- Incidence in athletic population 15–47%
- May be completely asymptomatic/incidental finding on radiograph
- Difficult to image, but MRI proving more useful
- Conservative treatment: activity modification, anti-lordotic brace
- Surgical treatment: direct repair preserving motion or spinal fusion if associated disc degeneration

Spondylolisthesis

Spondylolisthesis is a forward slippage of the vertebral body engendered by a break in the continuity or elongation of the pars interarticularis and presents in 4% of the adult population. Spondylolisthesis can be classified into six types by causation (*Table 37.8*) or by the degree of slip (*Table 37.9*).

For skeletally immature patients (<18 years old) who have progressive slips in the spine, and in individuals with intractable low back or radicular pain or neurological symptoms, surgery may be indicated. For low-grade slips (Meyerding grades I and II) fusion-*in-situ* is the procedure of choice. If there is **objective** evidence of neural compression (e.g. weakness of extensor hallucis longus), a spinal decompression should be performed at the same time. For high-grade slips (Meyerding grades III or IV) (*Figure 37.5*), opinion is divided on whether to reduce the slip first and then fuse, or simply to fuse *in situ*.

TABLE 37.8 Wiltse classification of spondylolisthesis (see *Further reading*).

Type 1	Dysplastic	• Associated with congenital deficiency of the L5/S1 articulation
Type 2	Isthmic	• Associated with a lesion of the pars interarticularis • Three subtypes: ◦ 2A: lytic defect of the pars ◦ 2B: elongated or attenuated pars ◦ 2C: acute pars fracture
Type 3	Degenerative spondylolisthesis	• Segmental instability due to disc degeneration/facet arthrosis
Type 4	Traumatic	• Acute fracture in the region of the posterior elements, other than the pars interarticularis
Type 5	Pathological	• Generalised bone disease resulting in attenuation of the pars (e.g. metabolic, neoplastic)
Type 6	Post surgical	• After decompression of the lumbar spine

TABLE 37.9 The Meyerding classification for the degree of slip of spondylolisthesis.

Grade I	1–25%
Grade II	26–50%
Grade III	51–75%
Grade IV	76–100%

TUMOURS OF THE SPINE

Metastatic tumours

The commonest malignancies that metastasise to the spine are shown in *Table 37.10*. Red flags picked up on history or examination will alert the clinician to this possible diagnosis.

Over 80% of patients with spinal metastases present with progressive pain, and only 20% present with spinal cord compression. Relevant investigations include full blood count (FBC), urea and electrolytes, liver function tests, calcium, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), prostate-specific antigen (PSA), serum protein electrophoresis, thyroid function tests (where a thyroid mass has been palpated) and nutritional indices. Plain radiographs may show an absent pedicle ('winking owl' sign), vertebral cortical erosion and/or vertebral collapse. MRI of the whole spine will detect most metastases. Most metastases are **osteoblastic** and will show up on bone scintigraphy; however, **osteolytic** lesions such as multiple myeloma and renal cell carcinoma may not show up on an isotope bone scan. Metastases from the prostate may be sclerotic. Biopsies may be obtained via a percutaneous CT-guided method or open biopsy.

TABLE 37.10 Commonest malignancies that metastasise to the spine and their frequency.

Breast	21%
Lung	14%
Prostate	7.5%
Renal	5%
Gastrointestinal	5%
Thyroid	2.5%

Treatment options include orthotics, steroids (dexamethasone), radiotherapy, chemotherapy, hormonal therapy, surgery or a combination of any of the above. Radiotherapy promotes reossification of the vertebral body and reduces tumour load. It can be very effective for reducing 'bone pain'. Lymphoma, breast, lung and prostate metastases are **highly radiosensitive**. Gastrointestinal adenocarcinoma, metastatic melanoma, thyroid and renal carcinoma are **radioresistant**. Small cell carcinoma of the lung, Ewing's sarcoma, thyroid carcinoma, breast carcinoma and neuroblastoma are usually sensitive to chemotherapy and should have chemotherapeutic agents as the first-line management. Adenocarcinoma of the lung is resistant to chemotherapy. Prostate metastases may respond well to antiandrogenic hormone medication.

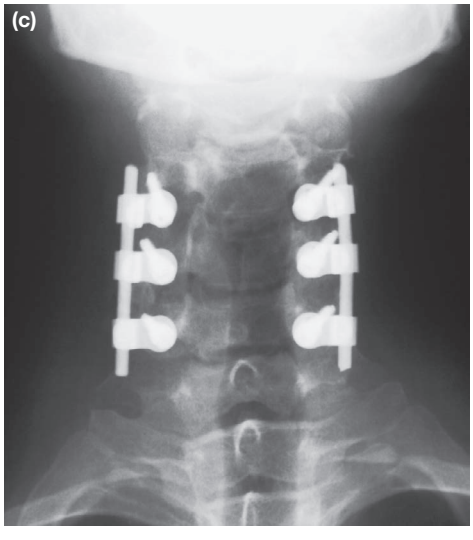
Henry W Meyerding, 1884–1969, Professor of Orthopaedic Surgery, Mayo Clinic, Rochester, MN, USA.
James Ewing, 1866–1943, Professor of Pathology, Cornell University Medical College, New York, NY, USA, described this type of sarcoma in 1921.

Figure 37.5 High-grade spondylolisthesis. Lateral standing radiograph **(a)** demonstrates Meyerding grade IV slip associated with high pelvic incidence. Anteroposterior (AP) radiograph **(b)** demonstrates the inverted Napoleon hat sign. T2-weighted mid-sagittal magnetic resonance imaging scan **(c)** shows the 'domed sacrum'. The patient underwent a modified Gaines procedure under one anaesthetic **(d)** with anterior vertebral resection of L5 along with the L4/5 and L5/S1 intervertebral discs, followed by resection of the posterior elements, articular process and L5 pedicles. AP **(e)** and lateral **(f)** radiographs demonstrate final reduction of L4 onto the sacrum with pedicle fixation from L4 to S2. **(g)** Postoperative full-length lateral standing radiograph at 12 months.

Robert W Gaines Jr, contemporary, surgeon, Department of Orthopaedic Surgery, University of Missouri, Columbia, MO, USA.

Extensive reconstructive tumour surgery should be reserved for those patients whose life expectancy exceeds 3–6 months. For patients with malignant spinal cord compression, the combination of decompressive surgery with stabilisation and postoperative radiotherapy has been shown to be superior in outcome when compared with radiotherapy alone. In one randomised trial, surgery and radiotherapy permitted most patients to remain ambulatory for the remainder of their lives, whereas patients treated with radiotherapy alone spent a large portion of their remaining time as paraplegics.

Summary box 37.7



Metastatic tumours of the spine

- Commonest presentation is progressive spinal pain
- Whole-spine MRI will detect most metastases
- Surgery is indicated for instability, pain, progressive deformity or neurological deficit

Primary tumours of the spine

Primary bone tumours of the spine account for only 2% of all spinal tumours. They arise *de novo* in the bone, cartilage, neural or ligamentous structures of the spine. They may be benign, intermediate or malignant. Benign primary spine tumours include osteoid osteoma, osteoblastoma (***Figure 37.6***), chondroma, chondroblastoma, chondromyxoid fibroma, giant cell tumours, haemangioma, lymphangioma and lipoma. Intermediate primary spine tumours include aggressive osteoblastoma, haemangiopericytoma, haemangioendothelioma and chordoma. Malignant primary spinal tumours include osteosarcoma, chondrosarcoma, Ewing's sarcoma, neuroectodermal tumours, malignant lymphoma, myeloma, angiosarcoma, fibrosarcoma and liposarcoma. The reader is

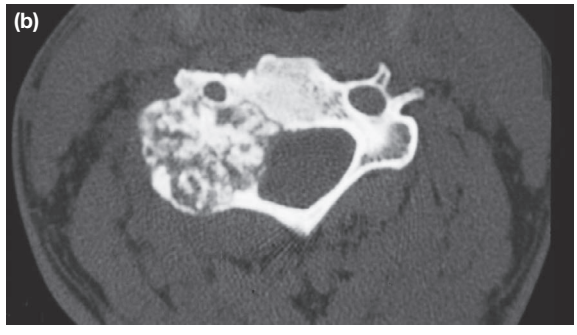


Figure 37.6 Osteoblastoma arising from the posterior elements of C5. This 21-year-old man presented with severe unremitting neck pain. Isotope bone scan **(a)** demonstrated increased uptake in C5. An axial computed tomography scan **(b)** further delineated the expansive lesion. The tumour was successfully removed with the aid of an intraoperative gamma probe to confirm complete excision; **(c, d)** postoperative anteroposterior and lateral radiographs, respectively, following reconstruction with a tricortical bone graft, lateral mass screws and rods.

referred to *Chapter 42* for further information on orthopaedic oncology.

In patients less than 18 years of age, 68% of all tumours are benign. For those patients who present over 18 years of age, more than 80% of tumours are malignant. Benign tumours tend to occur in the posterior elements; malignant tumours tend to involve the vertebral body.

Intradural tumours

These are rare. They may be intramedullary (within the substance of the spinal cord) or extramedullary (outside the cord). Most are extramedullary and benign; the commonest are meningiomas and neurofibromas.

Meningiomas are usually benign and arise from the meninges. They are generally slow growing and often warrant radiological surveillance. If the lesion is large and impinges on the spinal cord or nerve roots, steroids and early surgery may be indicated.

Neurofibromas are benign tumours that arise from the nerve sheath. There are three major types of neurofibroma: cutaneous, spinal and plexiform. In 90% of cases they present as solitary lesions, with the remainder presenting in patients with neurofibromatosis type 1 (NF-1), an autosomal dominant genetically inherited disease. NF-1 occurs in 1 in 3000 births and has been referred to as peripheral neurofibromatosis or von Recklinghausen disease. Diagnosis of NF-1 is confirmed when an individual has two or more of the following: at least six café-au-lait macules >5 mm diameter before puberty or six café-au-lait macules >15 mm after puberty, two or more neurofibromas of any type or one plexiform neurofibroma, multiple freckles in the axillary or inguinal regions, a distinctive bone abnormality involving the eye socket or arm/leg bones, optic glioma in the brain, two or more Lisch nodules in the eye, and a parent, sibling or child with NF-1. Neurofibromatosis type 2 (NF-2) is a genetically determined disorder that affects 1 in 40 000 individuals worldwide. A diagnosis of NF-2 is made when an individual has the following findings: schwannomas on both eighth cranial (vestibular) nerves or a parent, sibling or child with NF-2 plus one vestibular schwannoma in a person less than 30 years of age, or any two of the following: meningioma, glioma, schwannoma, juvenile cataracts.

INFECTIONS OF THE SPINE

Pyogenic infections

Pyogenic vertebral osteomyelitis is primarily a lesion of the disc and its osseous margins. The most common method by which an organism spreads to the spine is via the haematogenous route. The disc is nearly always involved in pyogenic vertebral infection. In contrast, granulomatous infection, such as tuberculosis, typically does not involve the disc space.

Risk factors for pyogenic vertebral osteomyelitis include advancing age, intravenous drug abuse, diabetes, renal failure, recent infections and trauma. *Staphylococcus aureus* accounts for 30–55% of the infections. Gram-negative organisms such as *Escherichia coli*, *Pseudomonas* species and *Proteus* species are associated with recent genitourinary infections and intravenous drug abuse. Anaerobic infections are uncommon, but may be seen in diabetic patients and after penetrating trauma.

If there is a failure of medical management (persistent pain, elevated erythrocyte sedimentation rate, C-reactive protein), operative interventions that should be considered are shown in *Table 37.11*.

TABLE 37.11 Operative interventions in pyogenic infections that should be used from a surgical perspective.

- Open biopsy (when a closed biopsy has failed)
- Drainage of abscesses
- Decompression of spinal cord compression
- Correction of progressive spinal deformity
- Stabilisation of progressive spinal instability

Epidural abscess

This condition is often a surgical emergency. The majority of cases occur within the thoracic spine. Without treatment, neurological deficit, including paralysis, may develop.

Tuberculosis

This is discussed in *Chapters 6 and 43*.

INFLAMMATORY SPONDYLOARTHROPATHY

Rheumatoid arthritis

Disease-modifying anti-rheumatic drugs (DMARDs) are a class of drugs indicated for the treatment of rheumatoid arthritis. Conventional medications have been used such as methotrexate, leflunomide, hydroxychloroquine and sulfasalazine. Newer biological agents are now available, including infliximab, adalimumab and etanercept. These medications have improved the outcomes significantly.

Between 33% and 50% of patients develop atlantoaxial subluxation (AAS) within 5 years of the diagnosis of rheumatoid arthritis. Some 2–10% of patients with AAS develop myelopathy over the next 10 years. Once diagnosed with myelopathy, 50% of patients may die within 1 year. The degree of subluxation may need to be checked by performing flexion and extension radiographs, and the theatre staff (especially the anaesthetist) need to be warned to take special care especially with intubation. The indications for surgery to stabilise the cervical spine are given in *Table 37.12*.

Friedrich Daniel von Recklinghausen, 1833–1910, Professor of Pathology, Strasbourg, France, described generalised neurofibromatosis in 1882.
Karl Lisch, 1907–1999, ophthalmologist, Wörgl, Austria.
Friedrich Theodor Schwann, 1810–1882, Professor of Anatomy successively at Louvain (1839–1848) and Liège, Belgium (1849–1880).
Hans Christian Joachim Gram, 1853–1938, Professor of Pharmacology (1891–1900) and of Medicine (1900–1923), Copenhagen, Denmark, described this method of staining bacteria in 1884.
Theodor Escherich, 1857–1911, Professor of Paediatrics, Vienna, Austria, discovered the *Bacterium coli commune* in 1886.

TABLE 37.12 Recommendations for spinal surgery in rheumatoid arthritis.

- AAS with a PADI of 14 mm or less
- AAS with at least 5 mm of basilar invagination
- Subaxial subluxation with a sagittal canal diameter of 14 mm or less

AAS, atlantoaxial subluxation; PADI, posterior atlantodental interval.

Ankylosing spondylitis

Should a patient with ankylosing spondylitis present following trauma, a high index of suspicion for occult fractures should be present. It is common for patients with ankylosing spondylitis to develop epidural haematomas with subtle neurological deficit.

Patients with a significant fixed flexion deformity at the cervicothoracic junction ('chin-on-chest' deformity), limited forward gaze and eating and swallowing difficulties may be treated with a closing wedge osteotomy at the cervicothoracic junction (*Figure 37.7*). Extension osteotomies can also be performed in the thoracic and lumbar spine.

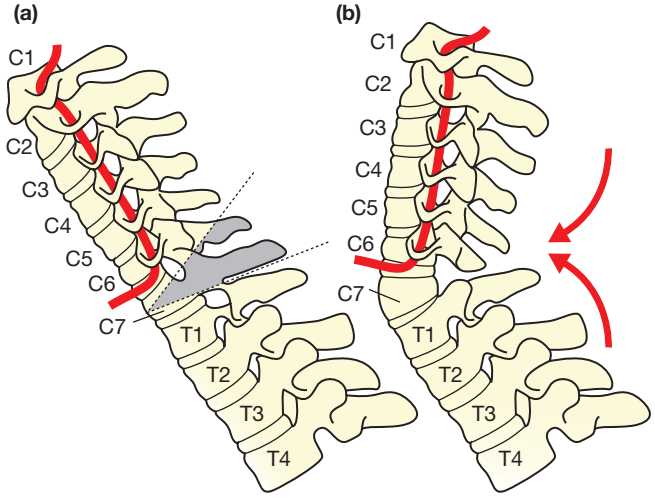

Figure 37.7 C7 closing wedge osteotomy for correction of cervicothoracic kyphosis in patients with ankylosing spondylitis. Planned resection lateral view **(a)** and lateral view after closure of the osteotomy **(b)**.

SPINAL DEFORMITY

Spinal deformity may be categorised into a coronal plane deformity (scoliosis) or a sagittal plane deformity (kyphosis and lordosis). Further classification may be made on the basis of aetiology into congenital, neuromuscular, idiopathic or syndromic. Appropriate radiographs for the assessment of scoliosis include a full posteroanterior and lateral standing spine. When surgery is contemplated, supine lateral bending radiographs are obtained to assess the flexibility of the curve(s). Curve magnitude is measured in degrees and is known as the Cobb angle. The criterion for diagnosis of scoliosis is a Cobb angle of 10° or more. The causes of scoliosis are given in *Table 37.13*.

TABLE 37.13 Aetiology of scoliosis.

- Idiopathic
- Neuromuscular
- Congenital
- Syndrome-related

Idiopathic scoliosis

Idiopathic scoliosis accounts for 70% of presentations. It can be classified into **early onset** (before 8 years of age) (*Figure 37.8*) and **late onset** (after 8 years of age; typical adolescent idiopathic scoliosis). The distinction is important, as the number of alveoli in the lung does not increase after the age of 8 years. Patients with severe curves in the early-onset group may develop cor pulmonale and right ventricular failure resulting in premature death. Adolescent idiopathic scoliosis is associated with a normal or near-normal life expectancy.

The prevalence of curves with a Cobb angle >10° is between 0.5% and 3%. The prevalence of curves >30° is between 1.5 and 3 per 1000. Risk factors for progression include female gender, remaining skeletal growth, curve location and curve magnitude. Not all curves stabilise when skeletal maturity is reached. In long-term studies, 68% experienced curve progression; the most marked progression of 1° per year was observed in patients with thoracic curves between 50° and 75°.

Idiopathic curves of less than 25° are monitored with clinical and radiographic examination. In growing children (premenarchal) with curves between 20° and 29°, a brace may be indicated. Bracing is used to **prevent** curve progression and generally does not lead to permanent curve correction. Curves beyond 45° are not amenable to brace treatment.

Surgery in the form of corrective instrumentation and spinal fusion is indicated for curve progression beyond 40°, truncal imbalance and unacceptable cosmesis. During surgery, continuous spinal cord monitoring is used in the form of somatosensory evoked potentials (SSEPs), motor-evoked potentials (MEPs) and free-run and stimulated electromyographic (EMG) activity to minimise the risk of neurological damage. The risk of neurological injury is 0.4% (1 in 250).

Neuromuscular scoliosis

This may be due to neuropathic disorders, such as cerebral palsy, spinocerebellar degeneration, syringomyelia, tetraplegia (*Figure 37.9*), spinal muscular atrophy and poliomyelitis, or **myopathic** disorders, such as Duchenne muscular dystrophy and myotonic dystrophy. There is good evidence that stabilisation of the spine in children with Duchenne muscular dystrophy who are able to walk (before respiratory compromise is too severe to preclude a general anaesthetic) may increase their lifespan by several years.

John R Cobb, American surgeon, wrote a paper in 1948 on how to measure the angle on a radiograph in scoliosis.
Guillaume Benjamin Amand Duchenne, 1806–1875, neurologist, worked successively in Boulogne and Paris, France, but never held a hospital appointment.

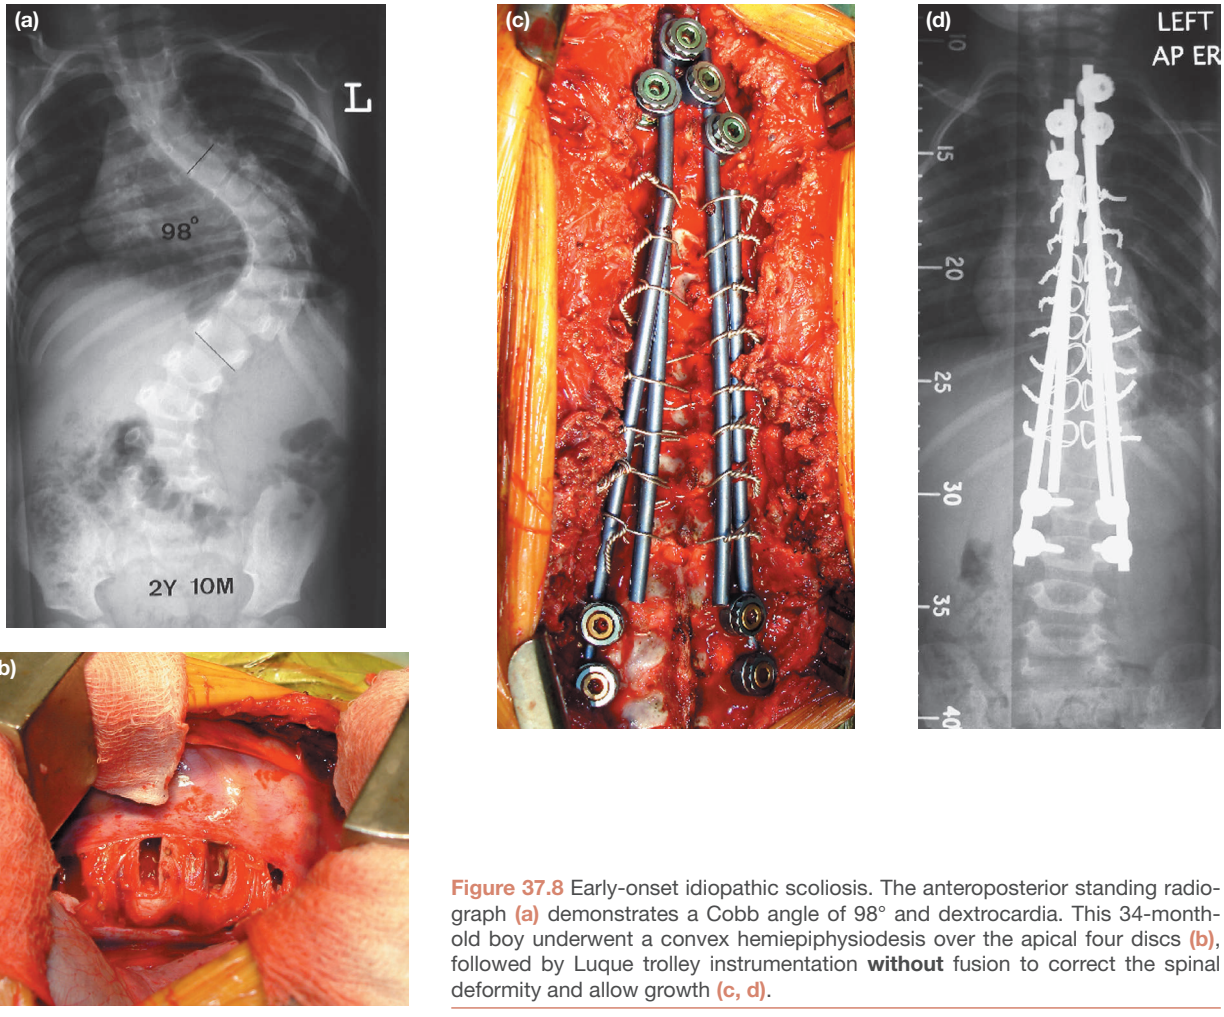

Figure 37.8 Early-onset idiopathic scoliosis. The anteroposterior standing radiograph (a) demonstrates a Cobb angle of 98° and dextrocardia. This 34-month-old boy underwent a convex hemiepiphysiodesis over the apical four discs (b), followed by Luque trolley instrumentation **without** fusion to correct the spinal deformity and allow growth (c, d).

Congenital scoliosis

This is caused by vertebral anomalies that produce a frontal plane growth asymmetry. The anomalies are present at birth, but the curvature may take years to be clinically evident. Close observation of spinal growth is required until skeletal maturity is reached. Brace treatment is ineffective for the primary structural curves, which are often short and rigid, but it may have a role in the control of compensatory curves. For progressive curves, surgical options include growing rod constructs such as magnetically controlled growing rod procedures, hemivertebra excision, correction and fusion or posterior instrumented correction and fusion.

Summary box 37.8

Spinal deformity

- Early-onset idiopathic scoliosis (<8 years old) has the potential to impair lung function
- Neuromuscular scoliosis: timely surgery may prolong life
- Congenital scoliosis: rigid curves do not respond to brace treatment

Scheuermann's kyphosis

Typically, in this condition, there is wedging of the seventh to 10th thoracic vertebrae. The patient presents with both apical pain and low back pain (due to attempts by the lumbar musculature to compensate for the thoracic hyperkyphosis). The incidence has been estimated at 1–8% of the population, and it is more common in males. Physiotherapy may be useful. Bracing for skeletally immature patients with kyphosis up to 65° may be effective in arresting progression. Indications for surgery include pain (apical or low back pain produced by compensatory hyperlordosis), progressive deformity greater than 70°, unacceptable cosmesis and neurological and/or cardiopulmonary compromise. If surgery is contemplated, it may require anterior release followed by posterior correction and fusion. Increasingly, posterior chevron osteotomies carried out at the time of posterior instrumentation may prevent the need for the initial anterior release.

DEVELOPMENTAL ABNORMALITIES

Developmental abnormalities of the spine and spinal cord can be divided into primary bony disorders (e.g. congenital

Eduardo Luque, contemporary, professor, Shriners Hospital for Crippled Children, Mexico City, Mexico.
Holger Werfel Scheuermann, 1877–1960, radiologist, Municipal Hospital, Sundby, Copenhagen, Denmark, described juvenile kyphosis in 1920.

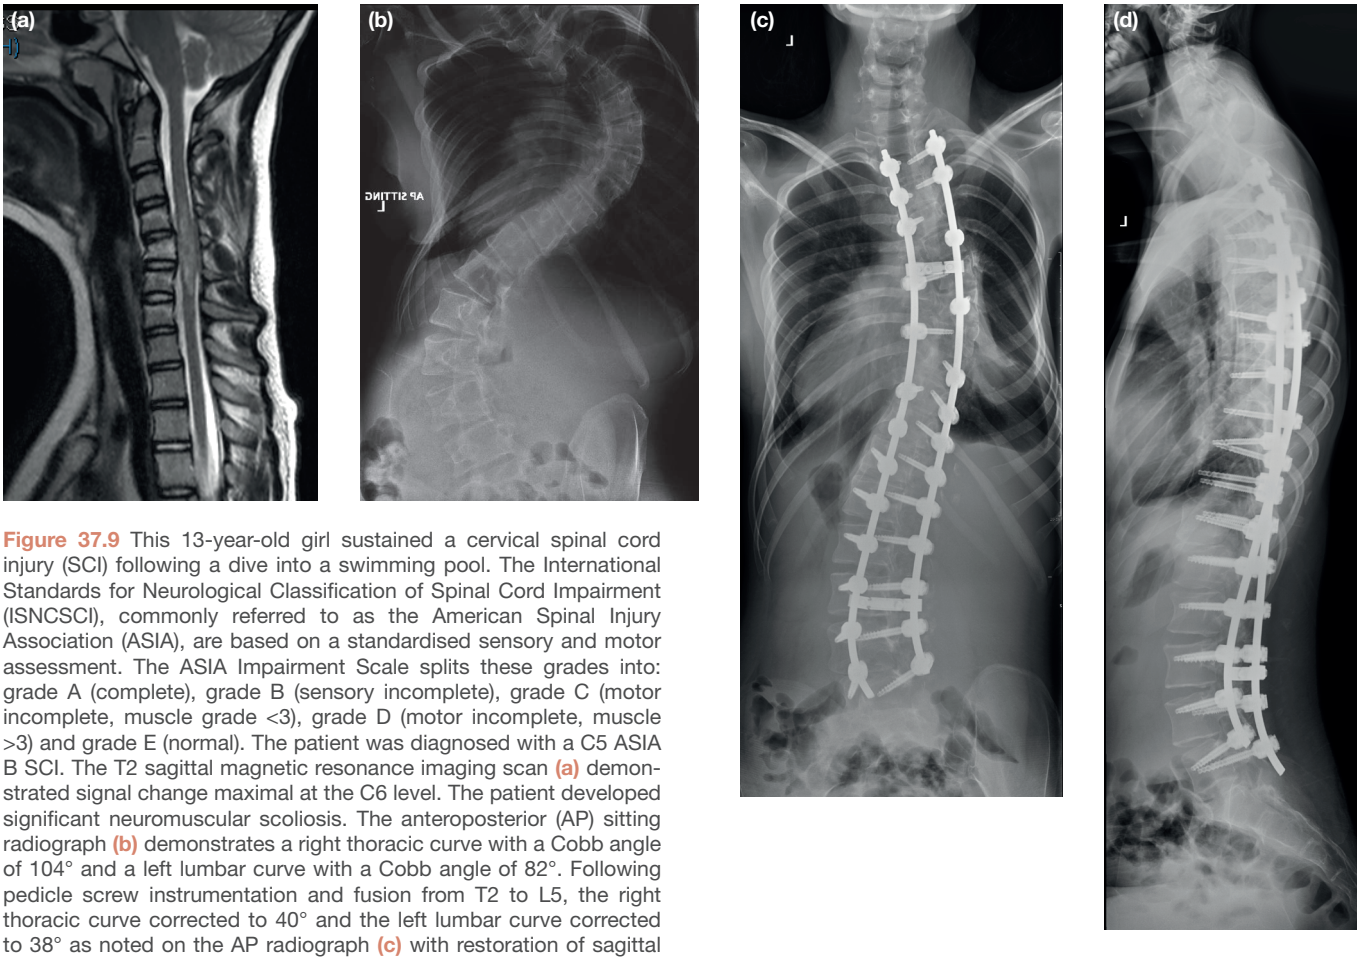

Figure 37.9 This 13-year-old girl sustained a cervical spinal cord injury (SCI) following a dive into a swimming pool. The International Standards for Neurological Classification of Spinal Cord Impairment (ISNCSCI), commonly referred to as the American Spinal Injury Association (ASIA), are based on a standardised sensory and motor assessment. The ASIA Impairment Scale splits these grades into: grade A (complete), grade B (sensory incomplete), grade C (motor incomplete, muscle grade <3), grade D (motor incomplete, muscle >3) and grade E (normal). The patient was diagnosed with a C5 ASIA B SCI. The T2 sagittal magnetic resonance imaging scan **(a)** demonstrated signal change maximal at the C6 level. The patient developed significant neuromuscular scoliosis. The anteroposterior (AP) sitting radiograph **(b)** demonstrates a right thoracic curve with a Cobb angle of 104° and a left lumbar curve with a Cobb angle of 82°. Following pedicle screw instrumentation and fusion from T2 to L5, the right thoracic curve corrected to 40° and the left lumbar curve corrected to 38° as noted on the AP radiograph **(c)** with restoration of sagittal balance **(d)**.

scoliosis, as discussed above) and primary neurological disorders (e.g. spina bifida, Arnold–Chiari malformation and spinal dysraphism).

Spina bifida

Spina bifida is caused by a failure of fusion of the vertebral arches and possibly the underlying neural tube. Spina bifida cystica has an incidence of 1 in 300 live births and is associated with hydrocephalus. It is now decreasing as a consequence of folic acid supplementation, antenatal ultrasound and the measurement of α-fetoprotein (AFP) levels. There are two basic types:

- **Meningocele**: the meninges herniate through the bony defect and are covered by skin.
- **Myelomeningocele**: the roof of the defect is formed by exposed neural tissue, with 75% of patients developing hydrocephalus.

A meningocele with good-quality skin over the defect may be treated conservatively. A meningocele with a more prominent sac can be excised at 3–6 months. The management of myelomeningocele is more controversial. Enthusiasm for closing all defects has been replaced by a more selective approach with the recognition that it was inappropriate to operate on children with severe hydrocephalus, a large open defect and no distal neurological function. The majority of these children die in their first year if closure is not attempted. With antibiotics, early surgical closure and shunts to prevent hydrocephalus, half the children who survive the first 24 hours will reach school age, but long-term problems remain, including skin problems, neuromuscular scoliosis, bone and joint deformity and the complications associated with a neuropathic bladder.

Arnold–Chiari malformation

Arnold–Chiari malformation occurs when the medulla oblongata and the cerebellar tonsils extend through the foramen magnum into the cervical spinal canal, causing pressure on the lower medulla. Hydrocephalus and impaired neurological function are common, and there is a strong association

Julius Arnold, 1835–1915, Professor of Pathological Anatomy, University of Heidelberg, Heidelberg, Germany, described this condition in 1894.
Hans Chiari, 1851–1916, Professor of Pathological Anatomy, Strasbourg, Germany (Strasbourg was returned to France in 1918 after the end of the First World War), gave his account of this condition in 1891.

with spina bifida and syringomyelia. Symptoms may include headache, vomiting, visual disturbances, mental impairment, cerebellar ataxia, sensory disturbances or paralysis. Management consists of decompressing the foramen magnum and, usually, the posterior arch of the atlas to restore normal cerebrospinal fluid flow.

Spinal dysraphism

This is a group of disorders arising from abnormal embryological formation of tissues; all are associated with a progressive neurological deficit as the result of spinal cord tethering and traction or cord compression. There is a strong association with spina bifida.

In diastematomyelia, there is an abnormal bony or cartilaginous spur projecting across the middle of the vertebral canal, dividing the dural tube and spinal cord in two. Between 50% and 70% of patients are seen to have a skin naevus, dimple or hairy patch when the spine is examined. Surgical release of the tethering has variable results.

Syringomyelia

Patients may present with sensory disturbance, weakness of the hands, loss of pain and temperature sensation, asymmetrical abdominal reflexes or progressive kyphoscoliosis. It is associated with Arnold–Chiari malformation and spinal cord tumours. Where syringomyelia is associated with an Arnold–Chiari malformation and scoliosis, a posterior cranial fossa decompression should be carried out first to resolve the syringomyelia. The scoliosis may then be corrected at a later date.

METABOLIC BONE DISEASES AFFECTING THE SPINE

Osteoporosis

Patients with osteoporosis may present with pain following minimal trauma, loss of height and exaggerated thoracic kyphosis. Medications used to prevent and treat osteoporosis include calcium, vitamin D, bisphosphonates (alendronate, risedronate, once-yearly intravenous zoledronic acid), denosumab, strontium ranelate, selective oestrogen receptor modulators (SERMs) such as raloxifene, hormone replacement therapy and teriparatide.

Patients with painful thoracic fractures may be treated with short-term bed rest, analgesics and a spinal orthosis. If the back is still painful 6 weeks after the injury, patients may be considered for vertebroplasty or kyphoplasty. Vertebroplasty involves the injection of polymethylmethacrylate (PMMA) bone cement under pressure into the vertebral body with fluoroscopic guidance. The goals of the procedure are to **stabilise the spine** and **decrease the pain** associated with compression fractures. Kyphoplasty, on the other hand, involves inserting bilateral bone tamps with balloons into the vertebral body. These are inflated under fluoroscopic control with the bone tamp re-expanding the body, and elevating the end plates to reduce the fracture deformity. The balloons are then deflated and removed, and PMMA is placed in the cavity created by the balloons. The goals of kyphoplasty are **spinal stabilisation, pain relief and restoration of vertebral body height**. Significant complications have been reported, including nerve root injury and spinal cord injury resulting from cement extravasation, along with cement embolism, infection and hypotension.

GLOBAL ISSUES IN SPINE SURGERY

It is important that the information presented in this chapter, which is widely used throughout the world for teaching and training, outlines the very best evidence-based treatment that is available for surgical conditions. The text has covered the essentials of spine surgery and has very rightly demonstrated current techniques that involve up-to-date equipment. It is, however, an inescapable fact that the majority of the world's population does not have access to state-of-the-art spinal surgery. There are two main reasons for this: first, the cost of spinal surgery and, second, the lack of trained surgeons.

Cost implications of modern spinal surgery

There have been dramatic advances in spinal surgery owing to modern imaging, modern instruments and implants, and advanced spinal cord monitoring equipment. The widespread availability of MRI in high-income countries such as the USA, the UK and most of Europe has meant that diagnostic accuracy is available to the whole population in these countries. This is not, however, the case for most of the world, where there is no free or state-sponsored MRI service, and a private scan costing US$500 is unaffordable to most. If a family cannot afford a scan, then they also cannot afford the cost of an operation, the spinal implants, spinal cord monitoring and the use of expensive disposable instruments such as high-speed burrs.

The lack of trained spinal surgeons

In the last 25 years high-income countries have seen the rapid development of spinal surgery, and the rapid development of spinal surgery as a complete career. It is now normal in such countries for spinal surgeons to practise only in the field of spinal surgery and no longer to undertake general orthopaedic or neurosurgical operations. This has inevitably led to refinement of skills and increasing subspecialisation. In low-income countries, where there may be a single orthopaedic surgeon for 1 million people, doing 'just spinal surgery' is not an option, and a much more general approach is needed. In the map shown in ***Figure 37.10***, each country in the world is represented with an area proportional to the number of people in the population per active surgeon. This represents surgeons of all types, but it shows that, in many parts of Africa, there are more than half a million people per surgeon. The map showing the population covered by each **spinal** surgeon would be even more striking.

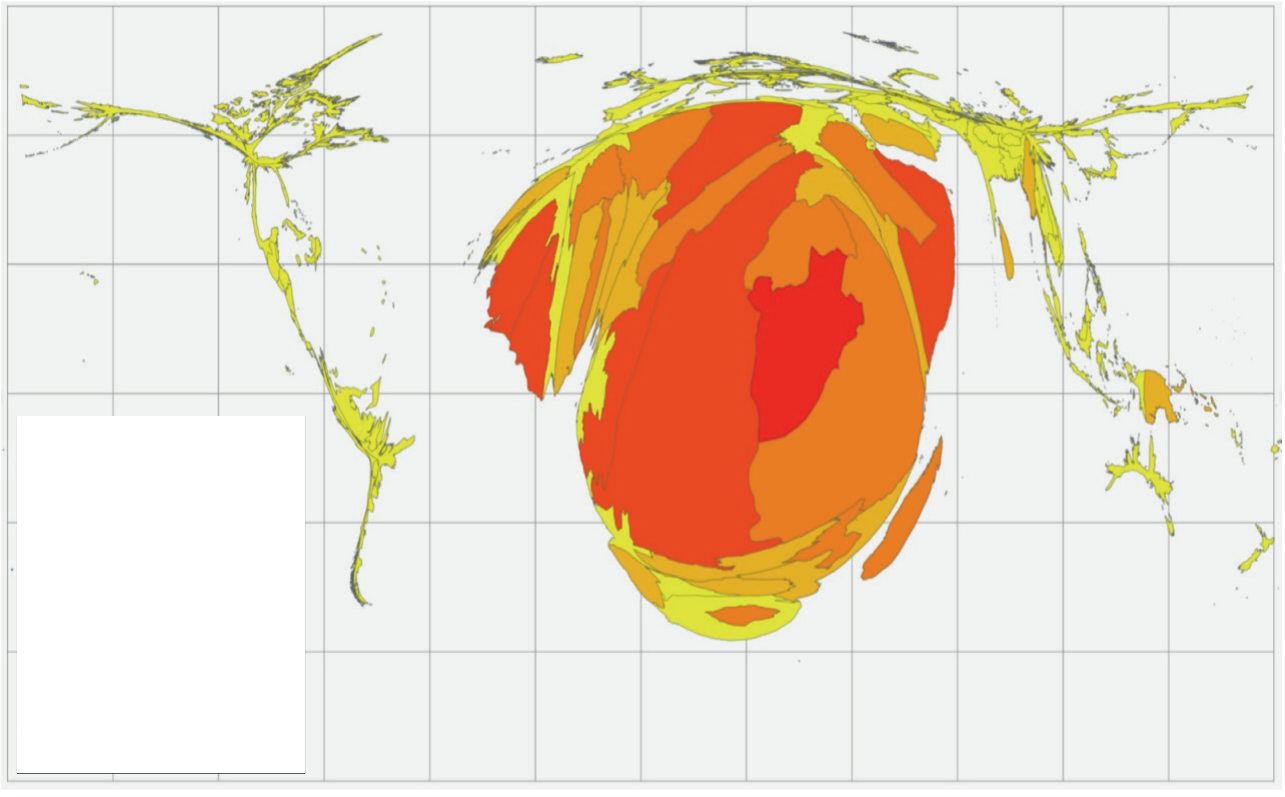

Figure 37.10 Global distribution of surgeons, anaesthetists and obstetricians. Each country in the world is represented with an area proportional to the number of the population per active surgeon. (Reproduced with permission from Holmer H, Lantz A, Kunjumen T *et al*. Global distribution of surgeons, anaesthesiologists, and obstetricians. *Lancet Glob Health* 2015; **3**(Suppl 2): S9–11.)

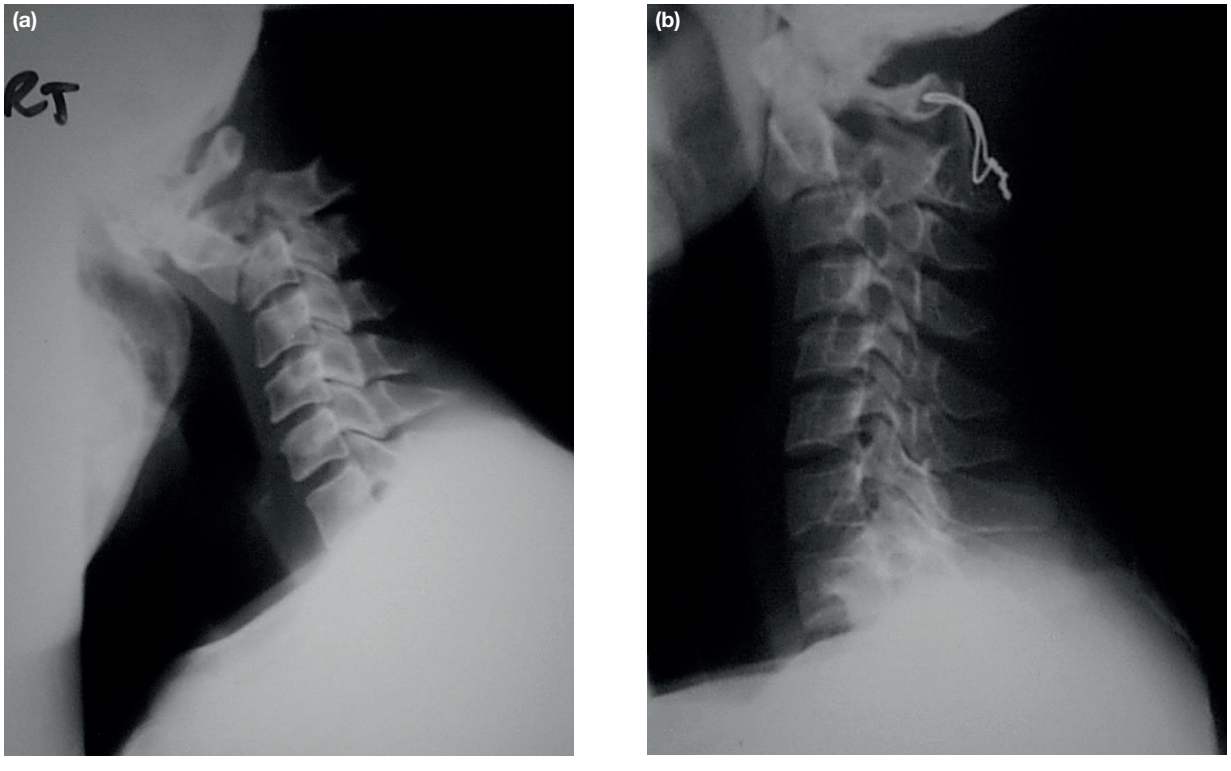

Figure 37.11 (a) Lateral cervical spine radiograph with a fracture/dislocation at C2/3 sustained by a patient living in a low-income country. (b) The surgeon used a low-risk, low-technology technique, wiring the arch of C1 to the spine of C2 with a piece of stainless steel wire, then laying on corticocancellous bone graft.

Can good spine care be given without modern imaging and equipment?

The key to good surgery in all disciplines is a surgeon who is dedicated to the care of his or her patient, who takes a good history and examination and then offers the best treatment that is available under the circumstances. In a high-income country this will often involve MRI scanning, dissection under microscope control and expensive titanium implants. In a resource-poor, low-income country it may involve just as much time and skill, but often a much more conservative approach. When surgery is needed the surgeon may have to do the best that he or she can with the equipment available. The case in ***Figure 37.11*** illustrates this point well. Note the lateral cervical spine radiograph with a fracture/dislocation at C2/3 sustained by a patient living in a low-income country. The pedicles of C2 are fractured, allowing C2 to subluxate forwards on C3 and compress the spinal cord. The patient was admitted several days after a car crash, holding his head with his hands for stability. In a high-income country where there is imaging and fluoroscopic-guided pedicle screw fixation, the fracture could easily be fixed. In the low-income country, there was no cervical spine instrumentation available and the surgeon used a low-risk, low-technology technique of wiring the arch of C1 to the spine of C2 with stainless steel wire, then laying on corticocancellous bone graft. The reduction was stable, the graft incorporated and the patient was thankful. It is not appropriate to say that this was inadequate treatment compared with the best that the world has to offer, because the best that the world has to offer was not available.

PART 5 | Elective orthopaedics

CHAPTER
38 The upper limb

Learning objectives

To understand:
- Anatomy and physiology relevant to upper limb pathology

To be able to explain:
- The diagnosis and treatment of common upper limb conditions

SHOULDER GIRDLE

Anatomy and function

The shoulder girdle (clavicle, scapula and the humerus, which articulates directly with the scapula at the glenohumeral joint) is controlled and supported by muscles crossing between the spine, thorax, scapula and humerus. The sternoclavicular joint is the only synovial joint between the upper limb and the axial skeleton. The glenohumeral joint is most closely controlled by the deltoid and rotator cuff muscles (subscapularis, supraspinatus, infraspinatus and teres minor), although 26 muscles in total act across this articulation, which controls the upper limb with respect to the torso. The scapula is integral to shoulder motion, both gliding and rotating on the posterolateral surface of the thorax. Of the 180° of elevation possible at the shoulder, around 50° is provided by scapular rotation on the chest while the clavicle elevates 30–60° concurrently. The remainder of the range of elevation occurs at the glenohumeral joint. During elevation both the humerus and clavicle rotate significantly: external rotation of the humerus bringing the greater tuberosity and cuff attachments from beneath the acromion, where they would otherwise limit the range (***Figure 38.1***).

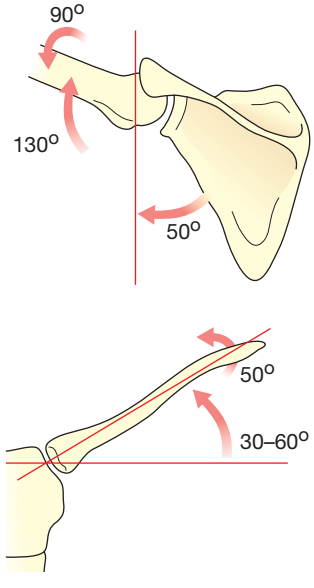

Figure 38.1 Relative motion of the elements of the shoulder girdle.

Congenital abnormalities

Sprengel's shoulder

The commonest congenital abnormality is due to abnormal scapular descent from its embryonic midcervical position. The typical presentation is a high, small, rotated scapula that remains connected to the cervical spine by a bony bar, fibrous band or an omovertebral body (***Figure 38.2***). Other congenital deformities impacting on upper limb function are rib abnormalities and cervical or thoracic abnormalities, including scoliosis and Klippel–Feil syndrome (congenital fusion of cervical vertebrae). Pseudarthrosis of the clavicle is a congenital abnormality that can be mistaken for a birth-related fracture. In later life it can be mistaken for a non-union when radiographs are taken after trauma and attempts to plate and graft the lesion are usually doomed to failure.

Acquired abnormalities

History

Patients usually associate the onset of their symptoms with an unusual event (trauma or excessive activity) even though the

Otto Gerhard Karl Sprengel, 1852–1915, surgeon, Grossherzogliches Krankenhaus (the Grand Ducal Hospital), Brunswick, Germany, described congenital high scapula in 1891.
Maurice Klippel, 1858–1942, neurologist, Hôpital Tenon, Paris, France.
André Feil, 1884–1955, neurologist, Paris, France. Klippel and Feil described this condition in a joint paper in 1912.

Figure 38.2 Sprengel's shoulder (right) of a 4-year-old girl.

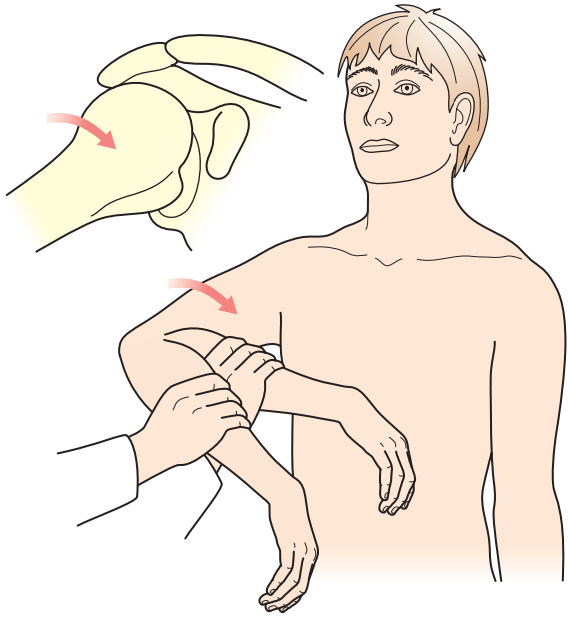

Figure 38.3 Hawkins' impingement test. Impingement pain is reproduced when the shoulder is internally rotated with 90° of forward flexion, thereby locating the greater tuberosity and anterior rotator cuff underneath the acromion and coracoacromial ligament.

causation may not be as clear as the patient thinks. Even so, the onset (sudden or gradual) and duration are important details to establish, as is the age, occupation and hand dominance of the patient. Pain presenting in the shoulder (or anywhere in the upper limb) can arise from the nerves of the neck, so the history should enquire about neck problems.

Examination

If the patient can localise the pain to an exact point around or within the shoulder, then the problem is unlikely to be referred from the neck. Tests for inflammation and impingement involve trying to reproduce the pain by loading the limb in the position that creates the problem (e.g. Hawkins' test for impingement; ***Figure 38.3***). Tests for tears in structures such as the rotator cuff look specifically for weakness, while apprehension tests check for instability (such as may predispose to recurrent shoulder dislocation).

Investigations

Radiographs are often of limited value because most shoulder pain arises from soft-tissue structures. However, a reduced subacromial space may be clearly visible in full-thickness rotator cuff tears (***Figure 38.4a***). The appearance of a typical subacromial spur can be seen on the radiograph in ***Figure 38.4b*** and morphological variants of the acromion are shown in ***Figure 38.5***. Patients with impingement pain and rotator cuff tears are much more likely to have a hooked acromion. The appearance of a spur, which produces the hook, is usually due to calcification within the coracoacromial ligament (CAL) insertion and it may be a secondary consequence of degenerative cuff disease rather than a causative lesion.

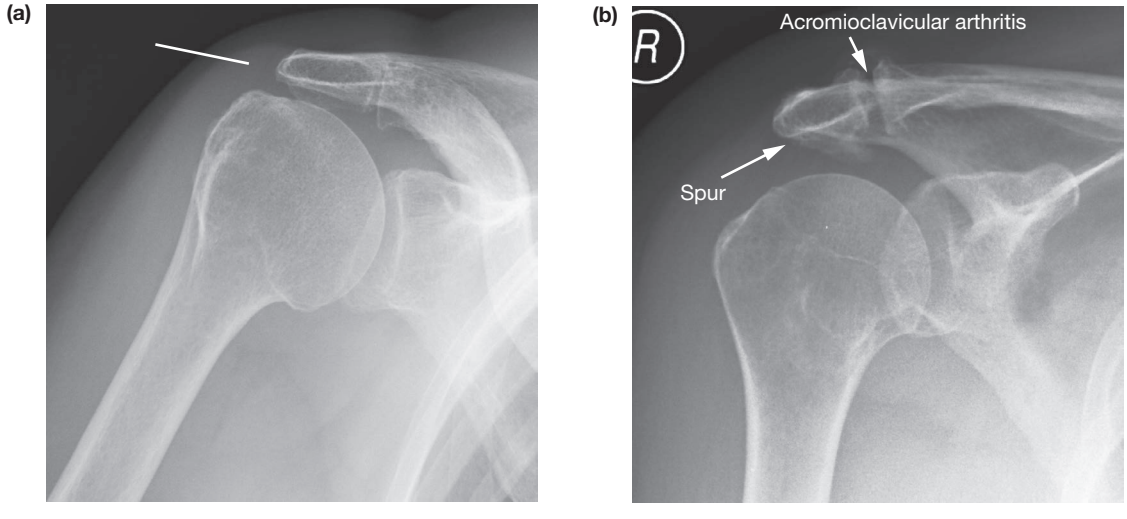

Figure 38.4 (a) Radiograph showing sclerosis on the undersurface of the acromion and the greater tuberosity, with reduced subacromial space. (b) Radiograph showing an acromial spur and arthritis of the acromioclavicular joint.

Richard J Hawkins, contemporary, Canadian orthopaedic surgeon.

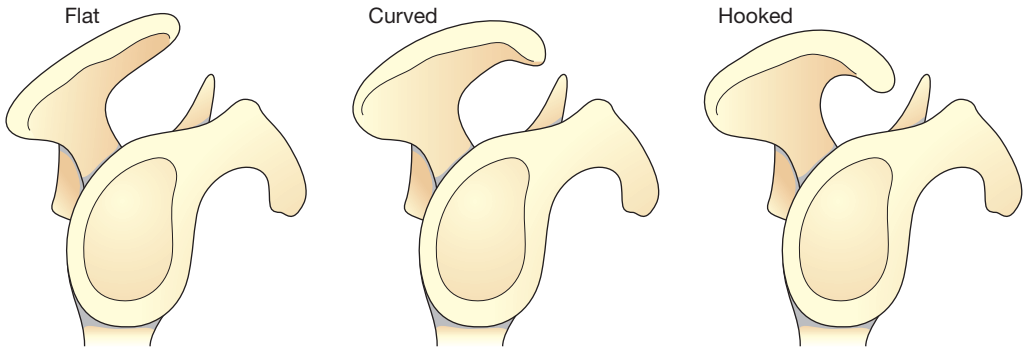

Figure 38.5 The three commonest acromial morphologies seen in adults. Children almost always have the flat morphology.

Both ultrasound and magnetic resonance imaging (MRI) allow the integrity and health of the rotator cuff to be checked whereas magnetic resonance (MR) arthrography also gives information on the integrity of the labrum of the glenohumeral joint (*Figure 38.6*).

Local anaesthetic injections may help to localise the source of pain. For example, a painful arc on forward elevation (Neer's sign) may be completely relieved by injecting local anaesthetic into the subacromial bursa in cases of subacromial impingement (Neer's test positive).

Rotator cuff degeneration and impingement

The rotator cuff moves in a confined space between the humeral head, the acromion and the CAL. Blood vessels cannot cross the glenohumeral joint cavity below the supraspinatus tendon or through the subacromial space above it, and vessels that enter from the insertional and muscle belly ends become constricted when the tendon is tensioned around the curved humeral head when the cuff is active. Blood flow is therefore limited, the tendon is exposed to external forces as it operates in a confined space and its capacity for self-repair is limited. More than any other tendon, therefore, it is prone to age-related degeneration, leading to tendinosis and partial- and full-thickness tearing; the rate of this is at least partly genetically determined. Even a trivial injury can inhibit rotator cuff function, so that it does not glide so easily in its subacromial space, starting a progression of inflammation, swelling and pain in the subacromial region. This subacromial pain may be termed impingement, which is felt to be attributable to abrasion of the cuff and bursa on the undersurface of the acromion. The impingement itself causes further bursal inflammation and pain, which further inhibits rotator cuff function, and a vicious circle is set up. The likelihood of subacromial pain developing is increased in patients with a spur beneath the acromion, which is seen increasingly commonly with age (*Figure 38.5*) and may be an effect rather than a cause of painful subacromial degeneration, as described earlier in this paragraph. The result is a painful arc of movement for the patient, which corresponds to the position where the inflamed segment of the supraspinatus tendon passes under the anterior acromial spur. The examiner may find that, although the patient cannot actively lift their arm through this segment (because of the pain), passively lifting the arm for the patient enables them to continue with pain-free movement once the area of impingement is passed (*Figure 38.7*).

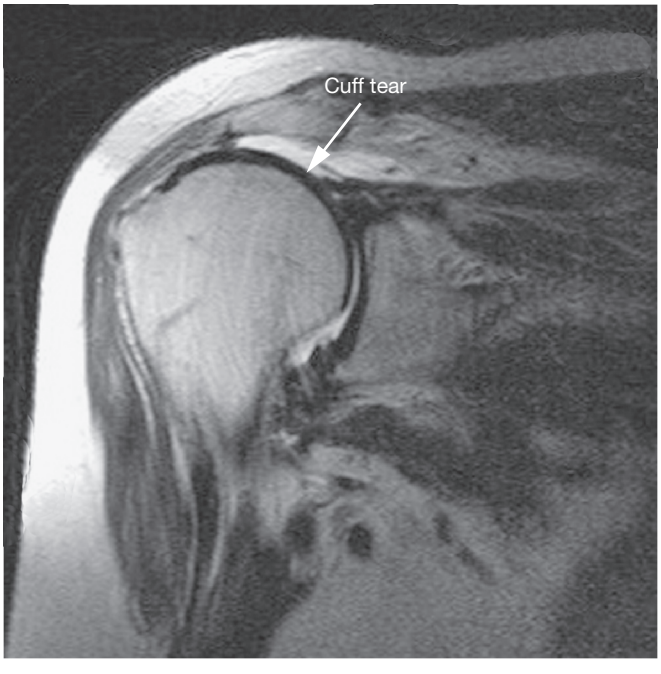

Figure 38.6 Magnetic resonance imaging scan showing a retracted cuff tear.

Treatment

Injection of steroid into the inflamed subacromial bursa may break the cycle of inflammation and impingement (*Figure 38.8*), allowing rotator cuff function to resume without impingement. Physiotherapy promotes normal cuff activity once the pain has been relieved in this way. A commonly performed procedure is arthroscopic removal of the subacromial spur, anteroinferior acromion and the CAL, which has been shown to give good relief of symptoms (*Figure 38.9*), but there is no evidence that it either improves the long-term prognosis or reduces the risk of rotator cuff tears developing.

Charles Sumner Neer II, 1917–2011, orthopedic surgeon, Columbia University, New York, NY, USA, developed the first widely used shoulder arthroplasty.

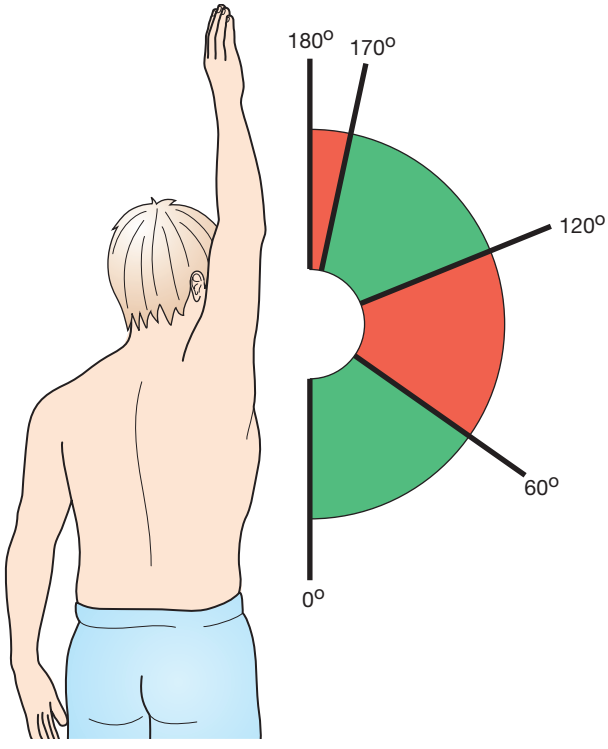

Figure 38.7 Arcs of shoulder girdle motion with subacromial impingement pain between 60° and 120° of abduction, and acromioclavicular joint pain between 170° and 180°.

Summary box 38.1

Rotator cuff degeneration and impingement

- Tendinosis and bursitis produce weakness secondary to pain (often a painful arc)
- A tendon tear produces weakness that is only secondarily painful
- Injection of local anaesthetic and retesting can distinguish those who do from those who do not have a tear – weakness persists if there is a significant tear

Summary box 38.2

Treatment of subacromial impingement

- Non-operative treatment includes injections and rotator cuff rehabilitation
- Surgery may be indicated if symptoms persist beyond 3–6 months of non-surgical management
- Surgery restores a flat acromion and makes more room for rotator cuff gliding but there is no evidence that it improves the long-term outlook

Rotator cuff tears

The rotator cuff has a relatively poor blood supply in the segment that glides between the humeral head and acromion, as described in ***Rotator cuff degeneration and impingement***. The cuff thins with age and eventually develops defects

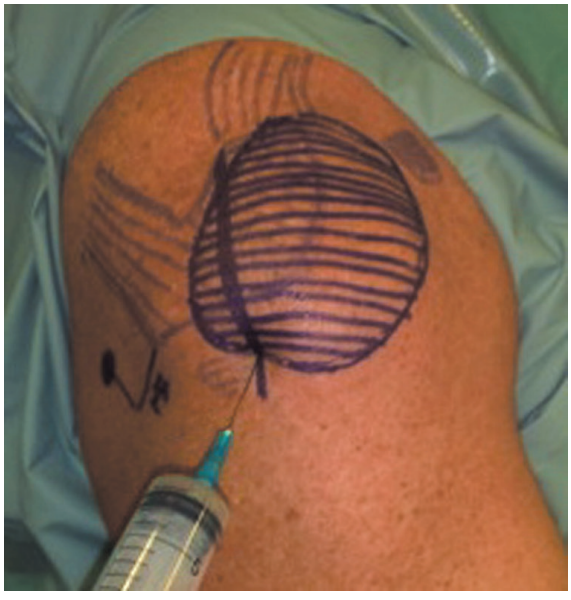

Figure 38.8 Technique of administering an injection into the subacromial bursa.

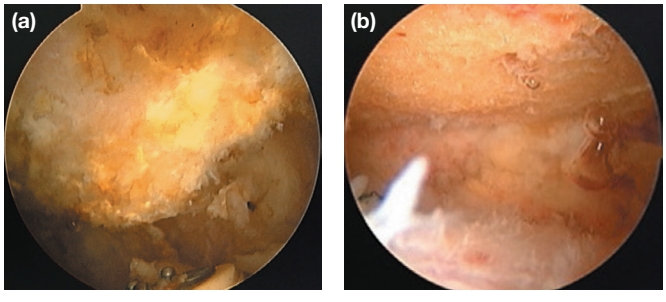

Figure 38.9 (a) Arthroscopic view of an acromial spur. **(b)** Arthroscopic view after the acromial spur has been removed and the cuff decompressed.

that are termed tears, whether or not there has been any trauma involved in their appearance. This means that tears are more common in older adults, and at any age they do not heal spontaneously. Tears usually begin at the anterolateral edge of the supraspinatus, and progress posteriorly to involve the infraspinatus and teres minor tendons. This creates a bare area over the greater tuberosity, as the torn cuff retracts medially (***Figure 38.10***).

History

In the younger patient with a healthier cuff the onset often requires relatively major trauma, e.g. breaking a fall from a motorcycle or significant height with the outstretched hand, but in older adults the onset may follow a simple fall, a painful period of tendinitis or the condition may apparently occur spontaneously.

Examination

The patient may have a mixed picture of subacromial pain and a tear, but if the pain is removed by injection of local anaesthetic the weakness will persist. Symptomatic tears are

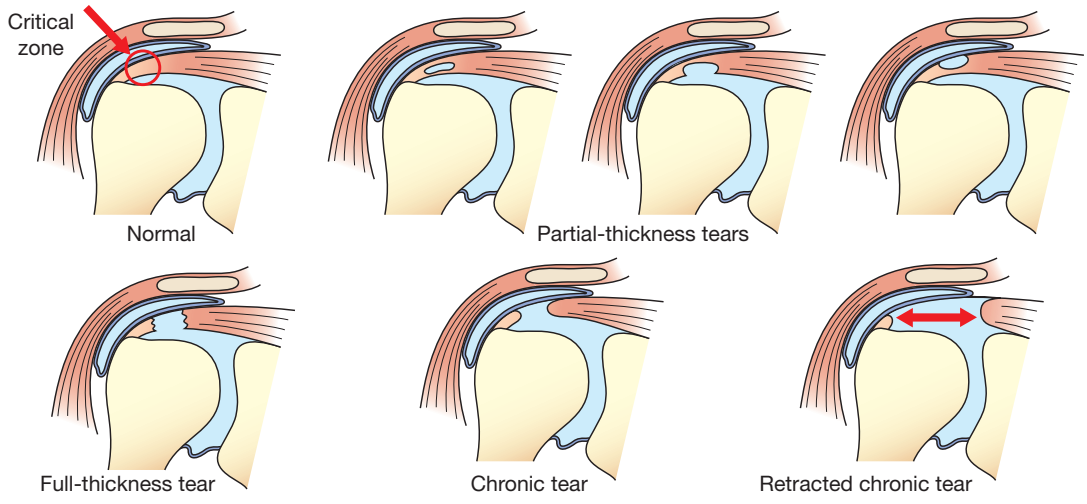

Figure 38.10 Various stages of rotator cuff tear. Initial partial-thickness tears progress to full–thickness and retracted tears but this process may be asymptomatic.

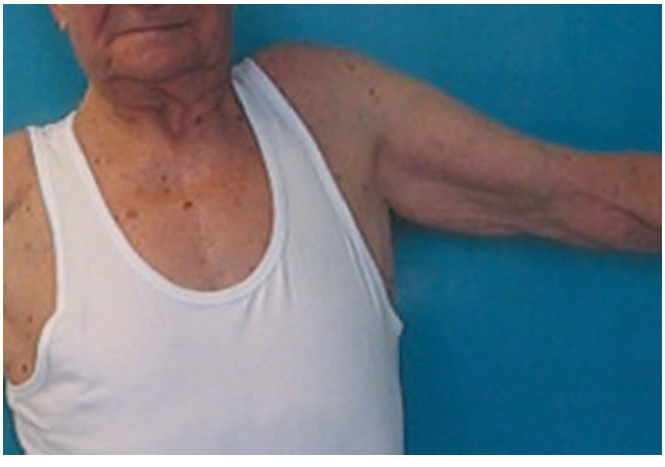

Figure 38.11 A 75-year-old man with a >5 cm retracted cuff tear attempting to abduct his shoulder; the lack of a stable fulcrum provided by the rotator cuff means that the deltoid is less effective and can only abduct to 60°.

associated with pain, weakness, limited active abduction, cuff muscle wasting and hunching of the shoulder when attempting abduction (***Figure 38.11***). Specific tests can localise the tear by identifying which muscles are affected, e.g. the 'empty can test' for supraspinatus.

Investigation

Both ultrasound scanning, in the hands of an experienced operator, and MRI are excellent tools for detecting rotator cuff tears and assessing the tissue quality. Tears are classified as small (less than 1 cm), intermediate (2–4 cm) and large (more than 5 cm).

Treatment

Treatment depends on the patient's age, lifestyle and severity of symptoms. Three to six months of rehabilitation are required after surgical repair before resuming full overhead loading, so this is not an operation to be carried out in those who cannot rest the shoulder, including those who need it for weight-bearing through bilateral crutches. Arthroscopic or mini-open repair with subacromial decompression can be considered for all tears, but is likely to give a better outcome in the young than in the old. It may not be possible to repair large tears owing to their size, or the attempt at repair may be fruitless because of fatty atrophy of the rotator cuff and loss of muscle contractility, in which case complex surgery, e.g. tendon transfers, patch grafts or reverse joint replacement (***Figure 38.12***), will need to be considered.

Summary box 38.3

Rotator cuff tears

- Occur more commonly in older age groups
- 4–20% of 40- to 50-year-olds have asymptomatic rotator cuff tears
- Up to 30% of 70-year-olds have an asymptomatic full-thickness tear
- Acute tears may present with little pain but profound weakness
- Earlier repair after traumatic onset with acute loss of function gives better results

Frozen shoulder (adhesive capsulitis)

This is an idiopathic condition causing stiffness and pain, most commonly affecting females in their fifties. It is also associated with diabetes, heart and thyroid disease.

History and examination

Frozen shoulder is characterised by the onset of severe pain that is often spontaneous, though patients may recall an episode of minor trauma, which is of unknown relevance. It may also complicate surgery or other painful shoulder conditions. The differential diagnosis includes infection, fractures and rotator cuff tear, though if the stiffness is global and there is no redness or temperature then osteoarthritis is the main

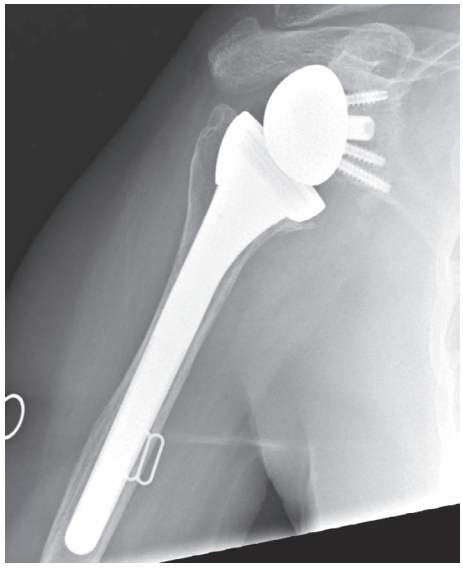

Figure 38.12 Reverse geometry total shoulder replacement.

alternative diagnosis. Initially there is severe pain but this improves with time. However, there is global loss of active and passive movement, limited by pain. The pathognomonic sign is loss of active external rotation. Radiographs are normal and distinguish it from osteoarthritis.

Treatment

The clinical course typically lasts 1–2 years, often considerably longer in individuals with diabetes, and is divided into painful, stiffening (freezing and frozen) and thawing phases. If untreated, frozen shoulder will resolve, and the majority of patients are left with no functional problems. In the first phase of the condition, treatment is pain relief. Corticosteroids can also be injected into the subacromial space or glenohumeral joint, although this is more often considered in the second phase. The latter can also be combined with a large volume (20–30 mL) of local anaesthetic to produce a distension injection. Despite the pain, the patient should be encouraged to perform as much active and passive movement as they can, and distension injections facilitate this. Operative options include manipulation under anaesthesia or arthroscopic release of the tight capsule, which usually produce pain relief and are indicated for prolonged stiffness.

Summary box 38.4

Frozen shoulder (adhesive capsulitis)

- Most commonly occurs in females in their fifties
- Spontaneous onset
- Produces severe pain with reduced glenohumeral motion
- Spontaneous resolution can occur over 1–2 years
- Differential diagnoses: calcific tendinitis and rotator cuff tear
- Injections, distension with saline, manipulation and surgical release may all help

Calcific tendinitis

Calcium salt deposition within the supraspinatus tendon is believed to be part of a degenerative process, possibly linked to the processes producing partial degenerative tears of the tendon. However, large deposits can occur in relatively young individuals with acute calcific tendinitis. Calcific deposits can be found coincidentally on radiographs taken for other purposes, but acute calcific tendinitis is agonisingly painful and associated with florid opaque lesions on radiographs. There is a spectrum of presentations between these two extremes

History and examination

In acute calcific tendinitis there is a rapid onset of severe shoulder pain with painful, restricted motion. However, in contrast to adhesive capsulitis, external rotation is usually possible. Subacromial calcific deposits can be seen on plain radiographs (***Figure 38.13***) and are well delineated on ultrasound scanning, with the calcifications casting acoustic shadows.

Treatment

Subacromial corticosteroid injections may help and can be accompanied by needling, aspiration or flushing of the deposits (barbotage). The condition is often self-limiting, with resorption of the calcium deposits. Surgery for resistant cases includes arthroscopic or open subacromial decompression and release or excision of the calcific deposits if they are prominent.

Arthritis of the shoulder

Rheumatoid arthritis

The glenohumeral joint is commonly involved in rheumatoid arthritis (***Figure 38.14***). As is typical of this condition, there is osteoporosis, destruction of the articular cartilage and synovial proliferation with pannus formation. The rotator cuff is weakened and frequently tears. Arthroscopic synovectomy may slow the progress of the joint destruction and lead to a reduction in pain and improvement in range of movement but has been effectively superseded, in many locations, by the introduction of biological therapies for rheumatoid disease.

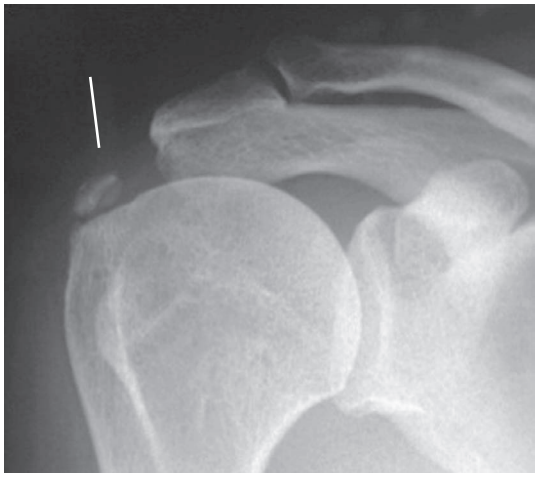

Figure 38.13 Radiograph demonstrating calcific tendinitis.

Figure 38.14 Rheumatoid arthritis of the shoulder.

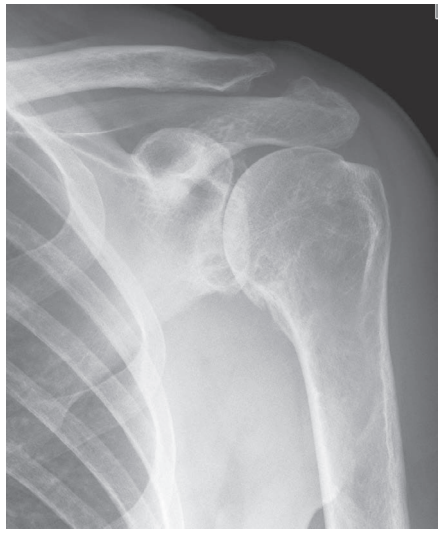

Figure 38.15 Osteoarthritis of the glenohumeral joint.

Intra-articular steroid injections may be helpful. Shoulder replacement is complicated by poor bone stock and anatomical shoulder replacement is further compromised by damage to the stabilising structures around the shoulder, especially the rotator cuff. In these patients reverse shoulder replacement may be an option if bone stock is preserved, although the patient should only expect a reduction in pain. Any increase in range of movement is a bonus, though is more likely with reverse shoulder replacement.

Summary box 38.5

Shoulder problems in rheumatoid arthritis

- Arthroscopic synovectomy may be effective but rarely needed
- Rotator cuff tears are common
- Glenohumeral joint replacement improves pain, but motion depends on rotator cuff involvement

Osteoarthritis of the shoulder

Glenohumeral joint osteoarthritis is either primary (*Figure 38.15*), secondary to trauma (*Figure 38.16*) or end-stage rotator cuff disease, i.e. cuff arthropathy (*Figure 38.17*).

Treatment

If medical treatment has failed, the surgical options are arthroscopic debridement or joint arthroplasty. Debridement is not predictable and is often reserved for young, active patients to delay the need for arthroplasty. Both total shoulder replacement (*Figure 38.18*) and hemiarthroplasty (*Figure 38.19*) have good reported results in appropriate patients, although pain relief is better with total arthroplasty, with the rate of hemiarthroplasty falling as the rate of total arthroplasty increases. An anatomical total shoulder arthroplasty can be performed if the rotator cuff is intact. However, in most patients with rheumatoid arthritis, and all patients with cuff tear arthropathy,

Figure 38.16 Post-traumatic arthritis with malunion of the proximal humerus, collapse of the humeral head, subchondral sclerosis and osteophytes.

Figure 38.17 A massive cuff tear that has led to superior migration of the humeral head and secondary osteoarthritis of the glenohumeral joint.

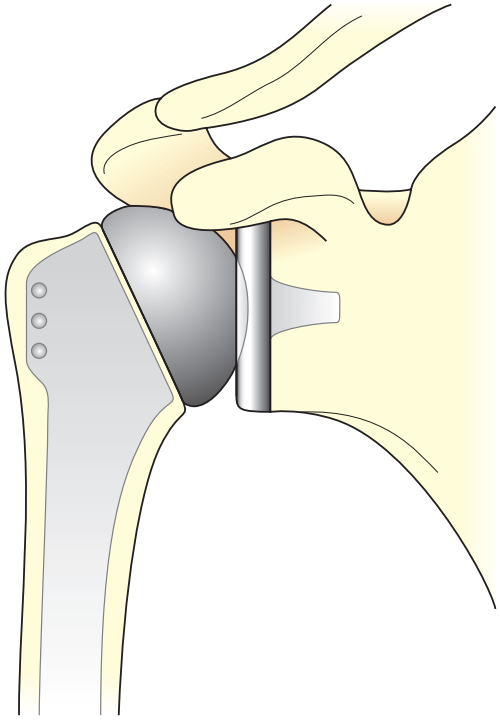

Figure 38.18 Anatomical total shoulder replacement performed for osteoarthritis. An intact rotator cuff is essential.

Figure 38.19 Shoulder hemiarthroplasty can be performed for arthritis, particularly if there is a deficient rotator cuff or in very young, active patients with a well-preserved glenoid.

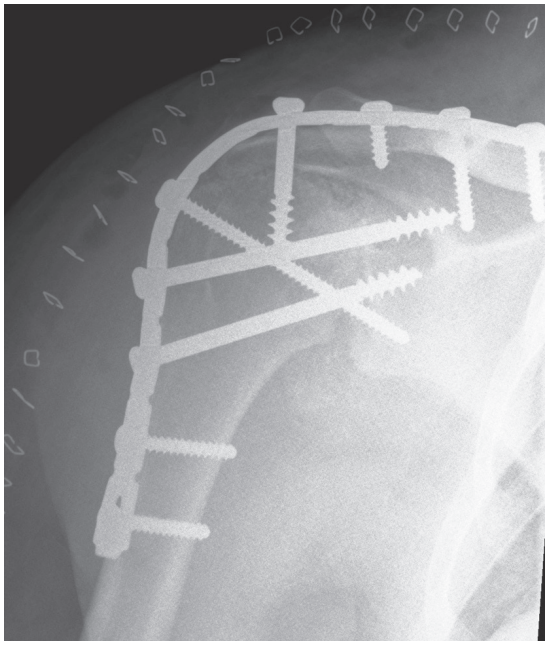

Figure 38.20 Arthrodesis of the shoulder.

the cuff is deficient and either a hemiarthroplasty or a reverse polarity total shoulder arthroplasty (*Figure 38.12*) should be used. Shoulder arthroplasty is an effective pain-relieving procedure, but less predictable in restoring motion, especially above shoulder level.

Arthrodesis of the joint is an alternative in younger patients with a history of sepsis or neurological problems (*Figure 38.20*). It is also used after brachial plexus injury, when nerve repair restores hand and elbow function but the shoulder remains flail because of loss of the C5 supply. Good scapulothoracic control, tested by the ability to shrug the shoulder powerfully, is a prerequisite to successful arthrodesis. Patients retain a moderate range of movement at the shoulder girdle as a result of scapulothoracic motion, which normally makes up approximately one-third of apparent shoulder elevation, the remaining two-thirds being glenohumeral movement, which is lost in arthrodesis.

Summary box 38.6

Arthritis of the shoulder

- Severe cases are treated with hemiarthroplasty or total shoulder arthroplasty
- Anatomical total shoulder replacement should not be performed if the rotator cuff is deficient but reverse shoulder replacement is appropriate
- Pain relief is good following arthroplasty, although improvement in range of motion is less predictable
- Glenohumeral arthrodesis is an option in the young or those with a history of sepsis
- Post arthrodesis, motion is fair but is entirely scapulothoracic

Acromioclavicular joint

Acromioclavicular joint (ACJ) arthritis is common and is often asymptomatic, noted as an incidental finding on radiographs (*Figure 38.4b*). Symptoms typically arise in males aged 20–50 years. Inferior osteophytes can impinge on the underlying rotator cuff.

History and examination

There may be a history of trauma to the ACJ. Pain is activity related and worse when using the arm overhead. There is prominence of the lateral end of the clavicle. The joint line is tender. Flexing and adducting the arm to place the hand around the opposite shoulder reproduces pain. There is a high painful arc, pain being worst for the last 20–30° of elevation. If symptoms are related to inferior osteophytes, impingement symptoms and signs can also be present.

Treatment

An intra-articular corticosteroid injection will usually help; even if the effect is short-lived it localises the problem accurately. Surgery involves arthroscopic or open excision of the lateral 0.5–1 cm of the clavicle (*Figure 38.21*). This gives good pain relief. In patients with symptoms that are predominantly those of impingement, arthroscopic removal of the inferior osteophytes with subacromial decompression should be performed.

Summary box 38.7

ACJ problems

- ACJ arthritis is common and is often asymptomatic
- It may become symptomatic secondary to trauma or repetitive overload
- Intra-articular steroid and local anaesthetic injection may relieve symptoms
- Excision of the lateral end of the clavicle gives good results

Long head of biceps tendon rupture

Rupture of the long head of biceps usually occurs in older adults and is due to constriction and degeneration of the tendon in the bicipital groove, especially at the superior end, beneath the anterior acromion. It is associated with rotator cuff tears. Most patients present with few symptoms, although they often seek advice because of the bulge they notice in their arm.

History and examination

Patients feel a sense of 'something giving way' in front of the shoulder, sometimes with relief of pain if there was any present beforehand due to biceps tendinitis. The upper arm is bruised and elbow flexion produces a swelling in the front and middle of the arm (*Figure 38.22*). The lump will be permanent and is initially tender. Power is slightly diminished in the early stages, when there may also be cramping pains on use of the arm.

Treatment

Reassurance that pain and bruising will resolve is sufficient. Power improves over several months and surgery (biceps tenodesis) is not needed for function, although it may help the cosmetic appearance.

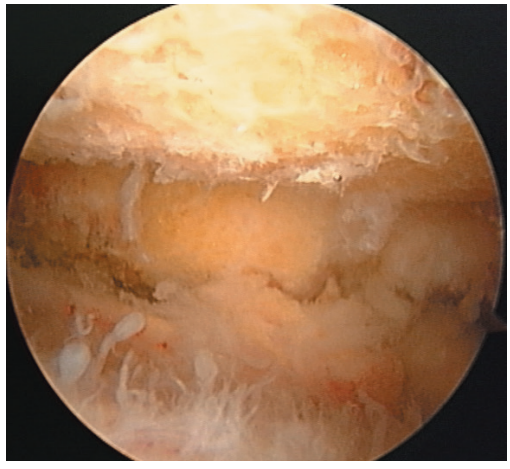

Figure 38.21 Arthroscopic end-on view of the clavicle after excision of its distal end.

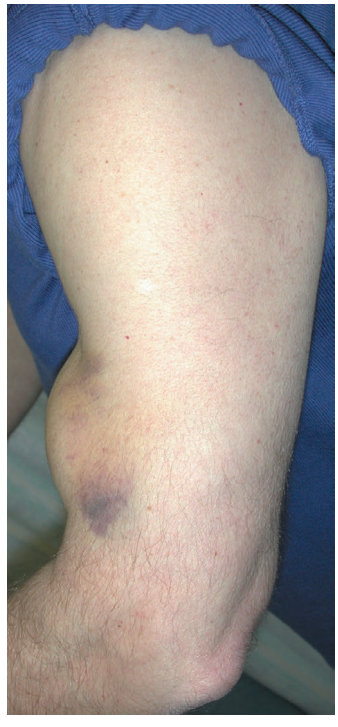

Figure 38.22 Bruising and change in the upper arm shape due to rupture of the long head of biceps.

Dislocation of the shoulder and instability of the glenohumeral joint

Three broad groups of shoulder instability exist.

Classification of glenohumeral instability

- **Traumatic**: unidirectional; involuntary; surgery is usually successful.
- **Atraumatic**: multidirectional, painful; involuntary; responds to surgery.
- **Habitual**: voluntary, with ligament laxity, painless; surgery usually contraindicated.

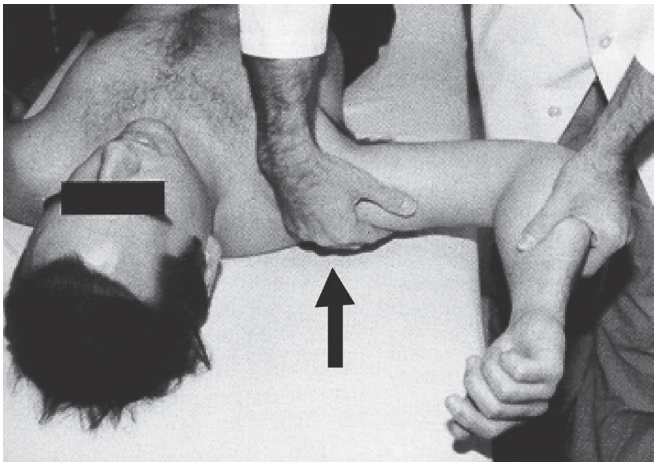

Figure 38.23 Apprehension test for anterior instability.

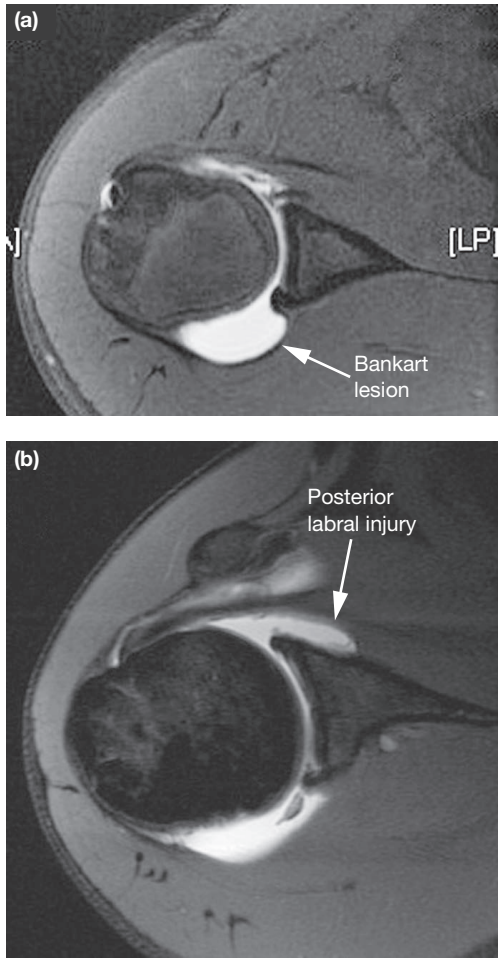

Figure 38.24 (a) Magnetic resonance (MR) arthrogram showing an anterior Bankart lesion. (b) MR arthrogram showing a posterior labral injury.

Recurrent traumatic anterior instability

History

Traumatic shoulder dislocation is the commonest of all dislocations, usually first presenting in patients under 25. The shoulder usually dislocates anteroinferiorly and initially there is a notable traumatic event. Subsequent dislocations usually require less force. The shoulder may sublux and relocate, or actually dislocate (complete separation of the joint surfaces).

Examination

Assuming that the patient presents with a history of instability following a previous anterior dislocation (after which the joint was reduced), examination of the shoulder reveals a full range of motion. However, with forced abduction and external rotation the patient experiences apprehension (a sense of impending doom as the patient feels the shoulder about to re-dislocate!) (***Figure 38.23***).

Investigations

On computed tomography (CT) or MR arthrography (***Figure 38.24***) detachment of the anteroinferior labrum (Bankart's lesion) (***Figures 38.25 and 38.26***) and damage to the humeral head (Hill–Sachs lesion) can often be seen. On CT without arthrography only the bone lesions will be seen, which can also include a marginal fracture of the anteroinferior glenoid margin (bony Bankart).

Treatment

The relative indications for surgery are repeated dislocations, or symptoms of instability that persist after reduction of the first dislocation, that are interfering with the patient's quality of life. Anterior instability can be treated with arthroscopic or open repair of the Bankart lesion with retensioning of the stretched anterior/inferior capsule, which prevents further dislocations in up to 90–95% of patients. Bony defects of the glenoid, and occasionally large Hill–Sachs lesions, may have to

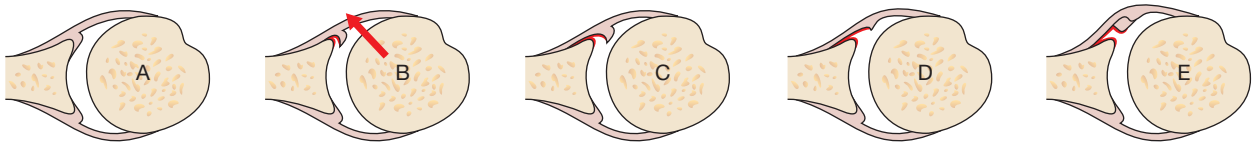

Figure 38.25 Schematic representation of Bankart's lesion, which forms a spectrum of pathology from minor labral detachment (B) to large detachments with glenoid rim fractures (bony Bankart; E).

Arthur Sydney Blundell Bankart, 1879–1951, orthopaedic surgeon, The Middlesex Hospital, London, UK.
Harold Arthur Hill, 1901–1973, radiologist, San Francisco, CA, USA.
Maurice David Sachs, 1909–1987, radiologist, San Francisco, CA, USA.

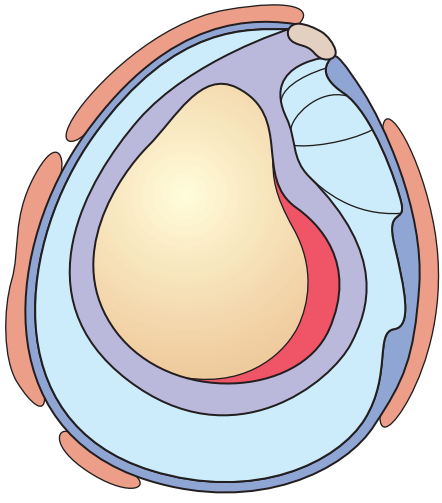

Figure 38.26 An end-on view of the glenoid labrum, demonstrating anteroinferior labral detachment (red) with the rotator cuff muscles (brown), long head of biceps tendon and labrum (grey).

be grafted. For the less common recurrent posterior instability, repair of the damaged labrum and tightening of the posterior capsule is needed.

Posterior dislocation of the shoulder

This is a relatively rare event and is easy to miss. The clue is often in the history, as the patient will often have had either an electric shock or an epileptic fit or been subject to severe restraint when their arm has been forced up their back (a half-Nelson) – all are mechanisms producing forced internal rotation of the glenohumeral joint.

The patient may be in severe pain but can be difficult to examine properly if they are post-ictal or are recovering from an electric shock. For the same reason, the radiographer may only be able to get an anteroposterior view of the shoulder; on this view, the shoulder may look normal to the unwary (*Figure 38.27*). It is the high 'index of suspicion' from the history that gives the best chance of making the diagnosis.

Treatment

This dislocation may be difficult to reduce if the posterior margin of the glenoid is embedded in the humeral head (a 'locked' posterior dislocation), so that open reduction is needed. A number of techniques are available, such as gently abducting the internally rotated arm above shoulder height while maintaining axial traction then externally rotating the arm before returning it down to the side – the reduced shoulder

Summary box 38.8

Recurrent traumatic shoulder instability

- An appreciable force leads to the first dislocation or subluxation
- Subsequent dislocations/subluxations require less force
- The commonest direction of dislocation is anteroinferior
- There is a positive apprehension sign
- Surgical treatment repairs the labral lesion and reverses traumatic laxity of the capsule

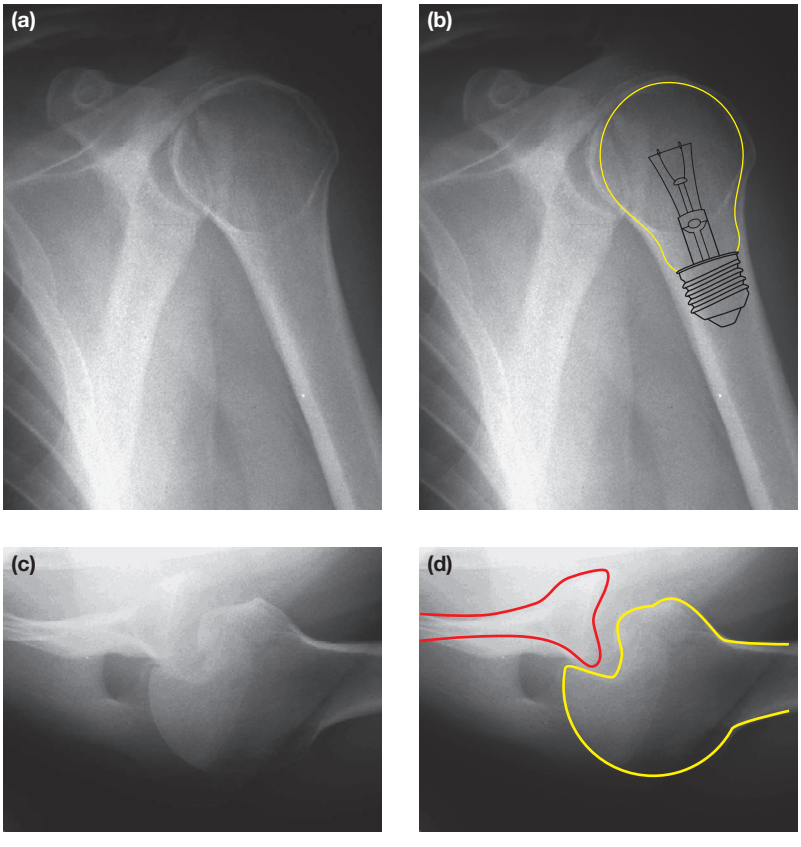

Figure 38.27 Posterior dislocation of the shoulder. (a) Anteroposterior view; (b) origin of the light bulb sign; (c) axial projection demonstrating how much easier it is to visualise the injury on this view; (d) axial projection highlighting this joint and further demonstrating the impacted fracture in the humeral head, or anterior Hill–Sachs lesion.

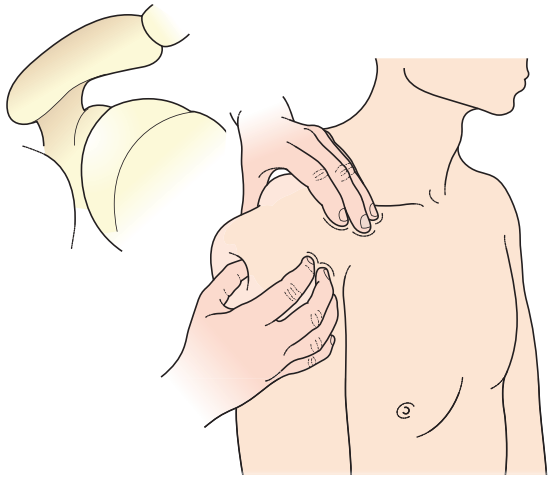

Figure 38.28 Generalised laxity can be appreciated by drawing the humeral head in anterior and posterior directions and feeling it slide up to, and possibly even over, the glenoid rim. A sulcus will be produced under the acromion if the humerus is drawn inferiorly (sulcus sign).

should then be placed in an external rotation brace to allow the stretched and torn posterior structures an opportunity to heal.

Atraumatic instability

History

There is usually no history of an initial injury. Instability may be multidirectional and is usually associated with subluxation rather than dislocation. The patient is often able to reduce the shoulder without assistance.

Examination

Generalised ligament laxity is common (see Beighton score in *Chapter 35*). Apprehension tests are positive, but often in more than one direction. Anterior and posterior drawing of the humeral head allows laxity to be tested in these directions, whereas downward traction on the humerus may produce a 'sulcus sign' as the deltoid is sucked into the space created by inferior subluxation of the humeral head (*Figure 38.28*). Overactivity of muscle groups such as pectoralis major should be sought, as this gives an avenue of treatment through rehabilitation.

Treatment

Specialist physiotherapy should be tried first in these patients, aiming to improve both the proprioception and firing patterns of the muscles around the shoulder (for instance, biofeedback to control an overactive pectoralis major or strengthening of underactive muscle groups). If this fails then surgery may be considered, by way of capsular tightening.

Habitual dislocation

Habitual dislocators are patients who can sublux the shoulder at will, usually either anteroinferiorly or posteriorly. The manoeuvre is painless. Patients have generalised joint laxity and may subluxate the shoulder as a 'party trick'.

Patients should be advised to stop subluxating the shoulder, which may then allow the capsule to tighten naturally with age. They may benefit from assessment and advice from a specialist physiotherapist. Surgery is associated with a high failure rate and should be avoided.

DISORDERS OF THE ELBOW

Anatomy and function

The elbow joint allows flexion and extension through the ulnohumeral articulation as well as rotation of the radial head, which articulates with both the capitellum of the distal humerus (radiocapitellar joint) and the proximal ulna (proximal radioulnar joint [PRUJ]). The rotation of the radius at the PRUJ, in concert with the distal radioulnar joint and interosseous membrane, permits pronation and supination of the forearm. The elbow joint possesses a slim soft-tissue envelope, traversed by multiple neurovascular structures. At the front, from medial to lateral, are found the median nerve, brachial artery and radial nerve. At the back, just behind the medial epicondyle is found the ulnar nerve.

Tennis elbow (lateral epicondylitis) and golfer's elbow (medial epicondylitis)

These are discussed in *Chapters 35 and 36*.

Arthritis of the elbow

Rheumatoid arthritis

Surgery may be required, especially in end-stage disease (*Figure 38.29*). Arthroscopic or open radial head excision and synovectomy are effective for painful, restricted pronation and supination. Elbow arthroplasty is effective for pain relief and functional restoration.

Osteoarthritis

Osteoarthritis of the elbow is usually primary (*Figure 38.30*) or secondary to trauma.

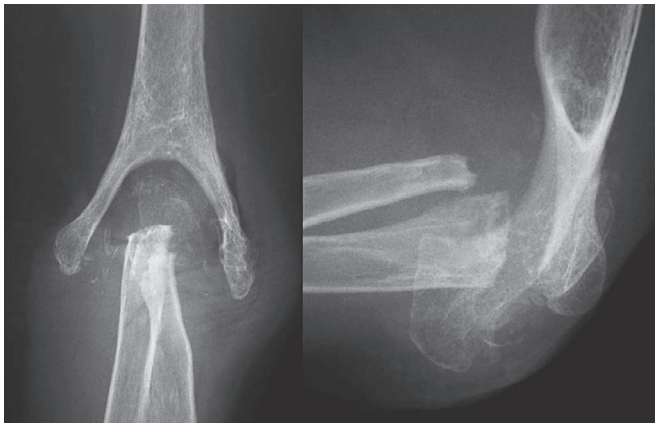

Figure 38.29 Typical end-stage unstable and destroyed rheumatoid elbow.

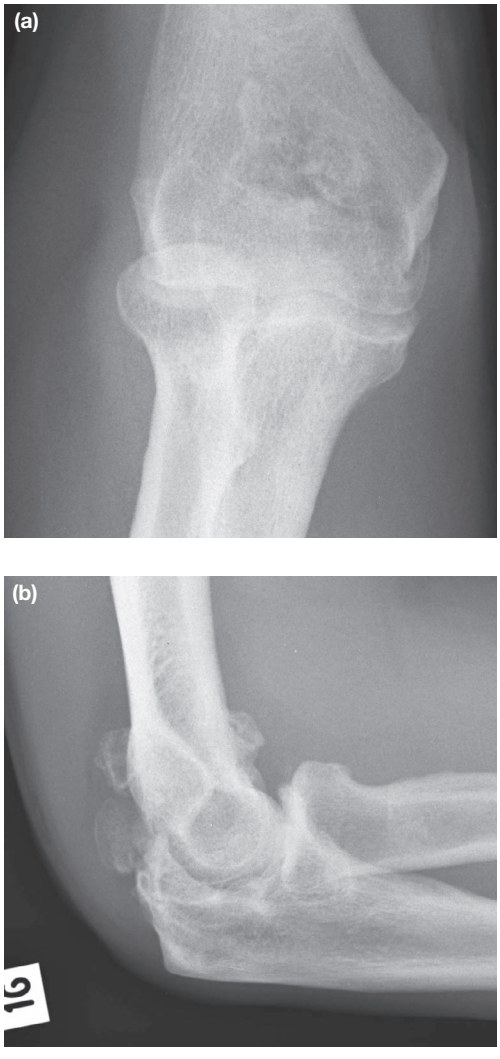

Figure 38.30 (a, b) Radiographs showing osteoarthritis of the elbow joint.

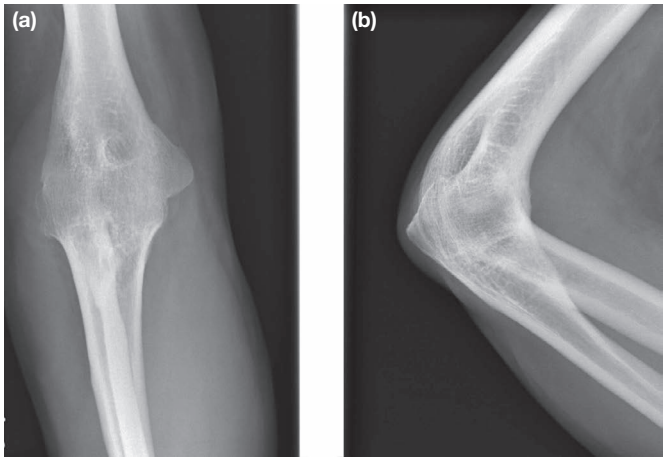

Figure 38.31 (a, b) Ankylosed elbow after tuberculosis. Arthrodesis is a surgical procedure to achieve the same end result, by excising the articular surfaces and compression plating across the joint.

History

Typical patients are middle-aged men in manual occupations. Symptoms can include pain, locking, crepitus and painful motion with loss of terminal flexion and extension. Ulnar nerve entrapment symptoms may be present.

Examination

There is restriction of extension and flexion with impingement pain as osteophytes and soft tissues are pressed together at the end of the available range. Pronation and supination tend to be spared in comparison with rheumatoid arthritis but there may still be crepitus felt over the radiocapitellar joint on rotation and pain when this is done with the fist clenched ('grip and grind' test).

Treatment

Surgery should be considered only if medical treatment fails. Arthrodesis may very rarely be offered for those performing heavy manual work (***Figure 38.31***) but is associated with significant residual functional loss. However, joint replacement will not survive long under heavy loading. Surgical debridement alleviates pain and increases range of motion by removing anterior and posterior osteophytes, the thickened capsule and loose bodies through a lateral approach (lateral column procedure). In earlier stages the olecranon osteophytes can be accessed through the triceps tendon, creating an olecranon foramen by drilling through the olecranon fossa to access the coronoid tip osteophyte and any loose bodies (the so-called 'OK' procedure). Interposition arthroplasty (for example, Achilles tendon allograft) may be considered in younger patients, although it can be associated with significant bone loss with time, possibly restricting future treatments. Prosthetic joint arthroplasty provides more predictable symptomatic relief (***Figure 38.32***) but high activity levels are associated with early loosening.

Summary box 38.9

Arthritis of the elbow

- Excision of the radial head and synovectomy improves pain and pronation–supination in rheumatoid arthritis
- Total elbow replacement gives good results in rheumatoid and low-demand osteoarthritic patients
- Arthrodesis may be the only surgical option in a high-demand manual labourer

Loose bodies in the elbow

The common causes are osteoarthritis, osteochondritis dissecans in the young (***Figure 38.33***) and synovial chondromatosis (***Figure 38.34***). Patients describe sudden pain and locking, and the need to manipulate the elbow for relief. Plain radiographs will usually confirm the diagnosis (***Figure 38.35***) but if there is doubt a CT or MR arthrogram will demonstrate filling defects in the intra-articular contrast. Arthroscopic clearance of the joint produces good results (***Figure 38.36***).

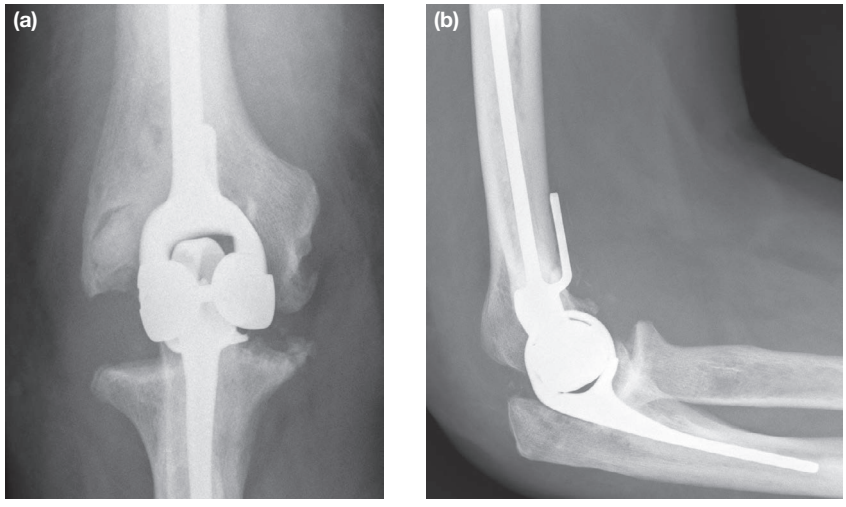

Figure 38.32 (a, b) Linked total elbow replacement.

Figure 38.33 Osteochondritis dissecans of the capitellum (Panner's disease).

Figure 38.34 Synovial chondromatosis.

Olecranon bursitis

This is a relatively common disorder in which the point of the elbow becomes red, warm, swollen and painful. Initially, septic arthritis may be suspected. However, on examination signs and symptoms are confined to the extensor aspect of the elbow (*Figure 38.37*), over the olecranon, and movement within an arc of 30–130° is almost always possible. Most cases settle with anti-inflammatory drugs. If the patient is pyrexial antibiotics should be given. Formal drainage of the bursa is indicated if purulent material is present.

Chronic olecranon bursitis may be associated with calcific nodules of the bursal lining (*Figure 38.38*). These can be excised if they prove troublesome.

Ulnar nerve compression

Compression of the ulnar nerve most commonly occurs in the cubital tunnel (behind the medial epicondyle) within the arcade of Struthers. It may become compressed by the medial intermuscular septum as the nerve passes into the posterior compartment of the distal humerus. Distally it may also become compressed as the nerve passes between the heads of the flexor carpi ulnaris (*Figure 38.39*).

History and examination

Patients describe tingling/numbness in the little and ring fingers. A positive Tinel's sign is usually present at the compression site, with wasting and weakness of the intrinsic muscles

Hans Jessen Panner, 1871–1930, radiologist, Copenhagen, Denmark, described this condition in 1927.
Sir John Struthers, 1823–1899, Professor of Anatomy, University of Aberdeen, Aberdeen, UK.
Jules Tinel, 1879–1952, physician, Hôpital Beaujon, Paris, France.

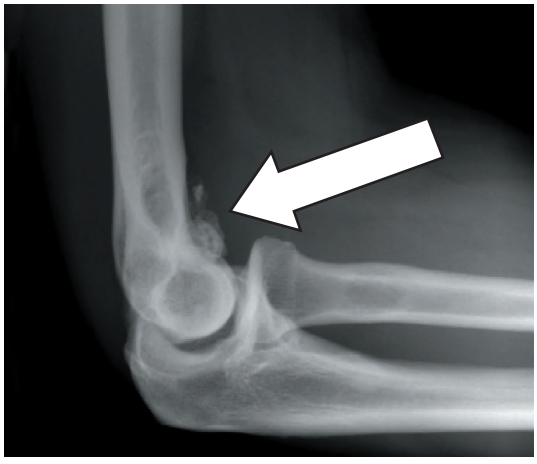

Figure 38.35 Radiographs showing loose bodies in the elbow (arrow).

Figure 38.36 Loose bodies removed arthroscopically from the patient in *Figure 38.35*.

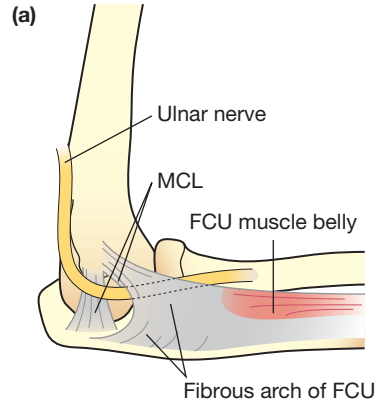

Figure 38.37 Olecranon bursitis.

of the hand (*Figure 38.40*). Froment's sign may be positive if there is weakness of the adductor pollicis (*Figure 38.41*). Nerve conduction studies have an unpredictable diagnostic value in the early stages. Radiographs may confirm medial osteophytes or loose bodies if compression is secondary to arthritis.

Figure 38.38 Large chronic olecranon bursa with dense calcific deposit.

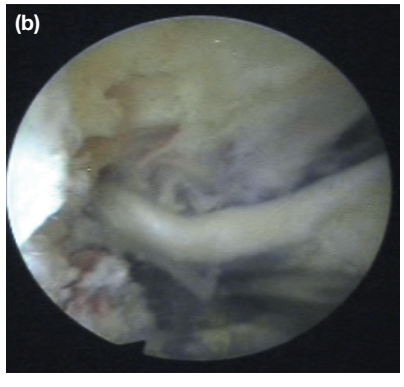

Figure 38.39 (a) Anatomy of the cubital tunnel site for ulnar nerve compression, with (b) a view of arthroscopic ulnar nerve decompression. FCU, flexor carpi ulnaris; MCL, medial collateral ligament.

Treatment

Splints preventing elbow flexion at night may be useful if only night symptoms are a problem for the patient. If symptoms persist, surgery can be performed; options include simple nerve decompression (most cases), partial medial epicondylectomy and/or anterior transposition of the nerve. Transposition is necessary in cases of valgus deformity or if the nerve is unstable after decompression.

Jules Froment, 1878–1946, Professor of Clinical Medicine, Lyons, France.

Figure 38.40 Intrinsic muscle wasting on the left due to ulnar neuropathy.

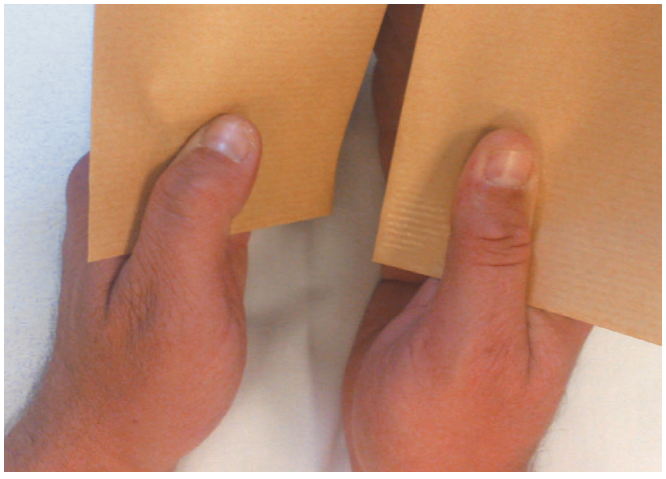

Figure 38.41 Froment's sign tests the adductor pollicis. The patient is asked to hold a piece of paper in a side pinch between the thumb and the index finger. The examiner attempts to pull the paper out. Owing to weakness of the adductor pollicis, the patient will compensate by flexing the flexor pollicis longus, which is supplied by the anterior interosseous nerve (median nerve).

Summary box 38.10

Other common elbow problems

- Loose bodies cause locking and can be removed arthroscopically
- If the ulnar nerve is compressed, weakness and wasting will be seen in the hands
- Simple decompression is usually successful

TUMOURS OF THE UPPER LIMB

Tumours are discussed in *Chapter 42*.

HAND AND WRIST

The hand and wrist work in concert to interact with the environment in which they are placed. The index finger works against the thumb for pinch grip; the thumb can press against the side of the flexed index finger for a key-pinch grip; the tips of the thumb, index and middle fingers provide a tripod pinch; all fingers curl for hook grip while the little and ring fingers provide the most power when making a fist. A mobile and stable wrist is required to optimise hand function through maximising range of movement and strength.

Clinical history and physical examination

History

Asking about the patient's occupation, hobbies (sport, musical instruments, fine art) and hand dominance are important when taking a history. In considering the problem concerned there are a number of symptoms that patients complain of: pain, swelling, stiffness, instability and pins and needles are commonly encountered in the hand and wrist. Sometimes these present together and sometimes in isolation, but all affect the function of the hand. It is vital to ask which of these issues causes the functional deficit, since there is no value in fusing a painful finger that is stiff if the main concern of the patient is the stiffness rather than the pain. A history of other medical comorbidities is important to glean, since these may well be part of the pathology or alter the management strategies that can be considered, e.g. carpal tunnel syndrome may be the first presentation of diabetes mellitus.

Examination

The examination of the hand should assess sensation, movement, power and clinically relevant special tests for the issues encountered. Perfusion is seen (pink is well perfused) and felt (slightly warm to the touch with palpable radial and ulnar pulses). Sensory innervation of the median (radial 3.5 volar digits), ulnar (ulnar 1.5 volar digits) and radial (first dorsal web space and back of the hand) nerves is required. To test the motor innervation one can assess the abductor pollicis brevis for the median nerve and the first dorsal interosseous muscle for the ulnar nerve. The radial nerve does not supply any muscles in the hand but supplies the muscles that drive wrist extension. In assessing movement and power, one should start by evaluating functional combined movements such as grip, 'thumbs up', flat hand, palm up (supination) and palm down (pronation) as well as wrist movements (flexion, extension, radial and ulnar deviation). After that, a more detailed assessment of each individual muscle/tendon group is required. While assessing movements, obvious side-to-side asymmetry may be encountered, such as rotational malalignment of the digits (*Figure 38.42*). There are also a number of special tests relevant to different pathologies seen.

Investigations

Radiographs can be used to assess for arthritis or bone tumours. Electrophysiological studies may be required to evaluate nerve function, assessing both sensory and motor supply. Ultrasound

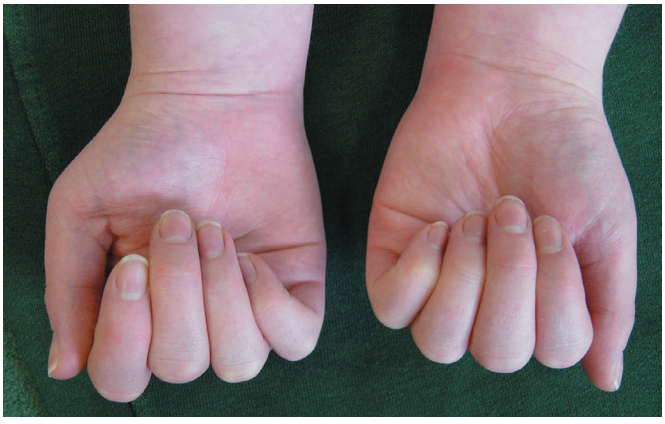

Figure 38.42 Rotational deformity of the little finger.

is a very useful investigation as it can assess soft tissues in a dynamic way while the patient is asked to perform movements, identifying issues such as tendon instability. In addition, since the hand has a thin soft-tissue envelope, many structures can be seen very well with ultrasound that would not normally be evaluated (e.g. erosions within the joints of the fingers as an early sign of inflammatory joint disease). MRI is useful for diagnosing avascular necrosis, ligament injuries or to characterise soft-tissue tumours.

Hand swelling and stiffness

Swelling followed by stiffness is the arch enemy of hand rehabilitation. The hand will swell after injury, surgery or infection. In response, the wrist flexes and then there is compensatory metacarpophalangeal joint (MCPJ) extension and interphalangeal joint (IPJ) flexion. If action is not taken swiftly, this position will become permanent, as collateral ligaments shrink and tissues fibrose. Hand elevation to reduce swelling, splintage in the position of safety to prevent collateral shortening (Edinburgh position: wrist extension, MCPJ flexion, IPJ extension) and early mobilisation prevent permanent stiffness.

Summary box 38.11

General principles of treatment

Avoid swelling and stiffness by:

- Elevation – reduce swelling
- Splintage – avoid contractures
- Movement – pump away swelling and encourage suppleness

Thumb ulnar collateral ligament injury

Chronic thumb overuse or overloading leads to stretching of the ulnar collateral ligament and instability (gamekeeper's thumb). The ligament can also rupture acutely if the thumb is forcibly abducted (skier's thumb). If valgus stress on examination causes significant opening of the joint on the ulnar side then the ligament needs to be repaired surgically, as the adductor aponeurosis interposes between the torn end of the ligament and its insertion (*Figure 38.43*), preventing healing and causing chronic instability.

Figure 38.43 Magnetic resonance imaging showing rupture of the ulnar collateral ligament of the thumb (skier's thumb).

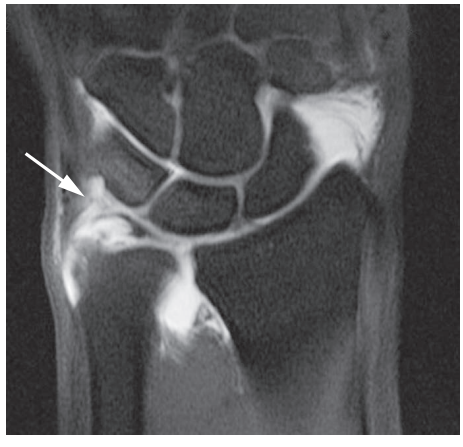

Figure 38.44 Magnetic resonance arthrogram showing peripheral detachment of the triangular fibrocartilage complex.

Triangular fibrocartilage complex

The triangular fibrocartilage complex (TFCC) consists of the ulnocarpal ligaments, extensor carpi ulnaris tendon sheath and a meniscus-like structure between the distal ulna and the carpus. It is continuous with the dorsal and volar wrist capsules and stabilises the distal radioulnar joint. It can undergo traumatic or degenerative tears, presenting with ulna-sided wrist pain and distal radioulnar instability. An MRI arthrogram or wrist arthroscopy aids diagnosis (*Figure 38.44*). Peripheral tears of the TFCC can be repaired open or arthroscopically, while central degenerative tears can be arthroscopically debrided.

Infections

Paronychia

Nail bed infection is the most common hand infection (*Figure 38.45*). After initial inflammation, pus accumulates beside and sometimes under the nail. It is best treated with incision, drainage and appropriate antibiotic therapy. This

Figure 38.45 Acute paronychia.

is occasionally facilitated by partial nail removal to allow full drainage of the collection.

Felon

A felon is an abscess within the specialised fibrous septae of the fingertip pulp. It causes intense pain and may lead to terminal phalangeal osteomyelitis. Incision and drainage through the midline of the pulp of the finger in the location of maximal swelling, followed by intravenous antibiotics, are recommended.

Flexor tendon sheath infection

Flexor tendon sheath infections present with Kanavel's cardinal signs:

- the affected finger is held in flexion;
- there is uniform swelling over the tendon and digit;
- tender to the touch;
- pain on passive extension of the finger.

Flexor sheath anatomy is important to understand, since infection within flexors 2 (index) to 4 (ring) is usually confined to that finger, whereas infections arising in the sheath of the thumb or little finger may extend via the radial and ulnar bursae, respectively, towards the wrist. Treatment is by open irrigation throughout the tendon sheath course; small incisions are made at the proximal and distal ends of the affected sheath and the sheath is washed out, delivering irrigation via a small nasogastric or feeding tube. The whole finger may require opening if the viability of the digit is threatened. This is followed by what is often an extended course of intravenous antibiotics. If infection is untreated tendon adhesions and necrosis occur. Infection can spread proximally, damaging the whole hand.

Summary box 38.12

Treatment of hand infections

- Elevate and splint in a functional position and give intravenous antibiotics
- Surgical drainage should include tendon sheath irrigation
- Early mobilisation

Mycobacterial infections

Tuberculosis may involve the tenosynovium, joints or bone. The most dramatic form is a compound palmar ganglion, with synovial swelling proximal and distal to the transverse carpal ligament, occasionally causing symptoms of carpal tunnel syndrome. The diagnosis is made by taking a biopsy. Synovectomy should be performed and the patient treated with the appropriate antibiotics.

Deep palmar infections

These infections occur in the palm but may be limited to a web space. The whole hand becomes swollen and tender as pus collects on either side of the septum. Treatment is incision and drainage with thorough washout of the wound. It is important that all deep spaces are opened: incisions on both the dorsal and volar aspects of the hand may be needed. If in doubt, an ultrasound scan or MRI can delineate the extent of the collections within the deep palmar spaces.

Arthritis

Rheumatoid arthritis

Rheumatoid arthritis presents with classic symptoms: morning stiffness, symmetrical arthritis, hand deformities and rheumatoid nodules. Diagnostic criteria include seropositive rheumatoid factor and radiographic changes (***Table 38.1***). The inflamed rheumatoid synovium (pannus) destroys ligaments, tendons and joints, producing pain, deformity and loss of function. Typical rheumatoid deformities in the hand include boutonnière (***Figure 38.46***), swan neck (***Figure 38.47***) and radial drift of the wrist (due to supination of the carpus), with compensatory ulnar deviation of the MCPJs (***Figure 38.48***). Pannus can cause extensor tendon ruptures, classically starting with the little finger and progressing stepwise in a radial direction (Vaughan-Jackson syndrome). With progressive deformity and instability of the wrist and hand, activities such as key pinch and the opening of jars become impossible to perform. The treatment should be dictated by the patient's levels of pain and disability, not purely on the basis of deformity.

TABLE 38.1 Radiographic differences between rheumatoid and osteoarthritis.

Rheumatoid arthritis	Osteoarthritis
Periarticular osteoporosis/ subchondral erosions	Subchondral sclerosis and cysts
Periarticular soft-tissue swelling	Less pronounced swelling
Joint space narrowing	Joint space narrowing
Marginal erosions	Marginal osteophytes
Joint deformity/malalignment	Less pronounced deformities
Ankylosis	Less common ankylosis

Allen B Kanavel, 1874–1938, Professor of Surgery, Northwestern University Medical School and President of the American College of Surgeons (1931–1932).
Boutonnière is French for 'buttonhole'.
Oliver J Vaughan-Jackson, 1907–2003, consultant orthopaedic surgeon, The London Hospital, London, UK, and a specialist in hand surgery.

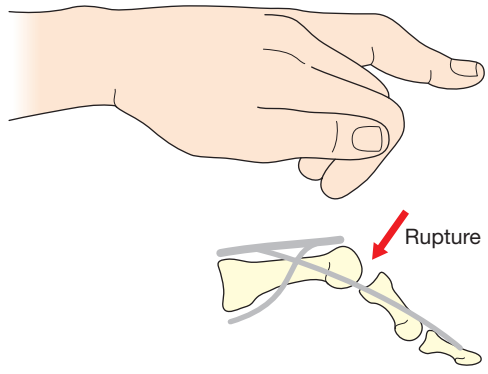

Figure 38.46 Boutonnière deformity.

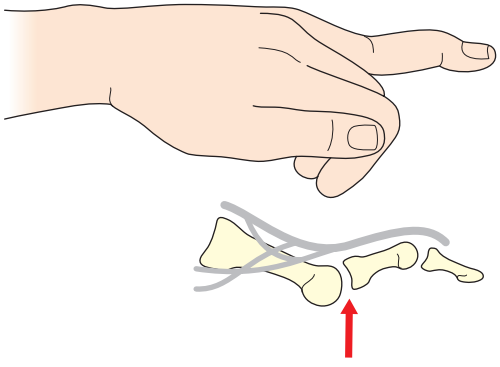

Figure 38.47 Swan neck deformity.

Figure 38.48 Rheumatoid hand showing ulnar drift at the metacarpophalangeal joints, which is seen compensating for radial deviation at the wrist joint.

Summary box 38.13

Manifestations of rheumatoid arthritis in the hand

- Swan neck, boutonnière finger deformities
- Extensor tendon ruptures (Vaughan-Jackson syndrome)
- Flexor tendon synovitis or rupture
- MCPJs: flexion, ulnar deviation, subluxation, dislocation
- Wrist: radial deviation, carpal supination, prominent ulnar head (caput ulnae), extensor tenosynovitis

Management

The primary indications for surgery are: (i) pain relief; (ii) functional improvement; (iii) to prevent disease progression; and (iv) cosmesis. Patients may require many surgical procedures over time and a helpful axiom is to start proximally and work distally, alternating between motion-sacrificing and motion-sparing procedures. The various procedures that can be considered are:

1. Synovectomy: improves pain, increases function and prevents tendon rupture.
2. Trigger finger releases and nerve decompression surgery (carpal tunnel syndrome).
3. Distal ulna excision: reduces pain, prevents extensor tendon rupture or protects repaired extensor tendons. Distal ulna excision leads to instability and so, in the young patient, a constrained ulnar head arthroplasty is preferred.
4. Arthrodesis of the wrist, thumb and some of the smaller joints: gives good pain relief and creates a stable axis against which other parts can function.
5. MCPJ and IPJ replacements: provide pain relief and functional improvement. Total wrist arthroplasty will also provide good pain relief and some motion (***Figure 38.49***).
6. Tendon reconstructions: some ruptured tendons can cause significant morbidity (***Figure 38.50***) and are often treated by either a tendon transfer or a local joint fusion.

Osteoarthritis

Wrist

The radiocarpal joint can develop primary or secondary osteoarthritis (after intra-articular trauma or infection). If conservative measures have failed then operative management includes limited or total wrist arthrodesis and total wrist replacement.

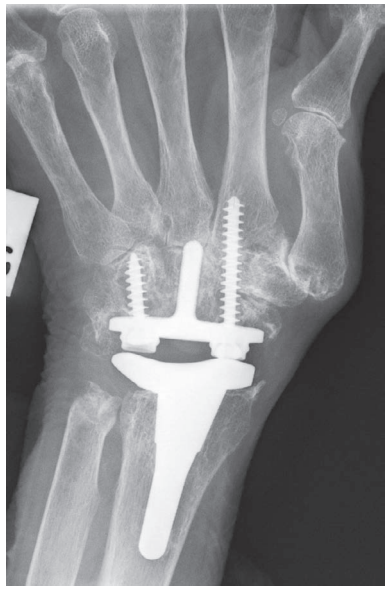

Figure 38.49 Total wrist replacement.

Figure 38.50 Rupture of the extensor tendons to the little and ring fingers.

Hand

Females are more commonly affected than males. The commonly affected joints are the distal interphalangeal (Heberden's nodes), proximal interphalangeal (PIP) (Bouchard's nodes) and the thumb carpometacarpal joints (***Figure 38.51***). Symptoms rarely correlate with the appearance, either clinically or radiographically. Treatment includes splinting, physiotherapy and steroid injections. Surgical options include arthrodesis for distal interphalangeal (DIP) and PIP joints (***Figure 38.52***), joint replacement (PIP and MCPJs) and excision arthroplasty (excision of the trapezium [trapeziectomy] for thumb carpometacarpal joint arthritis). Joint arthrodesis eliminates pain at the expense of motion, but function is often well preserved.

Other forms of arthritis in the hand

Psoriasis particularly affects the IPJs, but is asymmetrical in nature and causes fusiform swelling of the digits along with nail changes. Gout causes pain, joint swelling and redness, as well as occasionally tophi (monosodium urate crystal deposits), and can be difficult to differentiate from septic arthritis. Serum urate is not always raised in acute attacks but finding negatively birefringent sodium urate crystals on microscopy of aspirated joint fluid is diagnostic.

Dupuytren's contracture

Dupuytren's contracture is most often characterised as an autosomal dominant condition, common in northern Europe, predominantly in men in the fifth to seventh decades of life. Four out of seven cases occur in those with a family history but there are also many sporadic cases. It is associated with smoking, trauma, epilepsy, hypothyroidism, alcoholic cirrhosis and possibly human immunodeficiency virus (HIV) infection.

Figure 38.51 Hand deformities secondary to osteoarthritis.

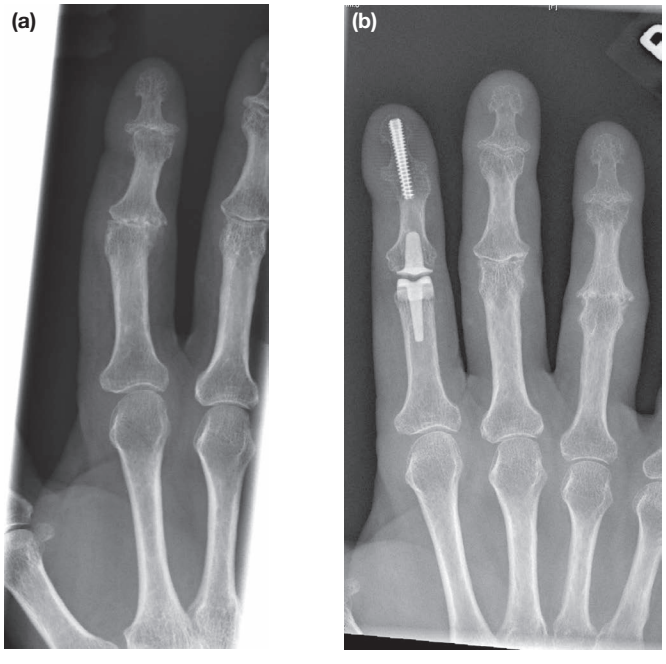

Figure 38.52 Radiographs of the distal interphalangeal (DIPJ) and proximal interphalangeal (PIPJ) joints treated with DIPJ arthrodesis and PIPJ arthroplasty/joint replacement. **(a)** Preoperative image; **(b)** after surgery.

It also appears very frequently as a clinical case in postgraduate examinations! The characteristic features are palmar nodules, skin puckering, cords of the palm and digits, and flexion

William Heberden (Senior), 1710–1801, physician, who practised first in Cambridge and from 1748 in London, UK, described these nodes in 1802.
Charles Jacques Bouchard, 1837–1915, physician, Dean of the Faculty of Medicine, Paris, France.
Baron Guillaume Dupuytren, 1777–1835, surgeon, Hôtel Dieu, Paris, France, described this condition in 1831.

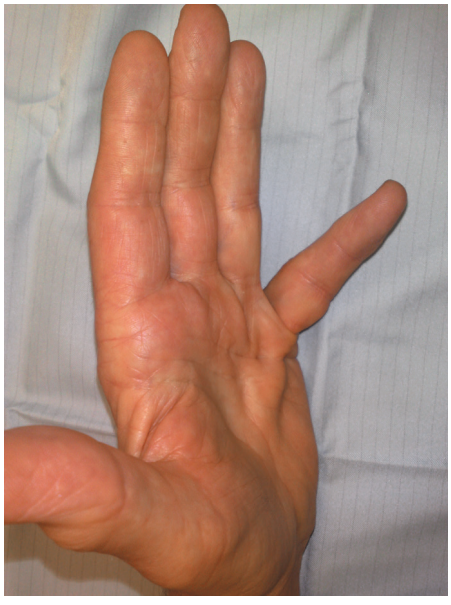

Figure 38.53 Dupuytren's contracture of the little finger metacarpophalangeal joint with a significant palmar cord.

Figure 38.54 Garrod's knuckle pads.

contractures of the digits (*Figure 38.53*). It is commonest on the ulnar side of the hand. Garrod's knuckle pads (thickened skin on the dorsum of the PIP joint) are another feature visible on examination and seen in more severe forms of the disease (*Figure 38.54*). The condition can also produce cords in the penis, causing it to become curved (Peyronie's disease) and may also produce plantar thickening on the sole of the foot (Ledderhose disease). Intervention is indicated when the patient cannot put the affected hand flat on the table owing to fixed deformity ('table-top test') or when any flexion contracture develops in the PIP joint. Milder cases may be treated by needle fasciotomy or collagenase injections, while more severe cases are managed surgically. Great care should be taken during surgery to avoid damage to the digital nerves, which may be trapped in the fibrous tissue. At the end of surgery, it may not be possible to obtain primary closure of the skin, so one should consider performing Z-plasties to lengthen the skin, full-thickness skin grafting taken from the anteromedial proximal forearm (hairless) or occasionally leaving an open wound to heal by secondary intention.

In late-stage disease a fixed contracture of the MCPJs and PIP joints may develop. In these cases excision of the fibrous bands may produce no improvement in the condition; if the contracted finger is preventing useful function of the hand, amputation may have to be considered.

Summary box 38.14

Dupuytren's contracture

- Autosomal dominant inheritance but many sporadic cases
- Fibroblastic hyperplasia with resultant skin nodules, cords and deformities
- Intervention is indicated if hand cannot be placed flat
- Severe disease is signified if hand cannot be placed flat; severe fixed flexion deformities may mean that amputation is the only surgical option

Tendon disorders

Trigger digit

Triggering occurs in the fingers or in the thumb as a result of a size mismatch between the flexor tendon and the sheath (usually at the A1 pulley) in which it glides.

The patient complains of painful locking or snapping of the finger, usually when attempting to straighten a bent finger. Occasionally, it may present as a finger that is too painful to bend, associated with pain and tenderness at the A1 pulley. There is often a palpable nodule in the tendon. Management is a steroid injection into the sheath; if this fails surgical tendon sheath (A1 pulley) release should be performed under local anaesthesia, taking care not to cut too much of the pulley and create bowstringing of the flexor tendon. Trigger digits, especially the thumb, can occur in infants and in such cases usually resolve spontaneously.

De Quervain's disease

De Quervain's disease is caused by tenosynovitis of the abductor pollicis longus (APL) and extensor pollicis brevis (EPB) in the first dorsal wrist extensor compartment (1st EC). It is predominantly seen in middle-aged females and is associated with pregnancy (new mother's wrist) and inflammatory arthritis. The clinical features are radial wrist pain, tenderness, swelling

Sir Archibald Edward Garrod, 1857–1936, Regius Professor of Medicine, University of Oxford, Oxford, UK, described this condition in 1893.
Francois de la Peyronie, 1678–1747, surgeon to King Louis XIV of France and founder of the Royal Academy of Surgery, Paris, France.
Georg Ledderhose, 1855–1925, German surgeon, described this disease in 1894.
Fritz de Quervain, 1868–1940, Professor of Surgery, Berne, Switzerland, described this form of tenosynovitis in 1895

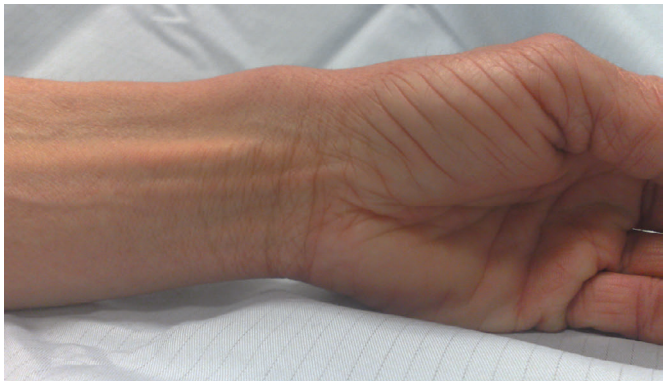

Figure 38.55 De Quervain's disease.

(*Figure 38.55*) and a positive Finkelstein's test (pain over the 1st EC associated with ulnar deviation of the wrist when the thumb is clasped in the palm). The management options are non-steroidal anti-inflammatories, splintage, steroid injections and surgical release of the extensor retinaculum of the first dorsal compartment. If surgery is considered, careful attention should be paid to fully releasing the APL and EPB, which frequently consist of bundles of separate tendon slips that lie in separate sheaths.

Compressive neuropathies

Median nerve (carpal tunnel syndrome)

The majority of cases of carpal tunnel syndrome are idiopathic. It is, however, associated with diabetes, thyroid disorders, alcoholism, amyloidosis, inflammatory arthritis, pregnancy and obesity.

Figure 38.56 Thenar muscle wasting in carpal tunnel syndrome.

History

The patient presents with tingling and infrequently numbness of the volar aspects of the radial three and a half digits. Patients also complain of being woken at night by pain and tingling, and that hanging their hand out of the bed provides relief. They may also complain of clumsiness when picking up small objects or when carrying heavy ones. Symptoms and signs are often bilateral.

Examination

Wasting of the thenar eminence is visible (*Figure 38.56*) in chronic severe cases, and there is sometimes weakness specifically of the abductor pollicis brevis. The tests for carpal tunnel compression are described in *Chapter 35* but the most reliable are: (i) Tinel's – percussion over the carpal tunnel and (ii) Phalen's test – reproduction of paraesthesia with full prolonged wrist flexion. More recently, Durkan's compression test, in which digital pressure over the carpal tunnel reproduces the symptoms, has been shown to be highly sensitive and specific. Electrophysiological studies may confirm the diagnosis, with evidence of slowing of nerve conduction through the carpal tunnel, however they can also be normal. Non-operative treatment includes night splintage of the wrist in extension and steroid injections. If surgery is required the median nerve is surgically decompressed by incising the roof of the tunnel (transverse carpal ligament), as either an open or an endoscopic percutaneous procedure.

Summary box 38.15

Carpal tunnel syndrome

- Night pain is common and relieved by shaking the hand
- Thenar wasting is an advanced sign
- Tinel's, Phalen's and Durkan's tests are useful
- Treatment includes splints and surgical decompression

Ulnar nerve (Guyon's tunnel syndrome)

Ulnar nerve compression in Guyon's canal can lead to tingling and numbness in the ring and little fingers with hypothenar wasting. There is preservation of dorsal sensation over the little and ring fingers, because, although these areas are innervated by the ulnar nerve, the dorsal sensory branches are given off prior to Guyon's canal and are thus unaffected. Compression is usually due to a ganglion, ulnar artery aneurysm or a fracture of the hook of hamate.

Harry Finkelstein, 1883–1975, American surgeon, one of the cofounders of the Hospital for Joint Diseases, New York, NY, USA.
George S Phalen, contemporary, orthopaedic surgeon and Chief of Hand Surgery, The Cleveland Clinic, Cleveland, OH, USA. He helped to establish the American Society for Surgery of the Hand.
John A Durkan, contemporary, American surgeon, specialist in orthopaedic and sports medicine.
Jean Casimir Felix Guyon, 1831–1920, Professor of Genitourinary Surgery, Paris, France.

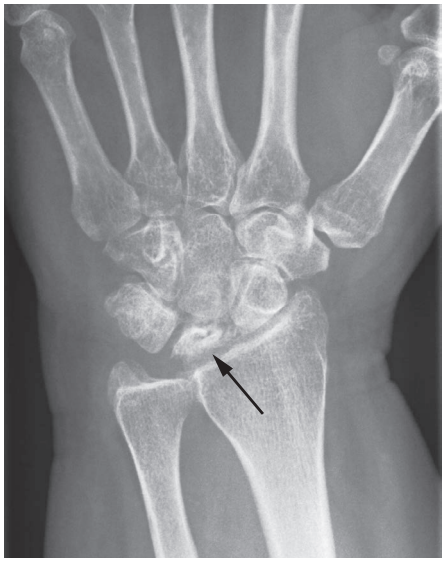

Figure 38.57 Avascular necrosis of the lunate (Kienböck's).

Avascular necrosis of carpal bones

Idiopathic avascular necrosis of the lunate (Kienböck's disease; *Figure 38.57*) or scaphoid (Preiser's disease) can occur. The clinical presentation is of wrist pain and the diagnosis can be confirmed with radiographs and MRI. The natural history of the condition is that it leads to collapse of the avascular carpal bones and subsequent arthritis of the carpus, which may be best treated with a partial or complete fusion of the wrist. This will at least give a strong and painless wrist. The limitation in movement caused by arthrodesis procedures is not as great as might be expected.

Ganglion cysts

Ganglion cysts are the commonest cause of a swelling in the hand and they are found most often on the dorsal (*Figure 38.58*) and volar (*Figure 38.59*) surfaces of the wrist, over the dorsum of the DIP joint (digital mucous cyst) or within the flexor tendon sheath at the base of the finger (seed ganglion). Dorsal and volar wrist ganglions can cause discomfort. The swellings are smooth, fluctuant and transilluminate brightly. Mucous cysts may discharge and can cause nail changes (*Figure 38.60*). Seed ganglions can be painful when gripping. Aspiration or surgical excision can be considered. Patients should be informed regarding possible recurrence.

Congenital malformations

There are many congenital malformations of the upper limb and these are discussed in *Chapter 44*. A classification summarising the main congenital defects and based on aetiology appears as *Table 38.2*.

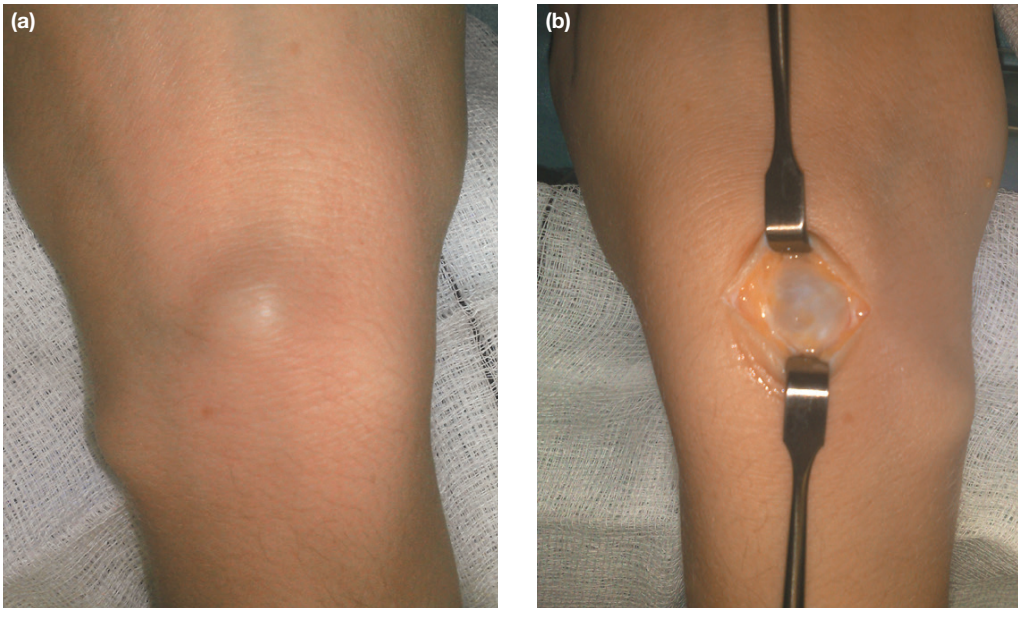

Figure 38.58 (a) Clinical and (b) surgical appearance of a dorsal wrist ganglion.

Robert Kienböck, 1871–1953, Professor of Radiology, Vienna, Austria, described this condition in 1910.

PART 5 | Elective orthopaedics

CHAPTER
39 The hip

Learning objectives

To understand:

- The anatomy and biomechanics of the hip and their clinical implications
- The clinical presentation, aetiology and management of common hip pathologies
- The principles of joint replacement including important complications
- The advances in surgical practice in this field

ANATOMY AND BIOMECHANICS

Applied anatomy

The hip is a ball-and-socket joint formed by the head of the femur and the cup-shaped acetabulum (Latin: 'little vinegar cup') (*Figure 39.1*). The joint allows a considerable range of movement in different planes and is still inherently stable because of its bony anatomy and the static and dynamic stabilisers. The static stabilisers are composed of the iliofemoral and pubofemoral ligaments anteriorly and the ischiofemoral ligament posteriorly; together with the joint capsule and the labrum (*Figure 39.1*). The muscles running across the joint (short external rotator muscles and gluteus maximus posteriorly, the iliopsoas anteriorly and the hip abductors laterally) constitute the dynamic stabilisers. The acetabular labrum is a fibrocartilaginous structure that is triangular in cross-section and attaches to the rim of the acetabulum, except at its base, where it is replaced by a ligament called the transverse acetabular ligament. The labrum helps in deepening the socket, thereby enhancing stability. It also acts as a fluid seal and thereby helps to improve joint lubrication. The femoral head derives its blood supply mainly from the retinacular branches of the medial circumflex femoral artery and has a small contribution from the artery of the ligamentum teres.

Summary box 39.1

Anatomy

- The hip joint is a ball-and-socket joint, with both static and dynamic stabilisers
- Static stabilisers include the capsule, ligaments and labrum
- Dynamic stabilisers consist of the muscles acting across the joint
- Blood supply to the femoral head is mainly derived from the medial circumflex femoral artery

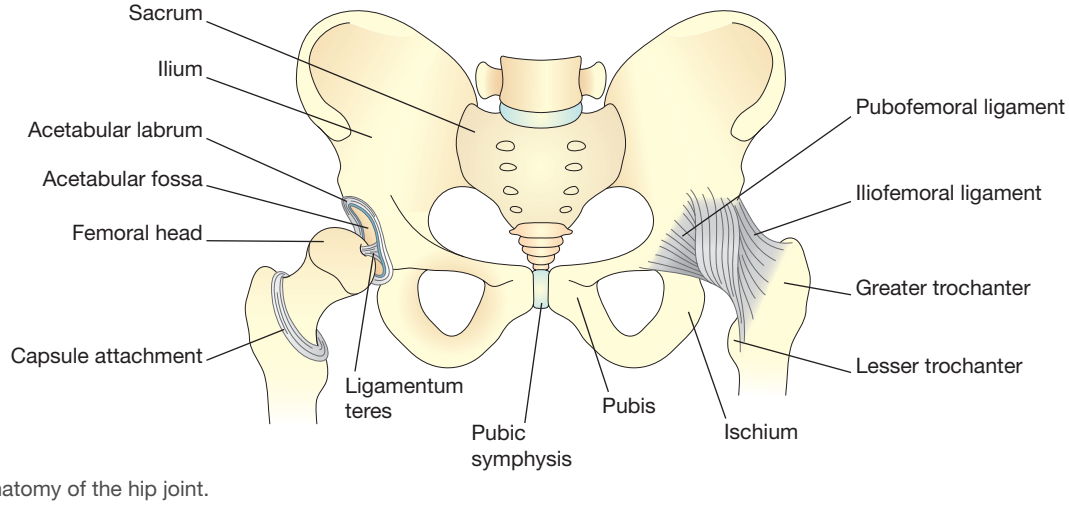

Figure 39.1 Anatomy of the hip joint.

Biomechanics of the hip joint

Kinetic analysis reveals that forces as high as three times body weight can be exerted across the hip joint during activities of daily living, and eight times body weight during physically demanding activities. This is primarily the result of contraction of muscles crossing the hip joint. The abductors, because of their insertion at the greater trochanter, help in supporting the pelvis when the patient stands on the ipsilateral leg and thereby form the basis of the Trendelenburg test (***Figure 39.2***).

Summary box 39.2

Forces going through the hip joint

- Lifting leg from bed – one and a half times body weight
- Standing on one leg – three times body weight
- Running and jumping - ten times body weight

CONDITIONS AFFECTING THE HIP

Common hip pathologies in the paediatric age group and secondary to trauma are covered in ***Chapters 29, 32 and 44***. This chapter focuses on the acquired pathological conditions in the adult.

Avascular necrosis

Avascular necrosis (AVN), or osteonecrosis of the femoral head, occurs because of an interruption in the blood supply to the femoral head, leading to bone death. This results in collapse of the femoral head initially, and eventually secondary osteoarthritis (OA). AVN can be primary (idiopathic) or secondary to other pathology (***Table 39.1***).

TABLE 39.1 Aetiology of avascular necrosis of the femoral head.

- Steroids
- Alcohol excess
- Idiopathic (see Perthes' disease; see ***Chapter 44***)
- Sickle cell disease
- Haemoglobinopathies
- Caisson disease ('the bends' in divers)
- Hyperlipidaemia
- Systemic lupus erythematosus
- Gaucher's disease
- Chronic liver disease
- Antiphospholipid antibody syndrome
- Radiotherapy
- Chemotherapy
- Human immunodeficiency virus
- Hypercoagulable states (protein C and protein S deficiency)

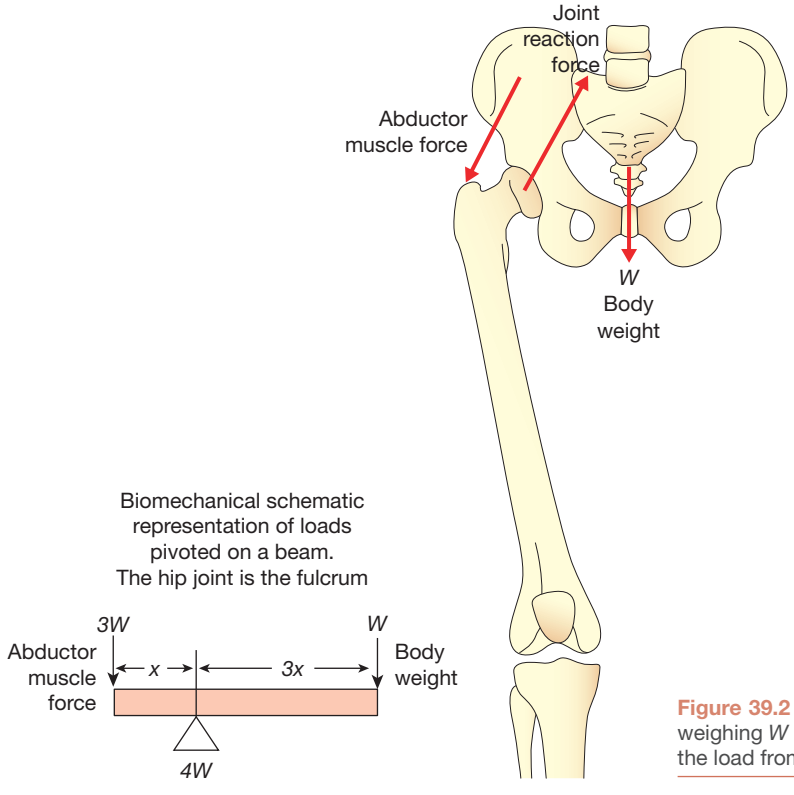

Figure 39.2 Load on the hip joint when a subject weighing *W* stands on one leg. Hopping increases the load from 4*W* to 10*W*.

Friedrich Trendelenburg, 1844–1924, Professor of Surgery successively at Rostock (1875–1882), Bonn (1882–1895) and Leipzig (1895–1911), Germany. The Trendelenburg position was first described in 1885.
A **caisson** is a watertight chamber used to protect construction workers during the building of underwater structures by means of pressurised air introduction.
Philippe Charles Ernest Gaucher, 1854–1918, physician, Hôpital St Louis, Paris, France, described familial splenic anaemia in 1882.
Georg Clemens Perthes, 1869–1927, Professor of Surgery, Tübingen, Germany, described osteochondritis of the femoral capital epiphysis in 1910.

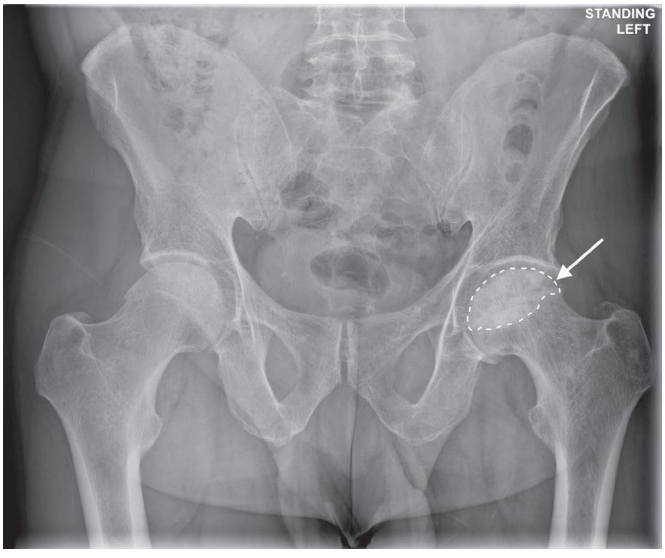

Figure 39.3 Radiological appearance of avascular necrosis of the femoral head of the left hip. There is evidence of femoral head sclerosis (dashed line and arrow) as a consequence of avascular necrosis.

Clinical features

AVN usually affects men aged 35–45 and is bilateral in over 50% of patients. The patient is frequently asymptomatic in the early stages. As the disease progresses the patient may complain of an ache in the groin and walk with a limp. Clinical examination in the early stages is usually normal but may reveal a positive Thomas's test and limitation in the range of movement as the disease progresses.

Investigations

A weight-bearing anteroposterior (AP) radiograph of the pelvis along with a lateral radiograph will show the classical features of AVN, including increased sclerosis in the early stages and the crescent sign indicating subchondral bone resorption. In the late stages there may be femoral head irregularity indicating the onset of arthritis (***Figure 39.3***), and flattening, indicating a segmental head collapse. However, radiographs may be normal in the early stages of the disease and, therefore, the most sensitive and specific way of investigating these patients is with magnetic resonance imaging (MRI). MRI allows accurate assessment of the extent of involvement of the femoral head and can also identify associated bone marrow changes. This helps in early diagnosis and the prediction of prognosis (***Figure 39.4***). In 1985, Ficat classified the disease into five stages. In 1995, Steinberg modified this classification into seven stages (0–VI) based upon both radiograph and MRI appearance (***Table 39.2***). Stages I–IV are further divided according to the extent of femoral head involvement (A; mild, B; moderate and C; severe).

Management

Conservative treatment in well-established cases usually leads to poorer outcomes and is therefore not recommended. The choice of surgical treatment depends upon whether the femoral head has collapsed or not. In the pre-collapse stage the principle is to preserve and preferably encourage revascularisation of the femoral head, whereas in the collapse stage the aim is to bring the undamaged parts of the femoral head into the load-bearing zone of the hip joint.

The surgical treatment for the pre-collapse stage includes core decompression, which is aimed at relieving the intravascular congestion in the femoral head and thereby pain. This can be achieved with or without bone grafting or combined with bone-marrow-derived cell therapies; a vascularised bone graft can also be used to stimulate bone formation and support the femoral head. Once the femoral head has collapsed, either a femoral osteotomy (which aims to transfer the weight-bearing area of the femoral head and thereby protect the collapsed segment) or a joint replacement (if degenerative changes have set in) is the preferred option (see ***Primary total hip replacement***).

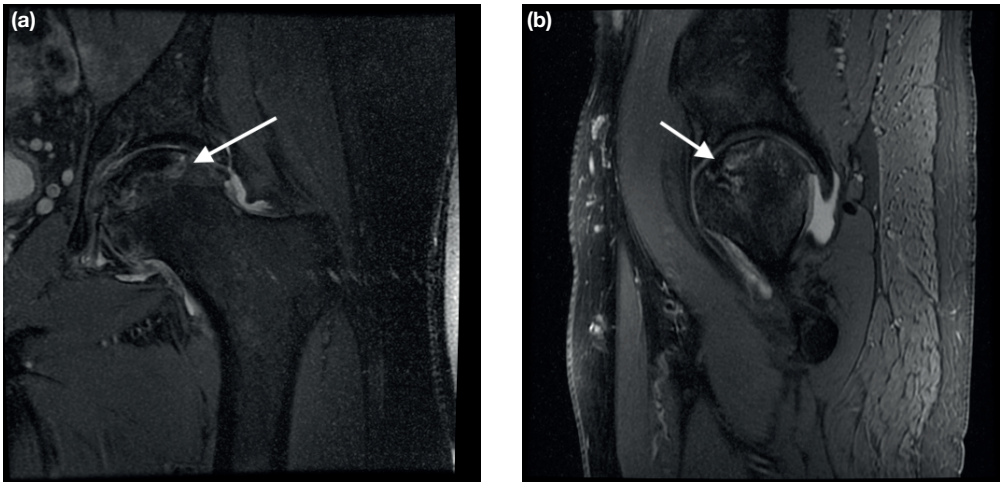

Figure 39.4 Magnetic resonance imaging scan of the hip joint showing avascular necrosis (arrows). (a) Coronal view; (b) sagittal view.

Hugh Owen Thomas, 1834–1891, general practitioner, Liverpool, UK. He is regarded as the founder of orthopaedic surgery although never holding a hospital appointment, preferring to treat patients in their own homes. He introduced the Thomas splint in 1875.

TABLE 39.2 Steinberg's classification of avascular necrosis of the femoral head based on the type of radiological change on radiographs and magnetic resonance imaging (MRI).

Stage	Description
0	Normal or non-diagnostic radiograph, bone scan or MRI
I	Normal radiograph, abnormal MRI or bone scan
II	Sclerosis and cysts
III	Subchondral collapse, crescent sign
IV	Flattening of the head, normal acetabulum
V	Acetabular involvement
VI	Obliteration of joint space

Summary box 39.3

AVN of the femoral head

- Patients can be asymptomatic in the early stages and therefore a high index of suspicion is necessary for initial diagnosis
- MRI scan is required for early diagnosis
- Treatment is based on whether the patient presents before or after the femoral head has collapsed
- In the pre-collapse stage treatment focuses on revascularisation of the femoral head
- In the collapsed stage, the aim is to reorient the damaged area of the femoral head or replace the joint if degenerative changes have set in
- Prognosis is dependent upon the extent of femoral head involvement

Femoroacetabular impingement

Femoroacetabular impingement (FAI) has recently been recognised as a cause of hip pain in the young adult and may lead to secondary hip OA. Two distinct types of FAI have been described – cam and pincer – although many patients have a mixed picture with both morphologies occurring simultaneously. Cam FAI is secondary to abnormal morphology of the femoral head and neck junction whereas pincer FAI is a result of anterior overcoverage or retroversion of the acetabulum. The cam deformity is typically described as an abnormal bony bump at the femoral head–neck junction (***Figure 39.5a***), measured as an alpha angle of >55° (***Figure 39.5b,d***). The alpha angle is ideally measured on the Dunn view, which is a 45° lateral view of the hip. This view is useful to identify subtle cam deformities that are not clearly visible on the AP radiograph (***Figure 39.5c,d***, arrow pointing to the cam deformity). The alpha angle can be measured on the AP radiograph if severe but the extent is accurately assessed on the Dunn view. The alpha angle is the angle made by a line along the centre of the femoral neck to the centre of the femoral head and another from the centre of the femoral head to the point on the femoral head outside the imaginary circle, as shown in ***Figure 39.5b,d***.

On the other hand, pincer deformity is defined by a lateral centre–edge angle (LCEA) measured on the AP radiograph (***Figure 39.5b***) of over 40° (normal 25–40°). The LCEA is the angle formed between an imaginary vertical line from the centre of the femoral head and another from the centre of the femoral head to the lateral edge of the acetabulum.

The impingement, which occurs during deep hip flexion or earlier with internal rotation as a result of the abnormal morphology, results in damage to the labrochondral junction. Patients typically present with groin pain and limitation of activities related to deep bending and rotation. Plain radiographs are useful in evaluating the bony deformity. Further evaluation with MRI typically reveals acetabular labral and chondral lesions and abnormal femoral head morphology in the case of cam deformity. Computed tomography (CT) scan, especially three-dimensional (3D) CT, is helpful in accurately assessing the proximal femoral morphology, acetabular coverage and posterior joint space and allows for planning management. Treatment options for FAI depend on the patient's symptoms and vary from non-operative treatment to hip preservation procedures that aim to address labral, chondral and bony pathology; this can be achieved with arthroscopy, safe surgical hip dislocation or osteotomy of the femur and/or acetabulum.

Hip dysplasia in young adults

Hip dysplasia is a condition in which there is under-coverage of the femoral head, secondary to a shallow acetabulum. Hip dysplasia is defined as an LCEA of <20° and/or an acetabular index of >10° (***Figure 39.6***). The acetabular index (also called the Tönnis angle) is the angle formed by an imaginary line through the superior weight-bearing portion of the acetabulum and an imaginary horizontal line (***Figure 39.6***).

Thorough screening and timely management of developmental dysplasia of the hip (DDH) as a child is aimed at preventing problems during early adulthood. In mild cases of DDH symptoms are not present until the person is a teenager or an adult. Abnormal biomechanics in hip dysplasia leads to progressive chondral damage and labral tears. Treatment options depend on the severity of dysplasia and the extent of damage in the hip joint, with options being hip arthroscopy, periacetabular osteotomy or total hip replacement (THR) in cases where there is evidence of arthritis.

Extra-articular hip pathology

Hip pain can also occur as a result of impingement of extra-articular structures resulting in restriction of activities. ***Table 39.3*** shows the common causes of extra-articular hip impingement. Snapping hip syndromes (shown in ***Table 39.3***) can also present with hip pain. Imaging modalities such as ultrasound and MRI may aid the diagnosis. Treatment begins with non-operative measures such as physiotherapy with surgical procedures aimed at treating the primary pathology in refractory cases. See ***Further reading*** for additional information.

Denis M Dunn, 1916–2001, consultant orthopaedic surgeon at the Colchester and District Hospital Group and honorary assistant surgeon at The London Hospital, London, UK.
Dietrich Tönnis, 1927–2010, German paediatric orthopaedic surgeon. He had an interest in the hip joint, especially dysplastic hips.

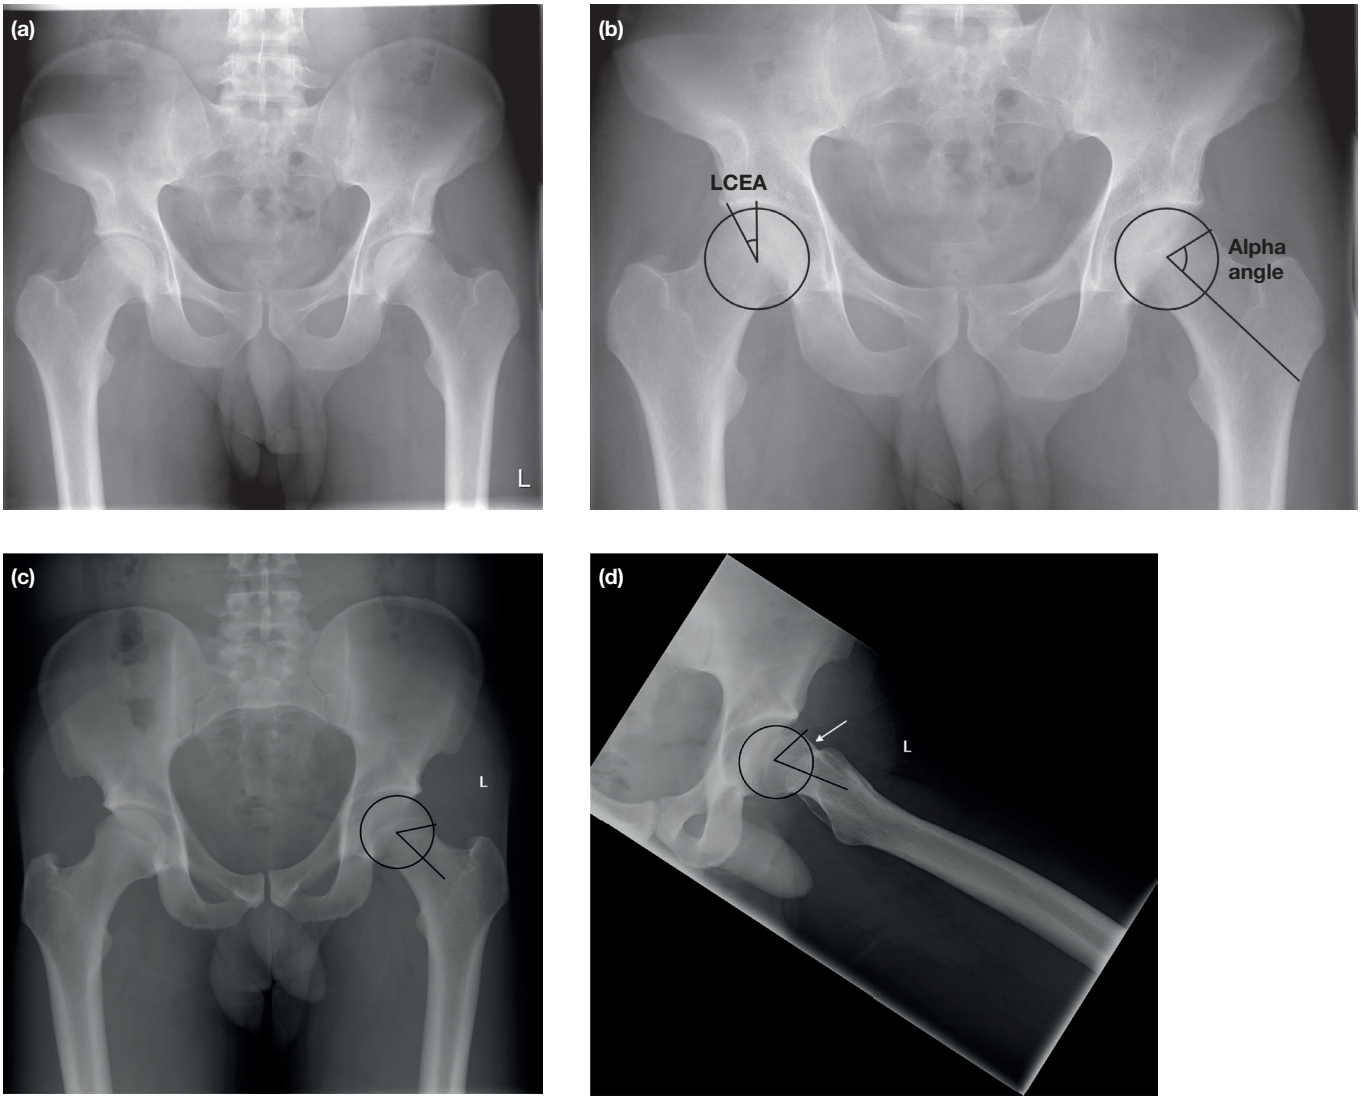

Figure 39.5 Radiograph showing cam femoroacetabular impingement (a), marked over the femoral head (b) with the arrow pointing to the cam deformity. (c) Anteroposterior radiograph and (d) a subtle cam lesion picked up on the lateral view. The alpha angle measurement is used to assess the severity of cam deformity (normal ≤55°). The lateral centre–edge angle (LCEA) is a measure of acetabular coverage (normal = 25–40°).

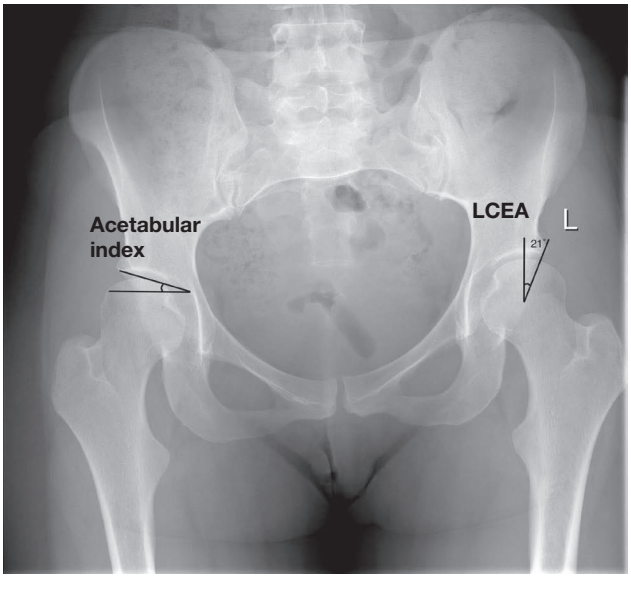

Figure 39.6 Plain radiograph showing bilateral hip dysplasia: uncovering of the femoral head as measured by a centre–edge angle (CEA) of less than 20°. Normal CEA is 25–40°. A CEA of 20–25° is categorised as borderline dysplasia of the hip. An acetabular index of >10° is suggestive of hip dysplasia.

TABLE 39.3 Extra-articular hip impingement and externally snapping hip syndromes.

Pathology	Description
Extra-articular hip impingement	
Iliopsoas impingement	Impingement between the iliopsoas muscle and the labrum, resulting in distinct anterior labral pathology
Subspine impingement	Impingement between an enlarged or malorientated anterior inferior iliac spine and the distal anterior femoral neck
Ischiofemoral impingement	Compression of the quadratus femoris muscle between the lesser trochanter and the ischial tuberosity
Deep gluteal syndrome	Entrapment of the sciatic nerve in the deep gluteal space resulting in pain in the buttock
Snapping hip syndromes	
Internal snapping hip syndrome	Iliopsoas tendon glides over the hip joint, producing a snapping sensation and eventually leading to labral tear
External snapping hip syndrome	Iliotibial band glides over the greater trochanter and snaps, producing an audible and/or visible snap

HIP PRESERVATION PROCEDURES

For the conditions above, in which degenerative change is not predominant, a variety of surgical procedures are now described with the aim of preserving the hip joint.

Diagnostic hip injection

Identification of the source of symptoms is essential to ensure appropriate management. Since the hip joint is deeply seated, several extra-articular pathologies can present with hip and groin pain and the diagnostic hip injection can help elucidate whether the pain is extra- or intra-articular in origin. This is performed as a day case procedure under image intensifier (portable x-ray machine) guidance under appropriate anaesthesia. Using aseptic precautions, a long spinal needle is inserted into the hip joint. The position of the needle is confirmed by injecting either a small amount of radio-opaque contrast dye or air to provide a contrast arthrogram. Once the intra-articular position is confirmed, a mixture of local anaesthetic and steroid is injected into the hip joint.

The procedure can also be therapeutic and is an essential tool that can help in prognosis as well prior to proceeding with hip preservation procedures (arthroscopy or osteotomy), especially in cases of uncertainty relating to the source of the pain and therefore the diagnosis.

Arthroscopy of the hip

The hip joint presents challenges to arthroscopy in terms of access and instrumentation of the deeply recessed femoral head in the acetabulum and the surrounding thick fibrocapsular and muscular envelope. Technical advances, including an improved ability to manage the capsule and gain exposure, have led to an expanding list of applications, including the treatment of symptomatic labral tears, FAI and the removal of loose bodies, e.g. synovial chondromatosis. Arthroscopy allows a clear view of the femoral and acetabular articular surfaces, the labrum, the ligamentum teres and the head–neck junction, along with the surrounding synovium and its folds, and the peritrochanteric space. Advantages include minimally invasive access to all these structures coupled with rapid recovery, in comparison with open surgery. However, there is a steep learning curve with hip arthroscopic procedures and adequate training of this procedure with a mentored independent practice in the early part of a surgeon's career is an essential part of achieving a successful outcome.

Osteotomies around the hip

The goal of an osteotomy around the hip is to redistribute forces evenly across the joint, thereby eliminating excessive point loading. This can be achieved by performing an osteotomy on the femoral or the acetabular side, depending upon the desired goal, e.g. an excessive valgus neck–shaft angle and an uncovered femoral head on the lateral aspect can be corrected by carrying out a varus femoral osteotomy. Similarly, a redirection osteotomy on the acetabular side can also be performed to improve coverage of the femoral head in cases of hip dysplasia. The common indications for an osteotomy around the hip in the adult age group are shown in ***Table 39.4***. Ideally, an osteotomy should be considered in a young patient who maintains a good range of movement of the hip and whose imaging studies (radiographs and/or CT scan or MRI scan) show a joint devoid of significant degenerative change.

TABLE 39.4 Indications for osteotomy around the hip in the adult age group.

Femoral osteotomy	Periacetabular osteotomy (PAO)
Perthes' disease Osteoarthritis in a young patient Slipped capital femoral epiphysis Avascular necrosis	Developmental dysplasia of the hip Acetabular retroversion (reverse PAO)

Thorough preoperative planning is essential to assess whether the desired position can be achieved. Increasingly 3D CT scans are used for preoperative planning. In addition, 3D printing has been used to understand the problem and plan surgical correction. Computer navigation and robotics are novel adjuncts that are aimed at obtaining an accurate correction of the concerned deformity.

DEGENERATIVE AND INFLAMMATORY DISORDERS OF THE HIP

Osteoarthritis

OA is referred to as primary when no predisposing cause can be found, and secondary when it develops after an insult to the hip joint. A multitude of factors, including genetic,

biochemical and mechanical influences, have been implicated in the development of primary OA. The exact mechanism for the development of primary OA remains unknown and it is therefore termed idiopathic. However, FAI has been proposed as an aetiological factor responsible for the development of OA by a Swiss group in 1999 (see *Further reading*). Secondary OA develops following trauma, AVN, dysplasia, slipped capital femoral epiphysis, inflammatory arthropathy or other known predisposing causes. The causes of OA of the hip are provided in *Table 39.5*.

TABLE 39.5 Aetiology of osteoarthritis.

Primary	• Cause unknown, termed idiopathic • Associations: for example, genetics, obesity
Secondary	• Trauma • Avascular necrosis • Inflammatory arthropathy (e.g. rheumatoid arthritis) • Perthes' disease • Developmental dysplasia of the hip • Slipped capital femoral epiphysis • Septic arthritis • Femoroacetabular impingement implicated as a possible cause

Clinical features

OA of the hip affects 10–25% of those aged 65 years or older. The most consistent symptoms are groin pain and limitation of movement. The pain may also radiate down to the knee joint; in some cases the only presenting feature may be a painful knee. In the early stages of the disease, pain is activity related but as the disease progresses the patient also complains of pain at rest. The patient frequently complains of night pain and may also find it difficult to get into a comfortable position while sleeping. Functionally, any activity that involves flexion and rotation is difficult to perform, e.g. putting on shoes and socks and getting into and out of a bath or a car. As the pain increases the hip joint gradually loses its movement because of muscle spasm, capsular contracture and osteophyte formation, leading to further limitation of activities.

Clinical examination may reveal gluteal muscle wasting. There may also be a limp, with a positive Trendelenburg's test. Leg length discrepancy, usually shortening, and limitation of movement, particularly internal rotation, are consistent features. Many patients present with a fixed flexion deformity that is best elicited by a modified Thomas's test (see *Chapter 35*).

Investigations

The characteristic features on a plain radiograph are (i) a reduction of the joint space, (ii) sclerosis in the subchondral bone, (iii) subchondral cysts, and (iv) osteophyte formation (*Figure 39.7*). Eventually, a collapsed femoral head may also be evident.

Management

There is no specific pharmacological therapy for OA; however, non-operative treatment with non-steroidal anti-inflammatories, regular exercise, physiotherapy and modification of lifestyle with loss of weight does help. Patients should also be encouraged to use walking aids (usually a walking stick in the opposite hand) to offload the affected hip joint and to reduce the workload of the ipsilateral abductors.

The indications for surgery are relentless pain (usually night pain), limitation of lifestyle and activities of daily living and failure of non-operative treatment. The surgical options include an arthrodesis (fusion), an osteotomy (realignment)

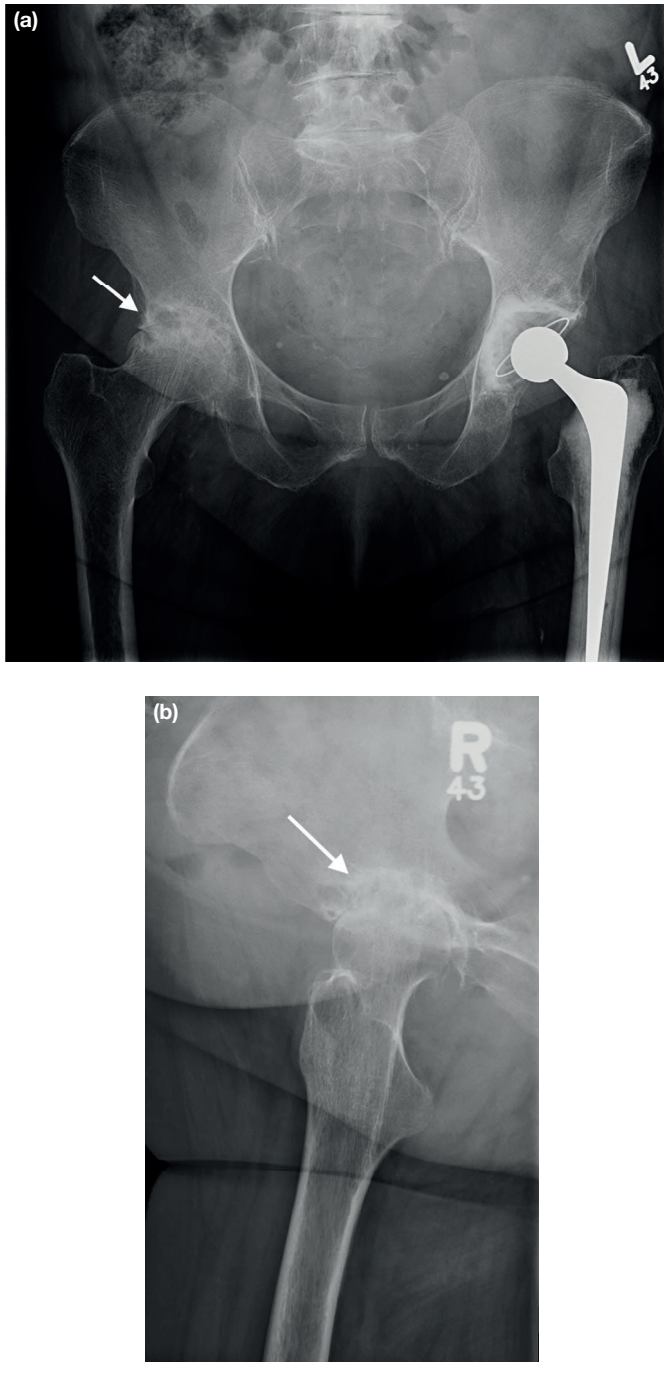

Figure 39.7 **(a)** Anteroposterior radiograph of the hip joint showing severe osteoarthritis of the right hip (arrow) and a cemented total hip replacement on the left; **(b)** lateral view of the right hip.

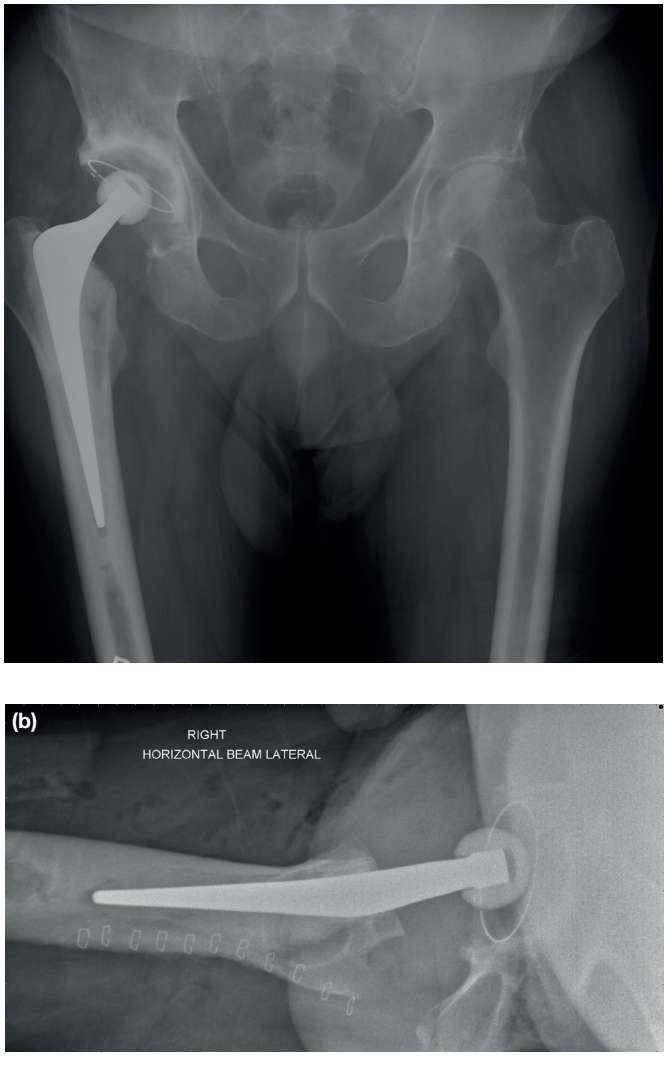

Figure 39.8 Radiographs showing a cemented total hip replacement *in situ*. **(a)** Anteroposterior view and **(b)** lateral view.

or a joint replacement (***Figures 39.7a, 39.8 and 39.9***). The indications are based on limitation of lifestyle and individual needs, thereby making it a truly life-improving and life-changing operation.

Summary box 39.4

OA of the hip

- OA is a degenerative condition leading to progressive damage of the articular cartilage and other joint structures
- The most consistent clinical features are groin pain and limitation of movement
- Characteristic radiological features are reduced joint space, subchondral sclerosis, subchondral cysts and osteophyte formation
- Non-operative treatment includes walking aids, non-steroidal analgesics, physiotherapy and weight loss
- Surgical options include osteotomy, arthrodesis or a joint replacement

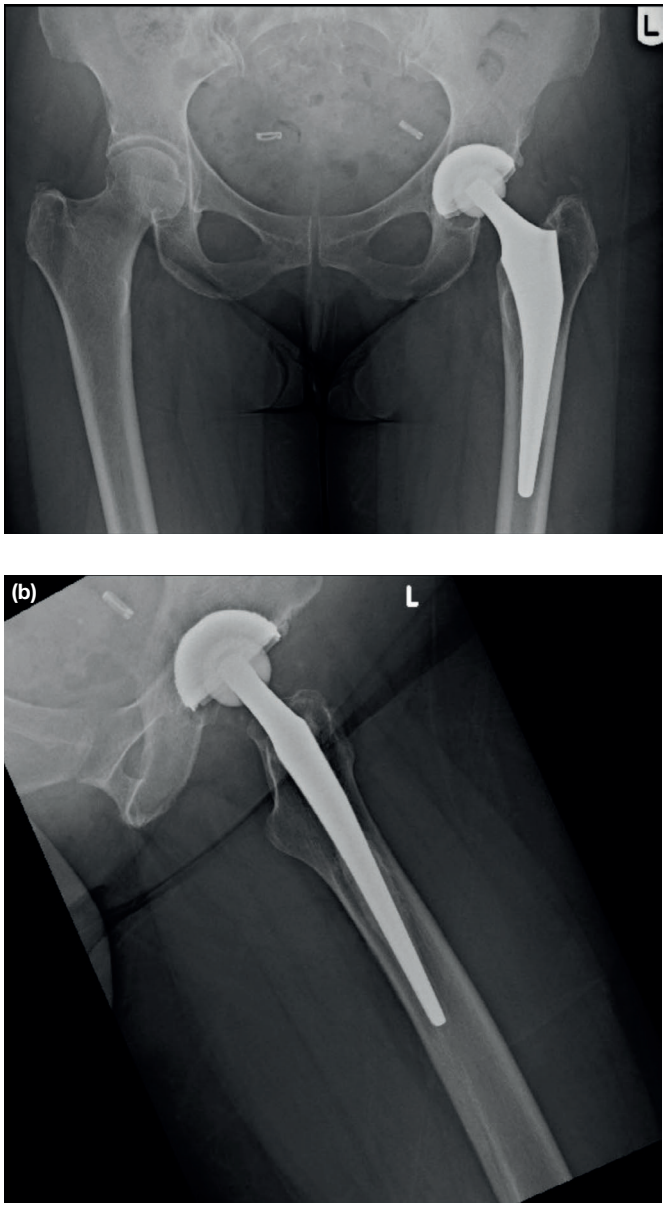

Figure 39.9 Radiographs of an uncemented total hip replacement. **(a)** Anteroposterior view and **(b)** lateral view.

Inflammatory arthritis

The hip joint can also be affected by inflammatory arthritides; however, these are not as common as OA. This group includes rheumatoid arthritis, ankylosing spondylitis, gout and chondrocalcinosis, juvenile rheumatoid arthritis and systemic lupus erythematosus.

SURGICAL PROCEDURES FOR DEGENERATIVE HIP CONDITIONS

Arthrodesis of the hip

Arthrodesis or fusion of the hip is an uncommon operation. It is generally reserved for young patients with severe OA who have

heavy manual jobs and in whom joint replacements are likely to fail early. The aim is to achieve a painless joint by fusing it in a functional position, which is about 30° of flexion, 15° of external rotation and 5° of abduction. This can be achieved by an intra-articular dynamic hip screw or by an extra-articular plate with screws.

Several problems can occur following an arthrodesis, including altered gait and excessive loading of the ipsilateral knee, the contralateral hip and the spine. Degenerative change in these joints in the long term is the rule rather than the exception.

Primary total hip replacement

Over 95 000 primary THRs are performed annually in the UK (National Joint Registry, UK). The success rate for THR is very high and the evidence supports the results being more than encouraging. In the modern era, with evidence-based technique and selection of prosthesis, over 95% of patients will have a well-functioning THR at 10 years after surgery. In the best series, 85% will still be functioning at 20 years, although some are still in place because the patient may have increasing comorbidities, preventing revision of the THR. Following surgery, pain is reduced and there is improvement in mobility and sleep, as well as social and sexual function. Nevertheless, with the ever-increasing number of patients with joint replacements, the number of patients whose replacement has failed and come to the point of revision, or even re-revision, is rising.

Principles and design of hip replacements

Joint replacement should be biocompatible and made of inert materials. It should be well fixed to the host tissue and the design should incorporate features that allow a good range of movement and stability. The bearing surfaces should produce low friction and minimise the amount of wear particles produced which in turn prevents early loosening. The material released from the bearing surface should be non-toxic. The procedure should remove the minimum amount of the patient's bone so that revision is possible, and it should create a biomechanically stable joint. Finally, any implanted joint should ideally outlive the patient and be cost-effective.

Materials for the femoral component

Implants available currently are made of cobalt chrome alloy, stainless steel or titanium. Metal implants are able to withstand high loads, are relatively inert and can be manufactured easily. However, they do pose problems in terms of ion release if they are used as bearing surfaces. Also, corrosion can be a cause for concern if two dissimilar metals are used.

Bearing surfaces

The design described by Charnley in 1961 revolutionised THR and became a gold standard by using a bearing surface of metal on high-density polyethylene. This is described as a hard-on-soft bearing surface and has a low coefficient of friction, which in turn produces lower wear of the polyethylene component, resulting in longer survival of the prosthesis. Hence the phrase low-friction arthroplasty was given to this implant. High-density polyethylene has good shock-absorbing properties but does wear slowly over the years, producing small particles that can stimulate an inflammatory response in the joint, which then leads to osteolysis and aseptic loosening of the implants. The activated macrophages resorb bone and may also stimulate osteoclasts to do the same. There has therefore been a move towards using bearing surfaces with a lower wear rate, such as ceramic on ceramic. With metal-on-metal bearing surfaces, although the wear rate is lower, the wear particles are smaller (nano rather than micro) and can lead to an adverse reaction, particularly in the soft tissues, resulting in failure. There is increasing evidence that these implants are less forgiving than conventional metal-on-polyethylene THRs, appearing to require more precise implant positioning. Ceramic femoral head bearings on polyethylene cups are low friction, but ceramic femoral heads on ceramic acetabular cups have the lowest friction of all. However, ceramic-on-ceramic bearings are expensive to manufacture, and are another example of hard-on-hard bearings and produce small-sized wear particles. A summary of the advantages and disadvantages of each bearing surface is provided in ***Table 39.6***.

Summary box 39.5

Features of an ideal joint replacement

- Biocompatible
- Well fixed to the host tissue, stable and allowing a good range of movement
- Bearing surfaces should be designed to minimise friction and have improved wear characteristics
- Material released from the bearings should be non-toxic
- Remove the minimum amount of bone
- Produce mechanical stability
- Should ideally outlive the patient

Fixation of implants

Artificial joints must be securely fixed to the bone on each side of the joint so that the implant does not work loose. This can be achieved with the help of cement or biological interdigitation between the prosthesis and bone (***Table 39.7***).

Traditionally, hip replacements were fixed into a bed of polymethylmethacrylate (PMMA) cement (***Figure 39.8***). The cement acts as a grout (spacer) and not as a glue between the implant and the bone. In the majority of cases, it gives an excellent outcome as shown by data in several national joint registries. However, it can cause potential problems: cement pressurisation can result in release of cement and marrow contents into the patient's blood stream. This can cause a drop in blood pressure. Improvements in cementing techniques allow for no gaps in the cement mantle between the femoral component and the bone. In spite of all the measures taken, occasionally there may be small areas in the cement mantle without cement.

Sir John Charnley, 1911–1982, Professor, Wrightington Hospital, UK, pioneer in hip replacement design, particularly the concept of low-friction arthroplasty.

TABLE 39.6 Bearing surfaces for hip replacements.

Type of bearing	Advantages	Disadvantages	Current use
Metal on polyethylene	Proven efficacy; easy to manufacture; cheap	Comparatively high friction; high wear rates; wear particles excite an inflammatory response that leads to osteolysis	Favourable in older age group >70 years
Ceramic on polyethylene	Lower wear rate	Expensive; ceramic fracture can be a problem	Preferrable in younger patients <70 years. Newer polyethylene – UHMWPE – has low wear rate
Metal on metal	Lower wear rate	Problem with metal ion release leading to adverse reaction to metal debris and severe osteolysis. Published examples of failure requiring early revision; implant recalls; expensive	Only a select group of patients – young male. Use head size larger than 48 mm
Ceramic on ceramic	Newer delta ceramics have the lowest wear rate	Very expensive; ceramic can fracture; squeaking	High-functioning young patients

UHMWPE, ultra-high-molecular-weight polyethylene.

TABLE 39.7 Fixation of implants.

Method of fixation	Component	Advantages	Disadvantages
Cemented	Femur	Implant does not need to fit cavity exactly; well-proven results	Cement polymerisation is exothermic with possibility of thermal injury; fragments may cause third-body wear and stimulate aseptic loosening; difficult to remove at revision
	Acetabulum	Cheap, can be used in osteoporotic bone	Higher shear forces leading to failure
Uncemented	Femur	No cement required; fixation more secure; dynamic and biological fixation	Risk of fracture; fit must be perfect; osseous integration may not be established; expensive
	Acetabulum	Good fixation into acetabulum; can be augmented with screws to secure fixation	Improper technique can lead to acetabular fracture

On the other hand, this problem can be obviated by using an uncemented prosthesis in which biological fixation can be achieved by providing a rough surface on the prosthesis for bone to grow into the porous surface of the prosthesis or by coating the surface of the prosthesis with hydroxyapatite, an osteoconductive agent, to encourage bone to bond to the prosthesis (*Figure 39.9*). These uncemented devices have also shown good long-term outcomes, although they can be associated with higher implant costs, increased risk of intraoperative fracture and difficulty in removing them if revision surgery is required in the future.

Surgical approaches to the hip, postoperative course and complications

The operation can be performed via a posterior approach, a trochanteric osteotomy, an anterolateral or Hardinge approach or an anterior approach (*Table 39.8*). Each approach has its own advantages and disadvantages. Minimally invasive surgery has been described that shortens the size of the incision and attempts to lessen soft-tissue damage. As access can be restricted, specialised instruments have been developed to facilitate this. Although the concept is attractive, no long-term benefits have been conclusively shown in minimally invasive hip surgery over the conventional technique. Eventually, whichever approach is used, it is essential to be able to implant a prosthesis so as to reproduce the patient's anatomy such that the implant has the correct offset, is at the correct centre of rotation with the correct component orientation, restores leg length and carries minimal risk of complications.

The postoperative course generally involves a 2- to 3-day stay in hospital but day case hip replacements are being performed in a select group of patients in some centres. The physiotherapist encourages the patient to mobilise safely and independently, avoiding any movements that might lead to a dislocation (*Figure 39.10*). Postoperative plain radiographs are essential to ensure that implants are in correct alignment and orientation, and rule out any iatrogenic fracture. Prior to discharge, the occupational therapist assesses the patient's home circumstances and arranges for any modifications that may be

Kevin Hardinge, b. 1939, orthopaedic surgeon, Wrightington Hospital, UK, described the direct lateral approach to the hip in 1982.

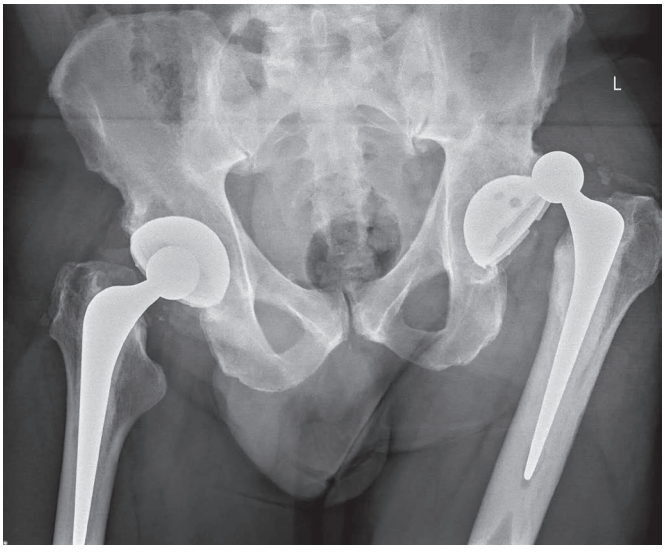

Figure 39.10 Anteroposterior radiograph showing dislocation of a left hybrid total hip replacement (cemented femoral stem and uncemented acetabular component).

required to assist the patient, e.g. a raised toilet seat. For the first 6 weeks patients are advised to avoid movements that make the THR prone to dislocation. Outpatient follow-up visits are arranged at 6 weeks and at 1 year post surgery. Although THR is generally a successful and safe procedure, it does have associated complications. A comprehensive list of complications is provided in ***Table 39.9***. Perioperative administration of antibiotics is a very important part in prevention of infection in addition to adequate aseptic precautions in the operating theatre. Venous thromboembolism is a risk following THR and deep vein thrombosis (DVT) is relatively common if no precautions are taken to reduce this risk. DVT can lead to pulmonary embolism (PE), which can be fatal. Hence steps need to be taken to minimise the risk for both DVT and PE, including adequate hydration, the use of regional anaesthesia and early postoperative mobilisation. In addition, both mechanical device (thromboembolic deterrent [TED] stockings, foot pumps or intermittent pneumatic calf compression devices) and chemical thromboprophylaxis (low-molecular-weight heparin, warfarin or oral anticoagulants) are commonly prescribed for a period of 4–6 weeks after surgery to reduce the risk of DVT (this depends on local and national guidelines).

TABLE 39.8 Surgical approaches to the hip.

Surgical approach	Anatomical interval and muscle
Posterior	Along the fibres of the gluteus maximus, and dividing the short external rotators
Trochanteric	A trochanteric osteotomy is required
Anterolateral/ Hardinge	Parts of the gluteus medius and minimus are reflected off the greater trochanter
Anterior	The interval is developed between the sartorius and tensor fascia lata superficially and rectus femoris and gluteus medius deeply

TABLE 39.9 Complications of total hip replacement.

Intraoperative complications	• Nerve injury – sciatic, femoral and obturator nerves • Vascular injury – femoral vein and artery • Femoral or acetabular fracture • Fragments of cement left in joint
Postoperative complications	• Infection • Deep vein thrombosis and pulmonary embolism • Leg length inequality • Dislocation • Heterotopic ossification • Septic/aseptic loosening • Implant breakage/failure

Revision total hip replacement

Revision of a THR is required if the patient is symptomatic secondary to failure of the implant by loosening (***Figure 39.11***), recurrent dislocations or a periprosthetic fracture. Rarely the femoral prosthesis itself can fracture, leading to pain and disability requiring revision surgery. Loosening of the implant can occur as a result of an infection or aseptic loosening. Aseptic osteolysis is caused by an inflammatory response secondary to particle wear, which can be from either polyethylene or metal.

In the initial stages of loosening the patient complains of pain, which is experienced mainly on weight-bearing. Thorough assessment to rule out infection is essential to plan further treatment. A history of infection (can also be reported as problems with wound healing) in the immediate postoperative period may suggest infection as a cause of premature implant loosening. The infection can be low grade, with *Staphylococcus*

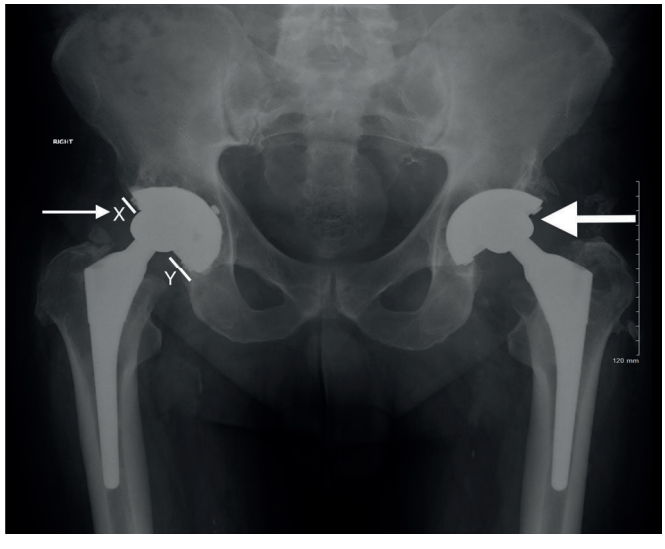

Figure 39.11 Significant acetabular wear, eccentric position of the femoral head (arrow indicating left side wear) and osteolysis behind the acetabular component. Right hip wear is also seen (thin arrow). Distance X should be equal to distance Y. Here, distance X is considerably smaller than distance Y, indicating eccentric wear of the polyethylene (thin arrow).

epidermidis multiplying slowly within a glycocalyx coating, and therefore normal measures of infection such as a raised C-reactive protein (CRP) may be equivocal (see ***Chapter 43***). The Musculoskeletal Infection Society (MSIS) has defined several criteria (major and minor) to help with the diagnosis of prosthetic joint infection. The diagnosis of infection is aided by an elevated CRP and erythrocyte sedimentation rate; a joint aspirate or biopsy is also useful to identify a pathogen. In addition, a labelled white cell scan and single photon emission CT (SPECT) can provide additional information.

Revision THR can be a single-stage or a two-stage procedure depending on the indication. If the loosening is secondary to infection, a two-stage revision is usually preferred. The first stage consists of implant removal, thorough debridement and implantation of an antibiotic-loaded cement spacer. Multiple deep specimens are sent for bacteriology to determine the organism and its antimicrobial sensitivity. The patient is subsequently prescribed an appropriate antibiotic regime (see ***Chapter 43***). At the second stage of the procedure, the cement spacer is removed and a new prosthesis implanted. In the case of aseptic loosening, revision is performed as a single-stage procedure. If there has been a significant amount of bone loss, bone grafting or trabecular metal augments may be required. The results following a revision hip replacement are not as good as those following a primary THR and the rate of complications, especially dislocation, is also higher. Specialised acetabular components such as dual-mobility implants are favoured in a revision setting, especially for recurrent dislocation in those with poor muscle function.

PART 5 | Elective orthopaedics

CHAPTER
40 The knee

Learning objectives

To understand:

- The anatomy and biomechanics of the knee and their clinical implications
- The clinical presentation, aetiology and management of common knee pathologies
- The principles of joint replacement, including important complications
- The advances in surgical practice in this field

APPLIED ANATOMY

The knee joint is a synovial hinge joint. It consists of two condyloid tibiofemoral joints and a sellar (or saddle shaped) patellofemoral joint. The shape makes the joint inherently unstable, but stability is achieved by a combination of static (ligaments) and dynamic (muscles) stabilisers acting across the joint.

Interposed between the tibia and femoral condyles are the medial and lateral menisci. These fibrocartilaginous structures aid shock absorption, increase the area over which load is dissipated and have a role in anteroposterior stability (*Figure 40.1*). Loss of the protective function of the meniscus through injury, degeneration or meniscectomy can accelerate degenerative change and progression to arthritis. Medial meniscal tears are three times more common than those in the more mobile lateral meniscus. Tears or meniscectomy that disturb the circumferential fibres and defunction the protective hoop stresses (such as radial tears, disruption of the root attachments or removal or large portions of the meniscus) can cause rapid deterioration of the joint.

The medial and lateral collateral ligaments are the primary restraints to valgus and varus stress, respectively. The medial collateral ligament (MCL) is a broad, flat ligament composed of a superficial and a deep layer. The deep layer is attached to the medial meniscus and to the tibia, close to the joint. The superficial MCL attaches more distally on the tibia. The MCL is commonly injured, but frequently heals with conservative management. The lateral collateral ligament (LCL) is a simple cord-like structure but works in combination with other structures (including the popliteus, biceps, popliteofibular ligament, iliotibial band, joint capsule) to form the lateral/posterolateral ligament complex. Injuries to the LCL are less likely to heal with conservative management and are more likely to require reconstruction.

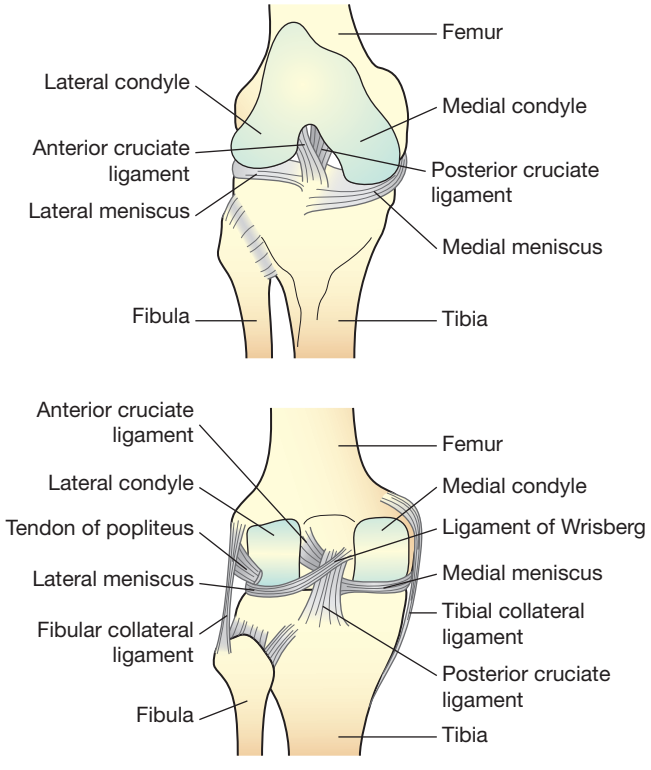

Figure 40.1 Anatomy of the knee joint.

The anterior and posterior cruciate ligaments are each made up of two bundles. The anterior cruciate ligament (ACL) has an anteromedial bundle that is tight in flexion and a posterolateral bundle that is tight in extension. The posterior cruciate ligament (PCL) has an anterolateral bundle (tight in flexion) and a posteromedial portion (tight in extension). The ACL and PCL prevent anterior and posterior translation of

Heinrich A Wrisberg, 1739–1808, German anatomist and gynaecologist.

the tibia on the femur, respectively. Single ligament or meniscal injuries are more likely to occur during sport. Multiple ligament injuries completely disrupt two or more of the four main ligaments and are associated with high-energy trauma such as car crashes. This can result in complete dislocation of the joint and damage to arteries and nerves.

Hyaline articular cartilage is a highly specialised connective tissue that lines the joint surface and has a low coefficient of friction. Hyaline cartilage is devoid of blood vessels, lymphatics and nerves and has a limited capacity for repair. The configuration of cartilage changes with ageing and with disease predisposing to injury.

The knee has bursae surrounding it that can become inflamed and infected.

Summary box 40.1

Anatomy of the knee joint

- Complex synovial hinge joint
- The shape of the joint surfaces makes it inherently unstable
- The static stabilisers are the joint capsule, menisci, cruciate and collateral ligaments
- The dynamic stabilisers are the quadriceps and hamstring muscles

BIOMECHANICS

Axes of the lower limb

The anatomical axes of the femur and tibia are defined by their medullary canal. The mechanical axis of the lower limb runs from the centre of the femoral head, through the intercondylar notch of the knee to the centre of the ankle joint. The angle between the anatomical and mechanical axes of the femur is usually between 5° and 7° (often called the valgus cut angle in arthroplasty) (***Figure 40.2***). A total knee replacement (TKR) is traditionally performed with the goal of lining up the components using cuts perpendicular to the mechanical axis. Knees with malalignment are more prone to injury or degeneration in the loaded compartment. Realignment surgery (tibial or femoral osteotomy) can offload the damaged compartment to reduce symptoms and slow progression to arthritis.

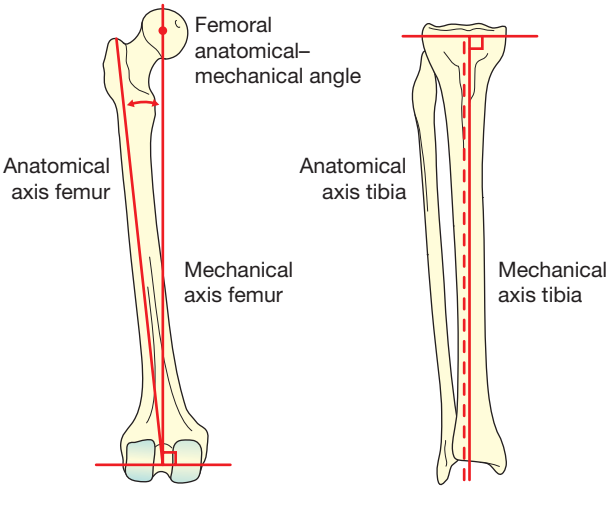

Figure 40.2 Axes of the lower limb. Anatomical and mechanical axes are coincident in the tibia but not the femur. (Adapted from Miller M. *Review of orthopaedics*, 4th edn. Philadelphia: Elsevier, 2004. By kind permission of the publishers.)

Kinematics and kinetics

Knee motion is predominantly in the sagittal plane. A limited degree of rotation also occurs and increases as knee flexion increases. The normal range of motion is between 5° of hyperextension and 135° of flexion. Magnetic resonance imaging (MRI) of cadaveric knees has revealed that, during knee flexion, a combination of rolling and sliding of the femur on the tibia occurs in addition to internal rotation of the tibia. This is because the larger medial femoral condyle rolls back less than the smaller lateral femoral condyle. This motion is facilitated by a more mobile lateral meniscus and lateral ligaments that are more lax in flexion.

The biomechanical role of the patella is to function as a pulley for the quadriceps. It increases the power of the quadriceps by increasing the lever arm. It has the thickest articular cartilage in the body and is designed to withstand loads as high as 20 times body weight when jumping. Abnormal alignment, surface contour, soft-tissue constraints or muscle balance can result in patellar dislocation.

Summary box 40.2

Biomechanics of the knee joint

- The femur has different anatomical and mechanical axes because of the offset of the proximal femur at the hip. These axes are the same in a normal tibia
- Knee motion is mainly in the sagittal plane with some rotation
- The patella acts as a pulley, increasing the lever arm of the quadriceps
- Loads of up to 20 times body weight are transmitted across the patella when jumping

CONDITIONS AFFECTING THE KNEE JOINT

The commonest conditions affecting the knee include injury to the soft-tissue structures and osteoarthritis (OA).

Soft-tissue knee problems

These can present as acute injures or as delayed, more chronic cases with additional degenerative problems. Specific structures commonly involved are the menisci, ligaments and tendons. These can also be associated with chondral or osteochondral injury.

Meniscal tears

The pattern of meniscal injury or degeneration is variable and can affect either the medial and/or the lateral meniscus.

There are several recognised patterns of meniscal tear: circumferential, radial, horizontal, flap and degenerate. MRI scan is the investigation of choice for identifying meniscal tears. Meniscal tears seldom heal. Meniscal tears associated with a specific injury or with mechanical symptoms, e.g. catching, locking and giving way, generally respond well to arthroscopic repair or debridement. Factors making a tear amenable to repair include younger age of patient, early presentation, simple tear configuration, knee stability and a tear in the vascular outer third of the meniscus. Degenerate tears in ageing joints, without an episode of injury and without mechanical symptoms, are primarily treated conservatively with arthroscopy considered after failure of conservative treatment.

Anterior cruciate ligament injury

The ACL rupture is the most common serious ligament injury in the knee. Injury is usually caused by a twisting or landing injury in a pivoting sport. It may be associated with an audible 'pop', immediate swelling and the need to be 'carried off' the field. The injury risk is higher among females; this is thought to be due to smaller ligaments, smaller femoral notches and different landing biomechanics. ACL deficiency can cause instability resulting in further damage to other structures, complex meniscal tears and chondral injury. Examination findings confirming an ACL injury include a positive Lachman test and a positive pivot shift test. MRI scan confirms the ACL rupture and identifies possible injury to secondary structures such as meniscus or cartilage.

Isolated ACL injuries are generally initially managed non-operatively with a knee brace, painkillers, swelling reduction and physiotherapy. Surgical reconstruction is considered in multiligament injuries, in cases of persisting instability after non-operative management, or in young patients or high-demand athletes who tend to fail conservative treatment (see *Chapter 36*). Surgical reconstruction of the ACL is best undertaken when the knee has recovered from the acute injury and has a good range of knee motion and muscle function.

Extensor mechanism rupture

This includes ruptures of either the quadriceps or patellar tendons. These are usually high-energy injuries but can occur more easily in those on steroids, following steroid injections or following previous open knee surgery that may have compromised the blood supply to these structures. They usually present with significant pain and swelling and the inability to actively extend the knee. Prompt surgical repair or reconstruction is required to avoid a significant long-term loss of knee function.

Articular cartilage injury

These can occur in isolation or in association with ACL injuries or patellar dislocations. Partial-thickness defects do not show any potential to heal. Full-thickness defects in younger patients may mount a healing response with fibrocartilage. In higher energy injury, bone may be included in the surface fragment (osteochondral injury). If picked up acutely the chondral and osteochondral lesions may be surgically fixed back in place. Delayed options for full-thickness defects include: removal of the loose body, microfracture, microfracture covered by a collagen membrane, osteochondral transplant (mosaicplasty) or chondrocyte transplant. Chondrocyte transplant usually involves autologous chondrocyte implantation (ACI) or matrix-assisted ACI (MACI). The age of the patient and the site and size of the defect determine the most appropriate treatment.

Osteoarthritis

OA commonly affects the knee joint. The prevalence of symptomatic knee OA in adults aged 60 years or older is approximately 10% in men and 13% in women. OA can be either primary (idiopathic) or secondary. Patients with primary OA tend to have other joints involved and may have a family history of arthritis. Secondary OA may occur following a previous intra-articular fracture, meniscectomy, ligament injury, osteonecrosis or in a neuropathic joint.

Clinical features

Patients usually describe pain, stiffness and swelling. Pain is usually worse with loading and with activity. Patellofemoral OA pain is worse on stairs and rising from a seated position. The natural history of OA is of a gradual steady deterioration from episodes of short-lived flare-ups progressing to constant pain that often affects sleep. Mobility deteriorates, walking distance reduces and walking aids are frequently required. In severe cases, patients may become dependent on a wheelchair or become housebound.

Examination reveals an antalgic gait in which the patient limps, spending a short time on the painful limb, and moves their centre of gravity to minimise the weight they are taking through this limb. In knee OA the deformity is usually varus, with bone loss on the medial side. Valgus deformity is more common in women, in rheumatoid arthritis and after lateral meniscectomy. The joint appears bulky owing to effusion, synovial thickening and growth of osteophytes. An effusion is frequently present and movement, particularly extension, is restricted. Crepitus can be both palpable and audible.

Investigation

Plain radiographs are the investigation of choice with typical features of joint space narrowing, subchondral sclerosis, osteophytes and subchondral cysts (*Figure 40.3*). These are best performed weight-bearing to show the extent of joint narrowing. MRI scan is not routinely required prior to knee replacement.

Treatment

Non-operative methods are the first line of treatment. Patients should be encouraged to lose weight, undertake regular exercise to prevent joint stiffness and use anti-inflammatory medication. Walking aids, such as a stick, orthotics and off-loader braces, may be beneficial. Intra-articular steroid injections can be used to settle an arthritic flare-up but are no longer recommended as a long-term solution because of concerns about infection and causing further joint cartilage damage.

John W Lachman, 1919–2007, Professor and Chairman of the Orthopedic Department at Temple University in Philadelphia, PA, USA.

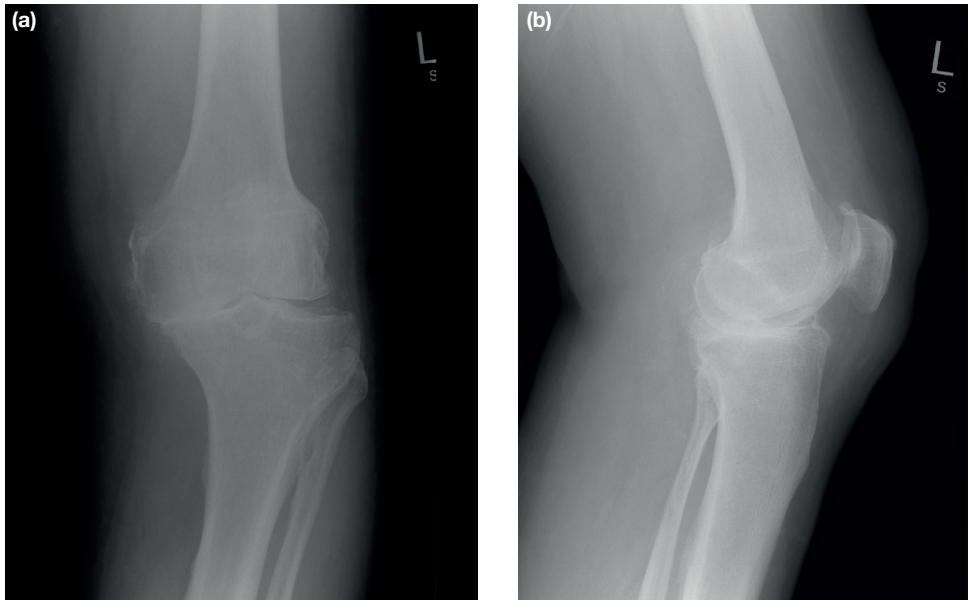

Figure 40.3 Anteroposterior (a) and lateral (b) radiographs of osteoarthritis of the knee.

Surgical options include osteotomy, partial knee replacement, TKR or arthrodesis.

Summary box 40.3

Knee OA

- More common in females
- Can be primary (idiopathic) or secondary (e.g. post traumatic)
- The main symptom is pain made worse by use
- Examination reveals swelling and a reduced range of motion with or without deformity
- The key radiographic features are joint space narrowing, subchondral sclerosis and cysts, and osteophytes
- Treatment is non-operative initially. Knee replacement is reserved for end-stage disease

SURGICAL PROCEDURES

Knee operations can be done either arthroscopically or open. Arthroscopic treatment is possible for most soft-tissue problems, while open surgery is required for osteotomy, replacements and arthrodesis. Procedures amenable to arthroscopic treatment are summarised in *Table 40.1*.

Meniscal surgery

This is performed arthroscopically, commonly using two portals, usually as a day case under general anaesthetic. The meniscus is inspected to define the configuration of the tear and whether it is in a part of the meniscus with sufficient blood supply to allow healing. If the tear is not amenable to repair, a combination of punches and arthroscopic shavers are used to remove any unstable or unhealthy meniscus, back to a healthy stable rim. Attempts should be made to repair meniscal tears in the young, and if the tear is repairable; commonly these will be circumferential or 'bucket-handle' tears. Repair includes freshening the repair site and then fixation with a combination of inside-out, outside-in or all-inside sutures or meniscal repair devices. Postoperative protection of the repair usually includes restriction of weight-bearing and use of a brace for between 6 weeks and 3 months.

TABLE 40.1 Indications for knee arthroscopy.

- Torn meniscus resection or repair
- Anterior/posterior cruciate ligament reconstruction
- Loose body removal
- Cartilage regeneration techniques, including microfracture
- Septic arthritis washout
- Inflammatory arthritis and pigmented villonodular synovitis (PVNS) – synovectomy
- Diagnosis of unexplained knee pain
- Tibial plateau fractures – allows intraoperative assessment and reduction of the articular surface

Cruciate reconstruction

An isolated ACL injury is most commonly treated with an arthroscopic intra-articular reconstruction. The graft can be a bone–patellar tendon–bone or four-strand hamstring autograft. Screws or fixation devices hold the graft in bone tunnels in the femur and tibia until it has healed. Return to full sport can take up to a year. Postoperative rehabilitation programmes are crucial to a favourable outcome. Complications following ACL surgery are usually a result of incorrect tunnel placement (placing the femoral tunnel too far anteriorly limits knee flexion) and early surgery. The graft re-rupture rate is approximately 1% per year.

Osteotomy

Varus or valgus alignment or deformity of the knee can abnormally load the medial or lateral compartment, resulting in premature degenerative change in that compartment. Osteotomy aims to divide the bone, correct the deformity and alter the load-bearing mechanics of the joint. The most

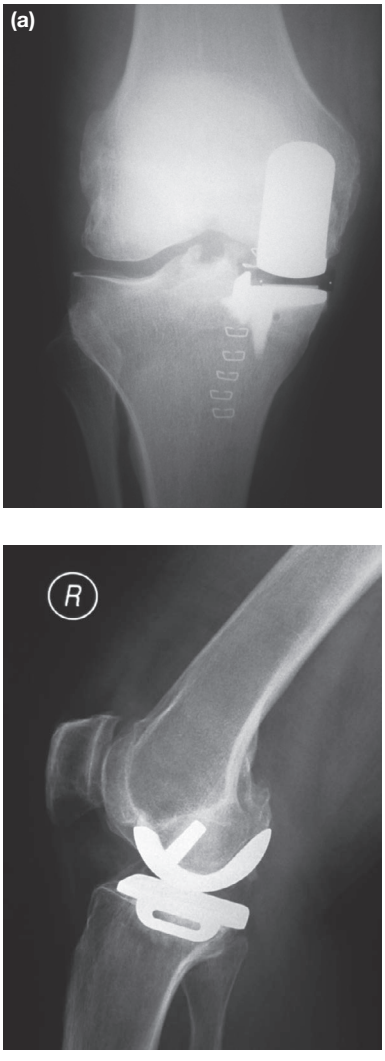

Figure 40.4 Anteroposterior (a) and lateral (b) radiographs of a unicompartmental knee replacement.

commonly performed operation is a high tibial osteotomy (HTO) for a varus knee. Realignment is achieved with either an opening-wedge medial HTO or a closing-wedge lateral HTO. The amount of angular correction is calculated preoperatively and then created in theatre with jigs under radiographic control. Fixation with modern plates and locking screws allows early weight-bearing and mobilisation. The ideal patient for osteotomy is a young, active and well-motivated individual with disease limited to one compartment.

Knee joint replacement

There are three compartments within the knee: medial and lateral tibiofemoral, and patellofemoral. In 20–50% of cases, OA affects only one compartment and these patients may be suitable for a partial or unicompartmental knee replacement (UKR) (*Figure 40.4*), while in tricompartmental disease a TKR is indicated (*Figure 40.5*).

Patients are suitable for UKR if disease is limited to one compartment, if ligaments are intact and if fixed deformity is less than 15°. UKR has complication rates of one-third to one-half

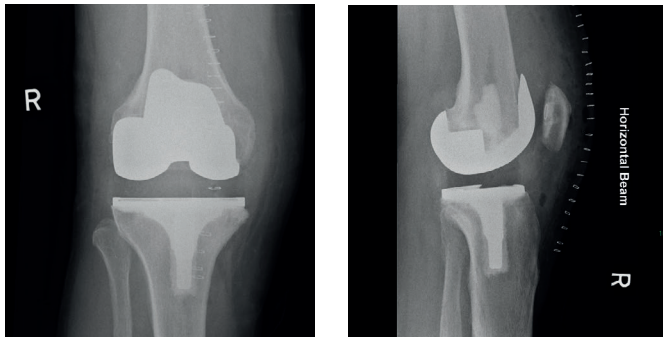

Figure 40.5 Anteroposterior (a) and lateral (b) radiographs of a total knee replacement.

those of TKR with a lower infection rate, lower medical risks and lower risk of death. UKR is associated with a more rapid recovery, shorter hospital stay, preservation of knee kinematics and generally superior function to that of TKR. Revision rates for UKR are significantly influenced by the surgeon's experience and the implant. In optimal conditions the revision rates are similar to TKR, but on national registries UKRs have higher 10-year revision rates (6–12 %) than TKRs (2–6%).

Isolated patellofemoral replacement is also performed but the numbers are low in view of the scarcity of isolated patellofemoral disease. Revision rates are higher than other partial knee replacements, largely because of progression of arthritis in the remaining compartments.

A TKR can be regarded as a resurfacing procedure in which the femoral articular surface is replaced with metal and the tibial articular surface is replaced by a tough polyethylene insert, usually inserted into a metal tibial baseplate. TKR is one of the most successful surgical interventions, with most patients getting significant pain reduction and improvement in mobility. Revision rates are less than 5% at 15 years. Patient satisfaction with TKR is generally lower than that achieved with hip replacement.

TKR implants are generally cemented into the bone using polymethylmethacrylate (PMMA) cement. The design of the articulation can provide varying amounts of stability or constraint. Unconstrained TKRs are the most common and can either retain or sacrifice the PCL; these implants are called cruciate-retaining (CR) or PCL-sacrificing (PS), respectively. The more constrained the implant the greater the force transmitted to the implant–cement–bone interfaces, therefore increasing the risk of loosening. More constrained implants are generally only used in revision cases. If the joint is very unstable or deformed then a hinged knee replacement is used as it does not rely on the ligaments for stability. Modern knee replacements try to reduce wear by using enhanced bearing surfaces such as cross-linked polyethylene, vitamin E-enriched polyethylene or ceramicised surface coatings.

The TKR surgical technique aims to correct the deformity and leave the leg aligned with the mechanical axis and with the joint parallel to the ground. More modern philosophies of TKR try to match the patient's more individual alignment in the hope that this feels more natural to the patient, but it may require additional technology to allow this to be done accurately, e.g. computer navigation or robotics. It is important

that the ligaments and soft-tissue envelope are well aligned and balanced to allow good stability, range of motion and patellar tracking. Early weight-bearing and mobilising are now possible, with some patients treated as day cases but most staying in hospital for 2–4 days.

Complications following TKR can be broadly classified into intraoperative and postoperative (*Table 40.2*).

TABLE 40.2 Complications of total knee replacement.

Intraoperative
- Implant malposition and malalignment; with subsequent contribution to instability, stiffness or pain
- Nerve or vessel injury, including tourniquet damage
- Fracture
- Patellar tendon avulsion
- Fat embolism

Postoperative
- Infection
- Deep vein thrombosis/pulmonary embolism
- Pain/stiffness
- Instability
- Osteolysis
- Component loosening
- Dislocation

Summary box 40.4

Aims of TKR
- Correct deformity caused by arthritis
- Align the knee to the mechanical axis or slightly under-corrected
- Joint line perpendicular to the mechanical axis
- Balanced collateral ligaments
- Ensure patellofemoral joint tracks normally

Knee arthrodesis

Knee arthrodesis is rare and is largely a historic procedure that is seldom acceptable to modern patients. It is therefore used as a salvage option after failure of multiply-revised and infected joint replacements, particularly if there is disruption of the extensor mechanism. It is occasionally considered as a primary intervention in rare cases where neurological abnormality would prevent the patient from having the muscle control necessary to control a knee replacement, e.g. stroke, spina bifida, polio, Charcot arthropathy. The ideal position of fusion is 7° of valgus and 15° of flexion. Arthrodesis can be performed using intramedullary nails, plates or extramedullary fixators.

Revision knee replacement

TKRs have excellent long-term survival, with 82% lasting over 20 years and over 95% lasting 10–15 years. In the first few years, revision surgery is most likely to be due to infection, and non-infective causes, such as instability and malalignment. Beyond 10 years, revision is usually a result of aseptic loosening of components, which is often a result of wear of the plastic insert and polyethylene-induced osteolysis. With any failed joint replacement, infection should be excluded as this can compromise the result of surgery and may require a different surgical strategy, e.g. a two-stage rather than a single-stage procedure. Revision arthroplasty is technically more challenging, requires more complex and expensive implants and has a higher complication rate. When done for the correct indication, results are very good. As with a primary TKR, the goal remains to provide a well-aligned, stable and pain-free knee (*Figure 40.6*).

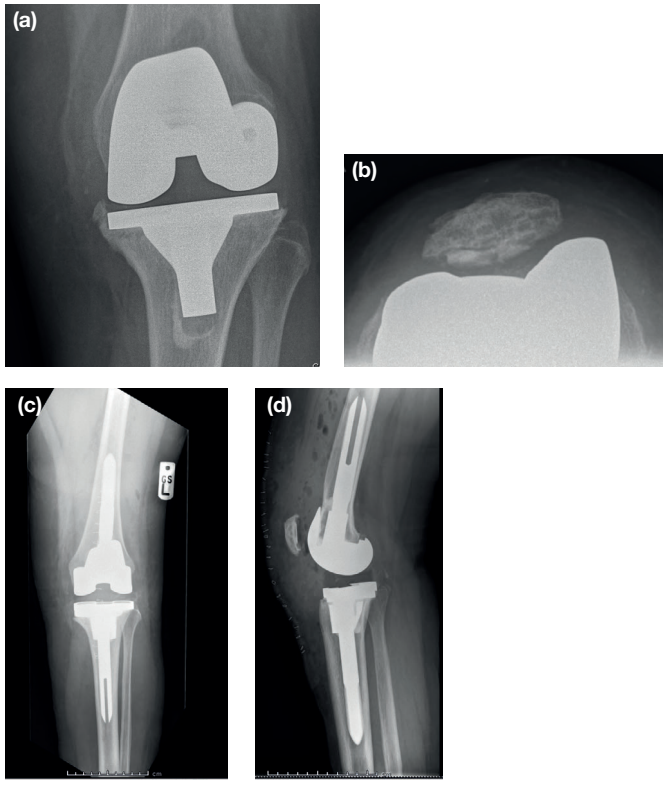

Figure 40.6 Radiographs of a malaligned knee **(a, b)** and a well-aligned revised knee **(c, d)**.

PART 5 | Elective orthopaedics

CHAPTER 41

The foot and ankle

Learning objectives

To understand:

- The basic anatomy and biomechanics of the foot and ankle
- The common problems affecting the foot and ankle in each age group
- The principles behind the treatment of each condition, be it conservative or surgical
- The significance of progressive neurological diseases

ANATOMY

There are 26 (25 with variant) main bones in the foot (seven tarsal bones, five metatarsals and 14 phalanges [13 in the biphalangeal fifth toe variant]) plus the two sesamoids of the hallux and a variable number of other sesamoid and accessory bones.

Movements at the ankle joint are mainly dorsiflexion and plantarflexion, but are more complex than this. The joint is actually a truncated section of a cone, meaning that the motion is not simply a hinge; in addition, movement of the ankle leads to rotation of the fibula at the syndesmosis. This means that the foot externally rotates with dorsiflexion and internally rotates with plantarflexion.

Stability is conferred upon the ankle by the congruence of the mortice and the integrity of principally the medial, lateral and inferior tibiofibular ligaments.

The subtalar joint is divided into anterior, middle and posterior facets and, along with the talonavicular and calcaneocuboid joints, makes up the triple joint complex. These joints are responsible for inversion and eversion of the hind- and midfoot. The joints are co-dependent such that limitation of one affects movement at the others. Fusion of the triple complex slightly affects movement at the ankle and vice versa.

The second tarsometatarsal (TMT) joint is recessed relative to the first and third and acts as a 'keystone'. Disruption of this joint (Lisfranc's injury) leads to loss of the transverse arch and an acquired flat foot.

The lower leg is divided into four compartments:

- the superficial posterior – gastrocnemius, soleus and plantaris;
- the deep posterior – tibialis posterior, flexor digitorum longus and flexor hallucis longus (FHL);
- the lateral – peroneus brevis and peroneus longus;
- the anterior – tibialis anterior, extensor hallucis longus, extensor digitorum longus and peroneus tertius.

There is only one muscle on the dorsum of the foot, the extensor digitorum brevis. The muscles on the plantar aspect of the foot are divided into four layers, the first being the most superficial, and the course of the neurovascular structures is a favourite examination topic. The plantar fascia is a very important structure that takes its origin from the heel and inserts into the bases of the proximal phalanges of the toes. At toe-off, the fascia tightens and accentuates the medial plantar arch and helps provide a rigid lever arm, the so-called 'windlass mechanism'. This is essential in the preservation of the integrity of the arch of the foot and function of the toes.

The blood supply of the foot is from the anterior tibial, the posterior tibial and the peroneal arteries. The following nerves supply sensation to the foot: posterior tibial, saphenous, sural, superficial and deep peroneal (***Figure 41.1***).

Summary box 41.1

Anatomy of the foot

- There are 26 major bones in the foot
- There are four layers of muscles in the sole of the foot
- The blood supply of the foot is from the anterior and posterior tibial arteries plus the peroneal artery

Jacques Lisfranc, 1790–1847, Professor of Surgery and Operative Medicine, Paris, France.

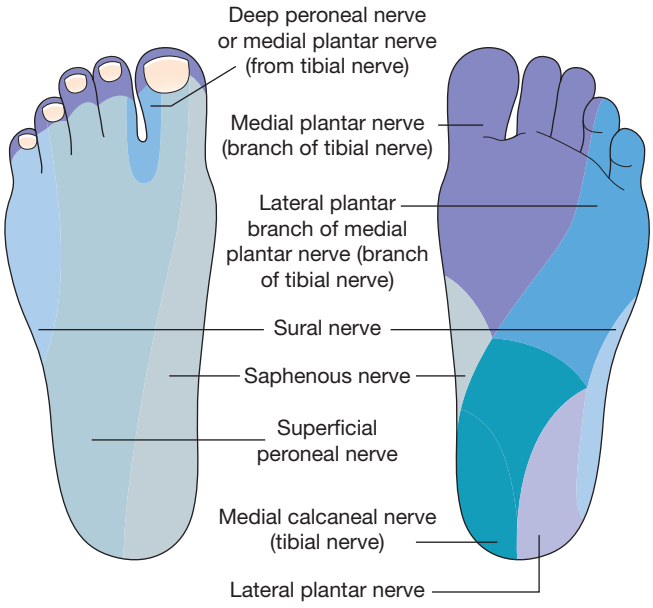

Figure 41.1 Cutaneous nerve supply of the foot (courtesy of Bartleby.com).

BIOMECHANICS

The walking cycle is divided into the stance (60%) and swing (40%) phases. The stance phase is divided into three intervals: (i) heel strike to foot flat; (ii) foot flat until the body passes over the ankle; and (iii) ankle joint plantarflexion to toe-off. During walking up to 12% of the gait cycle is spent with both feet in the stance phase, but with running there is a period when neither foot is in contact with the ground – the 'float' phase. During running the cycle time is shortened but the forces generated are very much increased.

Summary box 41.2

Biomechanics

- The gait cycle is divided into swing and stance phases
- Running generates increased forces, shortens the gait cycle and has a float phase when neither foot touches the ground

Examination

The examination of the foot is described in *Chapter 35*. The patient should be watched walking, and both the foot and the footwear of the patient need examining when looking for abnormal load and wear.

PAEDIATRIC CONDITIONS

These are discussed in *Chapter 44*.

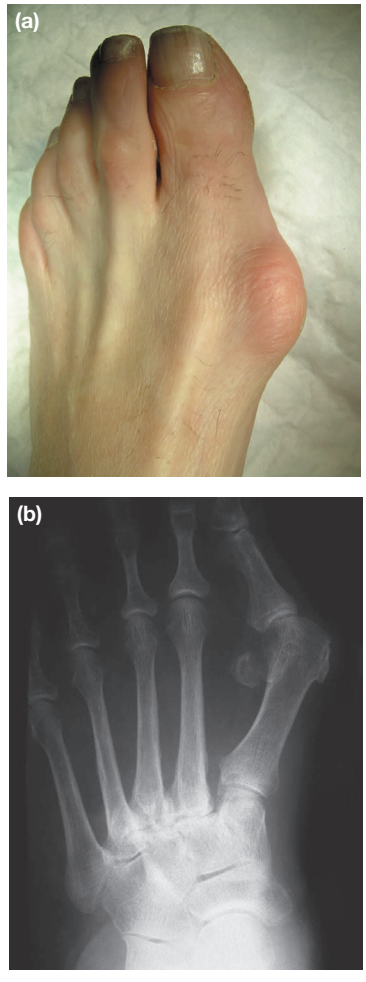

Figure 41.2 (a, b) Hallux valgus and bunion.

PATHOLOGY IN THE ADULT

The forefoot

Hallux valgus

Hallux valgus is deviation of the big toe away from the midline, i.e. towards the lesser toes, and is usually associated with a bunion, a swelling made up of both bone and bursa on the medial aspect of the first metatarsal head (*Figure 41.2*). It is a common condition that affects women more than men, and that is often bilateral. It is believed that the tendency to hallux valgus is inherited and that fully enclosed shoes accelerate the development of the condition, although not all agree.

With increasing deformity the first ray becomes defunctioned and elevated, and overload of the second metatarsophalangeal (MTP) joint often results in pain, swelling and eventually plantar plate disruption and dislocation. This can present with a prominent callosity beneath the second MTP joint and eventually hammering of the second toe.

Non-operative treatment of hallux valgus includes a wider toe box and pressure relief. Surgical intervention is commonly offered, but has a 10% rate of dissatisfaction.

For mild deformities a distal osteotomy (e.g. chevron) is usually adequate. For moderate deformities the surgeon is

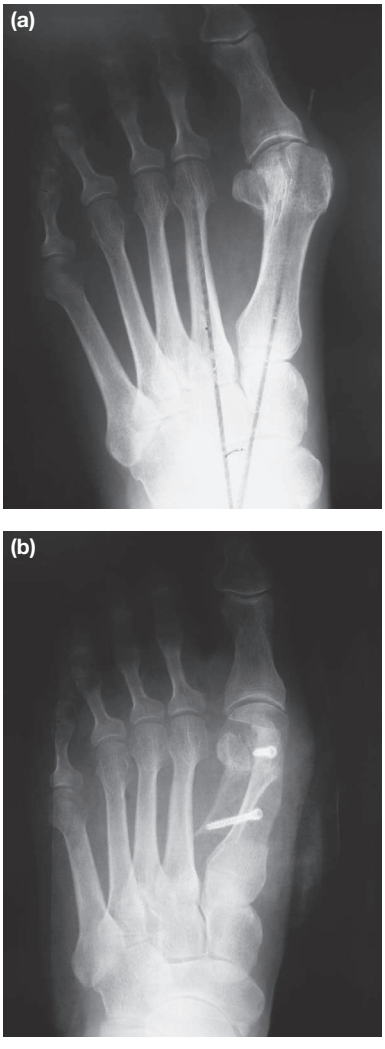

Figure 41.3 Pre- (a) and postoperative (b) radiographs of a scarf osteotomy.

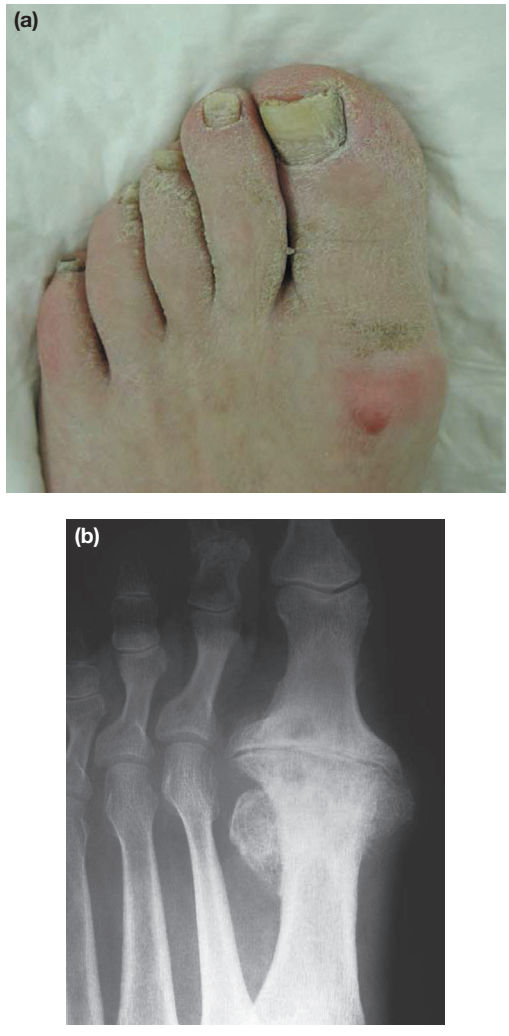

Figure 41.4 Clinical (a) and radiographic (b) appearance of hallux rigidus.

more likely to use a shaft, e.g. scarf (*Figure 41.3*) or Ludloff, or a basal (proximal chevron or crescentic) osteotomy. Severe deformities can be corrected by shaft and basal osteotomies but sometimes a fusion of the first TMT joint (modified Lapidus) or a first MTP joint fusion can be effective and is the preferred option for hypermobile or unstable TMT1 joint deformities. Minimally invasive techniques are developing and are widespread, especially in Europe, but there are few peer-reviewed series of outcomes from the UK and it has not become mainstream.

Basal osteotomies and fusions have a higher risk of abnormal elevation or depression of the rays, resulting in overload of the rest of the forefoot. However, they do allow a massive correction. They are best stabilised using plates.

Operations such as a Keller's excision arthroplasty, where the proximal third of the proximal phalanx is excised, serve to defunction the toe and sesamoids and are reserved for low-demand, high-risk patients in whom there is a high risk that healing of an osteotomy might fail.

The complications of bunion surgery are infection, cutaneous nerve damage, recurrence or overcorrection of deformity, stiffness and overload of the second MTP joint (transfer lesion); 10% of patients have significant reservations and 20% mild reservations about their outcome. Occasionally patients develop early arthritis following surgery and require revision to fusion.

Hallux rigidus

Hallux rigidus is a painful condition of the hallux MTP joint characterised by loss of motion, especially in dorsiflexion, and osteophyte formation on the dorsum and sides of the joint (*Figure 41.4*).

A **scarf** osteotomy is named after a carpentry term; it is an elongated Z-shaped osteotomy along the metatarsal.
Karl Ludloff, 1864–1945, German orthopaedic surgeon.
Paul W Lapidus, 1893–1981, Russian-born orthopaedic surgeon, Chief of the first Orthopedic Foot Clinic and Service, Hospital for Joint Diseases, New York, NY, USA.
William Lordan Keller, 1874–1959, Head of the Department of Surgery, Walter Reed Hospital, Washington, DC, USA, described this operation in 1904.

Summary box 41.3

Hallux valgus

- Bunions affect women more often than men
- Patients with hallux valgus have inherited a tendency to develop the condition
- Not all patients need surgery
- The choice of operation is determined by the severity of the deformity and presence or absence of any arthritis, instability of the joints or hypermobility

In adults there is often a history of trauma or repetitive microtrauma (sport) but, occasionally, there is a strong family history of the condition. Gout and rheumatological conditions may present in this way. Patients complain of stiffness and pain on weight-bearing.

The most effective non-operative treatment is provision of a stiff-soled shoe with a deep toe box or a rocker-soled shoe, which are now available on the high street.

The mainstays of surgical management are injection/manipulation, cheilectomy (a radical debridement and excision of the part of the joint blocking movement), fusion and interposition arthroplasty (Keller-type procedure or silicone interposition). Prosthetic arthroplasty, with hemi-, total, interposition or spacer arthroplasty, is available but many prostheses have been withdrawn because of high failure rates and few series extend beyond 9 years. Newer prosthetic inserts with claimed joint-preserving capabilities similarly fail to show advantages with regards to pain and have a high revision/reoperation rate but are still preferred by some who wish to retain mobility at MTP1 in the short to medium term.

Fusion is for the severely affected and is an effective means of abolishing pain, but affects the biomechanics and some patients are left with intractable pain beneath the sesamoids. A fusion will still usually allow sports participation.

Summary box 41.4

Hallux rigidus

- Hallux rigidus can affect adolescents as well as adults
- Stiff-soled shoes with a deep toe box are the most comfortable type of shoe
- Cheilectomy and fusion are the mainstays of surgical treatment

Sesamoid/sesamoid complex problems

Turf toe

Acute injuries (turf toe) can be managed non-operatively or surgically depending on the grade of the injury and the occupation of the patient. Grade 4 acute rupture may require surgery.

Turf toe is a plantar plate disruption usually from hyperextension injuries at MTP1 and may involve sesamoid fractures. Low-grade injuries can be treated non-operatively but high-grade injuries require reconstruction, especially in athletes (see *Chapter 36*).

Chronic conditions range from stress fracture to avascular necrosis (AVN) and sesamoiditis but are probably all the same phenomenon. Management includes offloading with orthotics, injections of steroids and, rarely, shaving/excision. Excision surgery carries a high risk.

Lesser toe deformities

Hammer, mallet and claw toes are frequent and are usually nonindicative but may be secondary to other deformities in the foot or to underlying neurological disease. Nonoperative treatment involves appropriate padding and footwear modification. For symptomatic flexible deformities soft-tissue surgery such as flexor/extensor tenotomies with/without capsulotomy is usually adequate, but for fixed deformities bony procedures are required such as interposition arthroplasty, fusion or excision arthroplasty.

Isolated lesser toe MTP extension/subluxation may result from a ruptured plantar plate at MTP joints and repair techniques have evolved recently, but the results are moderate at best and the trend is back to non-operative management where possible. Ultrasound and magnetic resonance imaging (MRI) are now well established for these injuries.

Freiberg's disease

Freiberg's disease (*Figure 41.5*) is an ischaemic necrosis of the epiphysis, resulting in pain and swelling of the joint. It will often settle with rest. Reshaping osteotomies are described, or excision of the proximal phalangeal head for severe adult cases with joint destruction. Excision of the whole metatarsal head should never be performed.

Morton's neuroma and metatarsalgia

Metatarsalgia usually occurs secondary to joint problems, overload or irritation of a nerve. Morton's neuroma is a painful

Figure 41.5 Freiberg's disease.

Albert Henry Freiberg, Professor of Orthopaedic Surgery, University of Cincinnati, Cincinnati, OH, USA, gave his account of this condition in 1926.
Thomas George Morton, 1835–1903, surgeon, Pennsylvania Hospital, Philadelphia, PA, USA, described this condition in 1876.

condition that, in most cases, arises from compression of the common digital nerve, most commonly between the third and fourth metatarsal heads and the second/third and is usually secondary to other forefoot pathology.

The diagnosis is confirmed by ultrasound or MRI. Non-operative treatments include advice about footwear, an orthosis (premetatarsal dome) to splay the metatarsal heads or an injection of steroids. Cryotherapy and even alcohol injections have been reported.

Surgery involves resection (the affected toes will be permanently partly hemi-numb if the nerve is removed) but this is not without risk of patient dissatisfaction, pain and recurrence, with around 5% reporting bad outcomes, often permanent. European colleagues often simply transect the intermetatarsal ligament instead.

Summary box 41.5

Morton's neuroma

- Morton's neuroma most commonly affects the second or third web space
- Surgical excision of neuroma is often successful but has a risk of pain syndrome
- Guided injections form the mainstay of treatment for most

Stress fracture

This may occur following sport or may be incipient. It usually presents in the forefoot and may mimic Morton's neuroma or metatarsalgia. An unexplained aetiology might require biochemical or biomechanical evaluation. Forefoot fractures can usually be managed non-operatively.

Stress fractures may occur in any bone. Those of the navicular, talus and tibial sesamoid often present with vague symptomatology but early diagnosis with MRI and management are essential with immediate offloading and protection with early fixation – if required, urgently – if a full fracture is seen developing. Vague, poorly defined midfoot pain in an athlete or military recruit mandates urgent scanning and offloading.

Follow-up investigation of bone metabolism/density and exclusion of myeloma may be required.

The midfoot

The midfoot comprises the cuneiforms and the cuboid and related joints.

Midfoot arthritis

The aetiology is usually not known but the risk factors include microtrauma, rheumatological causes, flat foot, Lisfranc or similar injuries (which may have been missed), Charcot and cavus foot. Patients are best managed non-operatively with orthotics, shoes, analgesia and modifications of their lifestyle.

Pain, often with palpable dorsal osteophytes, is the commonest finding. Injections and orthotics are the mainstay of treatment, with surgery high risk and having moderate outcomes. Fusion or interposition arthroplasty of the lateral two TMT joints has a universally poor outcome.

Charcot

An acute hot, red, swollen foot (which may or may not be painful) may be indicative of Charcot (often secondary to diabetes, which may as yet be undiagnosed) or other neuropathy. Immediate offloading in plaster and urgent management are indicated; National Institute for Health and Care Excellence (NICE) guidelines are available in the UK.

The presence of any unexplained swelling, heat, ulcer or deformity in a diabetic foot mandates an emergency and referral along NICE guidelines; failure to follow such guidelines can lead to significant sums being paid out by indemnity organsiations.

Tendinopathy

Rarely, dorsal pain may be due to tibialis anterior tendinosis at its insertion; management is usually non-operative. Injection carries a slight risk of rupture, which is ameliorated by a surgical boot with deep vein thrombosis (DVT) prophylaxis.

Ganglions

Midfoot ganglions are common and may cause neuralgia over dorsal bosses. Injection/aspiration should be attempted. Surgery may be required but recurrence is high and secondary neuralgia not infrequent.

The hindfoot and ankle

Ankle arthritis

The definitive operative treatment for arthritis of the ankle will usually be in the form of total ankle replacement (TAR) or more commonly arthrodesis (fusion); the latter is often carried out via an open approach but arthroscopic techniques have better outcomes, more rapid recovery and fewer complications and almost all surgical units in the UK now offer such techniques. Such techniques are mandatory in the presence of a poor soft-tissue envelope or in the presence of a clotting diathesis.

A UK national trial is currently under way to evaluate the relative outcomes of TAR versus arthrodesis (the TARVA trial), which are as yet undefined; the trial has been complicated further by the withdrawal/failure of the two leading implants.

The advantage of fusion is that it has a known track record, good outcomes (over 90% of patients do well) and minimal morbidity, especially with modern arthroscopic techniques, but not all do well with fusion. Function following isolated fusion is virtually normal for most patients and this is probably due to increased mobility at other joints. However, this may precipitate arthralgia elsewhere.

TARs were until recently three-component devices (except in the USA) but a two-component device is now the market leader in the UK by far. It is not yet known if this is relevant but allows an easier regulatory pathway in the USA. Outcomes

Jean Martin Charcot, 1825–1893, physician, La Salpêtrière, Paris, France.

seem to be related to accuracy of placement and modern instrumentation may be a key factor; custom implants based on preoperative computed tomography (CT) scans are becoming mainstream. TARs allow preservation of joint mobility but at the expense of larger incisions and possible eventual failure. Revision rates of <1% to 7% per annum are reported, with most showing an approximately 3% failure rate per year. Survivorship analysis does not record patients who are doing badly but who do not have further surgery and a recent paper showed revisions are under-reported. The changes in the regulatory pathways in the UK/European Union relating to the development of new implants may limit the development of TARs in these regions to the same levels of efficacy seen by total hip replacements and total knee replacements.

Hindfoot (excluding ankle) arthritis

The triple complex refers to the subtalar (talocalcaneal), calcaneocuboid and talonavicular joints. These joints are often affected by arthritis. Treatment options are limited and, if simple measures have failed, a fusion should be performed. Smokers and patients with diabetes have a massively increased non-union rate for all foot fusion procedures and should be warned of this when they give consent. Late presentation of coalitions usually requires fusion.

Ankle combined with other hindfoot arthritis

If surgical input is required, one option is to treat one set of joints and then see how the patient fares. For example, offer the patient an ankle fusion or replacement and then assess the outcome. Secondary surgery to the other joints can then be performed if required. The alternative is to treat all joints at once. The non-union rates of the ankle following a subtalar fusion or vice versa are high (up to 75%). For this reason, some clinicians advise TAR, not ankle fusion, following a previous subtalar/triple fusion.

Modern techniques now use third-generation hindfoot fusion nails that fuse both the ankle and subtalar joints. These are inserted with an open or arthroscopic fusion technique.

A pantalar fusion is quite disabling but may be necessary in patients with rheumatoid arthritis or with deformities/stress fractures and in those with a failed arthroplasty with subtalar joint involvement, pantalar arthritis or AVN with collapse of the talus.

Summary box 41.6

Midfoot and hindfoot

- Joint disorders are degenerative or inflammatory
- The mainstay of surgical treatment remains fusion, although ankle replacements are becoming more successful
- Rheumatoid arthritis must be medically controlled as well as possible before surgery
- Knee deformities should be corrected before tackling foot problems

Rheumatological presentations in the foot

The early presentations of rheumatological disease may include synovitis of the lesser MTP joints and widespread small joint disease, often in association with enthesopathy such as plantar fasciitis or Achilles tendinosis. However, the classic deformity is of hallux valgus with or without hallux rigidus deformity and subluxation or even dislocation of the lesser MTP joints in the forefoot and arthritis and deformity in the mid/hindfoot.

The patient may present with a bunion and prominent lesser metatarsal heads, which can often be felt to be dislocated on clinical examination and are painful to palpation. Joint-sparing surgery is preferred, with preservation of the metatarsal heads if possible, often shortening and relocating the MTP joints. Destruction of the joints can be treated with proximal phalangeal partial excisions. Fusion of the first MTP joint is the usual requirement. Late recurrence can be managed with excision arthroplasty.

Excision of the metatarsal heads produces an almost instantaneous and gratifying relief of pain. If a plantar approach is used an ellipse of skin can be excised to move the metatarsal padding back over the end of the metatarsal. While most surgeons avoid scars on the plantar aspect of the foot wherever possible, this is one procedure where the results are good. However, such surgery leaves no room for revision in later years.

The requirement for rheumatoid forefoot correction has fallen dramatically in the last 20 years with the advent of disease-modifying drugs; most trainee surgeons will now have never seen a Fowler's procedure (or similar), which was once a mainstream and common procedure.

Midfoot

Rheumatological disease may also affect the midfoot and here the outcome is usually just pain and stiffness. Options are limited to injections and fusion surgery if non-operative measures have failed.

Hindfoot and ankle

Rheumatological disease also affects the hindfoot and ankle. Many patients require surgical hindfoot fusions and the options for the ankle are discussed in ***Ankle arthritis***. Outcomes of TAR are favourable in patients with rheumatoid arthritis, although increased deformities may make the outcomes less predictable.

The rheumatological diseases also affect soft tissues. Patients are more prone to developing enthesopathy, tendinitis and tendinosis, and even tendon rupture. The Achilles tendon should never be injected with steroid for fear of rupture; similarly, the tibialis anterior and tibialis posterior tendons are risky for injection.

Tendon disorders

Tenosynovitis/tendinitis is probably a misnomer as the histological data support neither pathology in many cases. It often occurs as a result of injury or overuse or is secondary to inflammatory disease. Rest, anti-inflammatory medication

Alan W Fowler, 1920–2013, orthopaedic surgeon, Bridgend Hospital, UK.

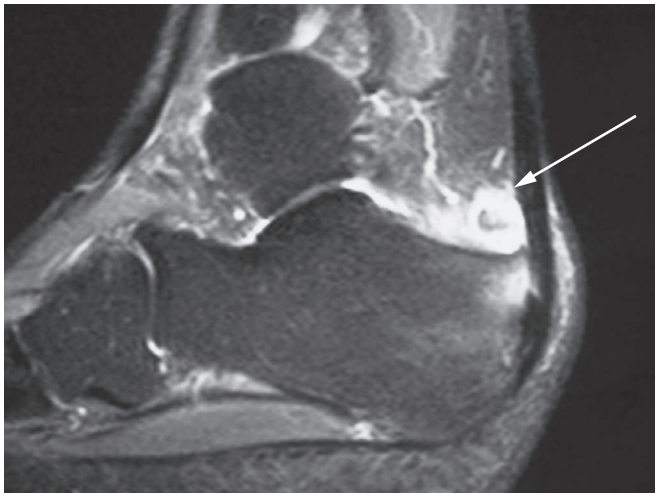

Figure 41.6 Insertional Achilles tendinitis (arrow).

and physiotherapy are often helpful but, in inflammatory conditions, tenosynovectomy may be required.

The tendons most commonly affected by degeneration are the Achilles (*Figure 41.6*), tibialis posterior and the peronei (brevis more than longus).

Ruptured Achilles tendon

The Achilles tendon rupture is relatively frequent in the 40- to 50-year-old age group who are undertaking vigorous sport after a long period away from such activities, but can occur in any age and with little provocation. One-quarter are missed in primary care or in the accident and emergency department and the recording of the Simmonds test is mandatory. The test is non-reliable after 1 week. Management of acute rupture is more frequently non-operative nowadays, provided ultrasound has shown closure of the gap in plantarflexion (although the importance of this even is now debated), and many protocols are described for non-operative management. Surgical fixation is an alternative but large meta-analyses have shown little if any advantage of surgical fixation with an increased complication rate.

Many patients do not suffer the acute rupture classically described in all textbooks and many seem to have a series of micro-tears that gradually lead to total rupture. Studies have shown that older adult patients with Achilles rupture regained 70–90% of the normal power with no treatment whatsoever when reviewed at 1 year; for many patients, this is enough to allow some of them to return to normal function.

Non-operative options for a missed rupture include a sprung ankle–foot orthotic ankle brace, while operative options involve reconstructive surgery with or without FHL tendon augmentation or synthetic ligament replacement.

Achilles tendinosis

Non-insertional tendinosis is frequent, often related to overuse and is usually managed non-operatively. Multiple tendon problems should alert the clinician to the presence of seronegative arthritides. Shockwave therapy is a recent addition to the armoury. Steroid injections may rupture the Achilles tendon and are discouraged; high-volume saline, dry-needling and sclerosant injections have all been described but are used less frequently with the advent of shockwave. Surgery for non-insertional tendinosis has moderate success.

Insertional tendinosis is usually associated with a Haglund's bony deformity or the presence of intratendinous bony spurs/shelves seen on lateral radiograph. Significant intratendinous bony spurs rarely get better without surgical input in the author's experience. Minimally invasive or mini-open excision of the prominent posterolateral corner of the calcaneum in Haglund's deformity, detachment, debridement and reattachment or reshaping osteotomy form the mainstay of modern surgical techniques for insertional problems, but both conditions have a relatively high rate of failure and complication with surgery.

Peroneal tendon problems

The peroneal tendons may develop tendinosis, may subluxate or may become involved in an inflammatory process with or without bony overgrowth at the inferior retinaculum (*Figure 41.7*). An associated varus heel will amplify the problem and will need addressing with an appropriate reconstruction/osteotomy or fusion. Investigation as to whether the varus heel caused the peroneal problem or vice versa should be established or recurrence is guaranteed.

Peroneal tendon subluxation can occur spontaneously or after injury. It may be associated with the groove at the back of the fibula being too shallow to contain the peroneal tendons, but may just be secondary to a superior retinaculum tear. The patient may be able to demonstrate a tendon subluxation over the fibula. Surgical repair is usually required and involves deepening of the groove.

Tendinosis/tendinitis can be managed non-operatively, although injections have occasionally caused rupture. Surgical debridement or repair of splits/tears/ruptures is well described but has only moderate success.

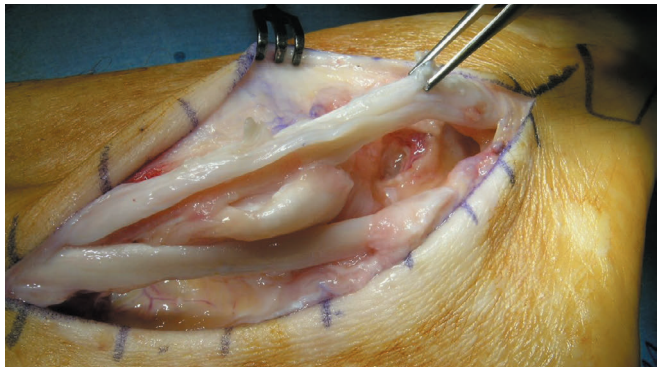

Figure 41.7 Split and degenerate peroneus brevis.

Patrik Haglund, 1870–1937, Swedish orthopaedic surgeon.

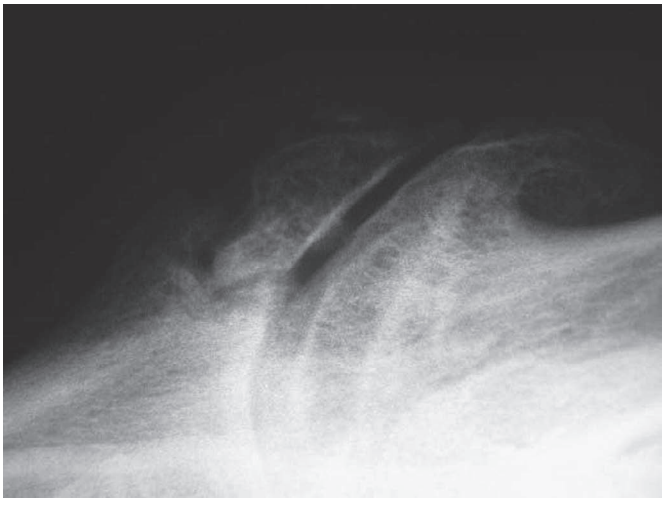

Figure 41.8 Tarsometatarsal arthritis.

Figure 41.9 A tibialis posterior tendon-deficient foot.

Acquired flat foot

There is a wide range of normal appearance of adult feet. Pathological causes of a flat foot include:

- tibialis posterior tendon dysfunction;
- tarsometatarsal arthritis/injury (***Figure 41.8***);
- Charcot neuroarthropathy, e.g. diabetes (see ***Diabetes***);
- inflammatory/degenerative arthritis of the subtalar/talonavicular/naviculocuneiform joints;
- spring ligament rupture;
- tarsal coalition.

Summary box 41.7

Acquired flat foot

- Tibialis posterior tendon dysfunction and tarsometatarsal osteoarthritis are common causes of an acquired flat foot
- Orthoses, rest and non-steroidal anti-inflammatory drugs (NSAIDs) can help with symptomatic relief
- Surgery is a major undertaking but is often highly successful at achieving symptomatic relief

The tibialis posterior tendon tends to fail in overweight individuals and those who have flat feet. Often, after unaccustomed exercise, the tendon swells and is painful. The condition occurs mainly in women; the key test, which is that the patient cannot stand on tiptoe on that leg alone, indicates a significant advanced stage tendon problem. Many individuals will require surgical treatment in the form of a medial displacement calcaneal osteotomy, flexor digitorum longus or FHL tendon transfer and spring ligament repair. Failure to treat this condition can lead to spectacular deformity (***Figure 41.9***).

An acute traumatic flat foot may develop in young athletes and military recruits after traumatic injury. Examination shows a new-onset flat foot but with a functioning tibialis posterior tendon with single-leg tiptoe preserved; here the injury is an isolated spring ligament tear and early surgery prevents late-onset secondary deformity.

Ankle instability

Most people who sustain an ankle sprain will recover, particularly if they receive prompt physiotherapy. However, some individuals develop significant instability. On examination an unstable ankle due to ligament disruption will show a marked 'anterior drawer' sign.

If physiotherapy is unsuccessful at resolving the problem, a reconstruction may be needed with ligament augmentation. Anatomical techniques such as the Broström procedure are favoured and may be supplemented with synthetic augments for early mobilisation. Peroneal tendon harvesting for reconstruction is now obsolete with the new reconstruction techniques and implants.

Other aetiologies of instability include osteochondritis dissecans (OCD) lesions, syndesmosis instability and peroneal tendon pathology.

Osteochondral lesion of the talus

Patients with persistent pain (and sometimes instability) in the ankle following an injury should be suspected of having an osteochondral lesion, with MRI or CT usually required for diagnosis.

Repair of cartilage is not yet possible and large meta-analyses of experimental techniques such as grafting, cell culture, implants and stem cells have not yet shown any statistical benefit. Debridement and microabrasion/microfracture form the mainstay of treatment. Large fragments seen early might benefit from early fixation. Juveniles seem to have a high spontaneous recovery rate and surgery should not be necessary.

L Broström, described the surgical treatment of chronic ligament ruptures in 1966.

Synovitis

Many patients have ongoing pain following ankle injury that is simply due to synovitis within the ankle joint, prominence of the syndesmotic ligament into the joint, impaction injury or undiagnosed fracture or OCD lesion. MRI is mandatory for these cases but usually misses the synovitis. Synovitis may be treated non-operatively, with an injection of steroid. Persistent symptoms may require arthroscopic debridement.

Neurological foot conditions

Pes cavus

The development of unilateral pes cavus is likely to be due to an upper motor neurone lesion, so an appropriate neurological examination should be performed and spinal imaging is mandated.

Pes cavus is usually bilateral and most cases will be associated with an underlying neurological condition, the most common being Charcot–Marie–Tooth disease. These patients may present with characteristic progressive small muscle wasting, thin calf musculature, hand symptoms, aches and pains, and cavovarus feet. Examination may show early loss of vibration sense. Precise diagnosis is confirmed with nerve conduction studies and genetic testing.

The key deforming force is always relative preservation of the tibialis posterior tendon. Surgical correction of the deformity is often required. The principal goal of treatment is to obtain a foot that can be placed flat on the ground, and with the power of the muscles around the ankle in balance. It will always be necessary to transfer the tibialis posterior tendon. The most commonly performed procedure is to transfer the tibialis posterior tendon to the dorsolateral side of the foot, with a lateralising heel osteotomy and dorsiflexion osteotomy of the first ray with or without a Jones procedure to the great toe and Hibbs procedure to the lesser toes. Older textbooks all universally relay the mistaken belief that it is peroneal overactivity that is the deforming force … it isn't!

Summary box 41.8

Pes cavus

- Pes cavus needs neurological investigation
- About 80% of cases of pes cavus are associated with a neurological disease
- The commonest cause is Charcot–Marie–Tooth disease
- Unilateral pes cavus – think diastematomyelia/tumour

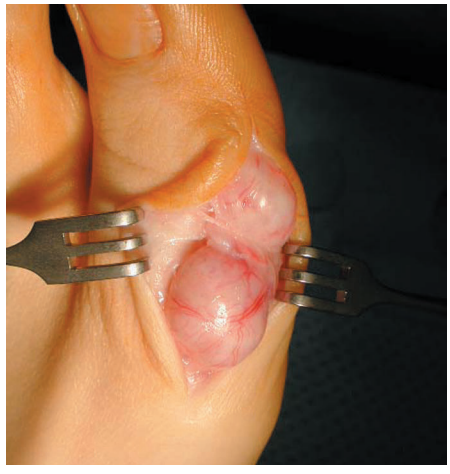

Figure 41.10 Angioleiomyoma of the hallux.

Tumours

The most common benign tumours of the foot are ganglia, giant cell tumour and angioleiomyomas (***Figure 41.10***); these tumours may need surgical excision.

Pigmented villonodular synovitis is a locally aggressive condition found in the ankle and is diagnosed by MRI or at histology. Imatinib medical therapy and en bloc resection are becoming more mainstream for cure rather than repeated arthroscopic suppression. Surveillance for recurrence is mandatory.

The most common 'tumour' seen in the foot is the plantar fibroma or Ledderhose's disease, which presents as a painful, often growing, lump in the sole along the plantar fascia. The condition is linked to Dupuytren's contracture and Peyronie's disease. Surgery should be avoided. Ultrasound or MRI will confirm the multifocal nature of the disease and exclude other pathology.

Any large or growing lump in the foot needs formal work-up along tumour guidelines, especially in the presence of night pain.

Infection

Septic arthritis in the foot or ankle is rare except in patients with diabetes and constitutes a surgical emergency; when it occurs it usually follows a surgical procedure but it can also arise as a result of haematogenous spread. Treatment is immediate surgical drainage and administration of appropriate high-dosage antibiotics once cultures are obtained.

Pierre Marie, 1853–1940, neurologist, Hospice de Bicêtre, Paris, France, later becoming Professor of Pathological Anatomy in the Faculty of Medicine, and finally, in 1918, Professor of Neurology.
Howard Henry Tooth, 1856–1925, physician, St Bartholomew's Hospital and the National Hospital for Nervous Diseases, London, UK, described peroneal muscular atrophy in 1886 independently of Charcot and Marie.
Sir Robert Jones, 1857–1933, British orthopaedic surgeon.
Russell A Hibbs, 1869–1932, Professor of Orthopedic Surgery, Columbia University, New York, NY, USA, described an operation for 'claw foot' in 1919.
Georg Ledderhose, 1855–1925, German surgeon, described this disease in 1894.
Baron Guillaume Dupuytren, 1777–1835, surgeon, Hôtel Dieu, Paris, France, described this condition in 1831.
François de la Peyronie, 1678–1747, surgeon to King Louis XIV of France and founder of the Royal Academy of Surgery, Paris, France.

The most common causative organism is *Staphylococcus aureus* with methicillin-resistant *S. aureus* (MRSA) becoming more common. Even with prompt treatment chondrolysis often occurs and subsequent degenerative changes develop rapidly.

In immunocompromised patients, opportunistic infections can arise and, in those with diabetes, failure to treat with debridement can lead to amputation. It is important to realise that radiographs in the early stages of infection are usually normal and that diagnosis is made on clinical suspicion and with blood tests and more sophisticated imaging such as MRI or bone scanning.

Tuberculosis can affect the foot and is associated with major bony damage; it responds surprisingly well to debridement and appropriate antituberculous therapy (***Figure 41.11***).

Figure 41.11 Tuberculosis of the foot (arrow).

Figure 41.12 Charcot foot: radiographs taken at the time of a trivial injury **(a)** and 6 weeks later **(b)**.

Diabetes

Patients with diabetes have foot problems secondary to neuropathy and microvascular changes. They are at increased risk of infection and ulceration, and trauma (sometimes trivial) can lead to collapse of the foot, also known as Charcot neuroarthropathy (***Figure 41.12***).

Ulceration and amputation

Ulceration can lead to major morbidity and amputation (***Figure 41.13***). Ulcers need to be treated urgently, and when ulcer healing has occurred the aim should be to keep the foot ulcer free. NICE guidelines detail optimal management pathways with urgent admission and radiological and clinical assessment in a multidisciplinary team setting, followed by debridement, antibiotics if required and formal offloading. Ulceration is a surgical emergency and mandates immediate referral along NICE guidelines in the UK. Most amputations are preceded by ulceration.

Charcot

Charcot is a condition in which patients develop a neuropathic destruction of the joints. It is often described as painless but

Figure 41.13 Diabetic foot ulcer.

actually the majority of patients have some pain. In the western world diabetes is the biggest cause but in the rest of the world leprosy is also important. However, any other neurological condition can cause this disease.

Charcot often presents with a hot, swollen, red extremity. It is often misdiagnosed as cellulitis, gout, fracture or DVT, and many present late because of the difficulty in diagnosis.

If there is no history of skin damage, infection is unlikely, but MRI and even biopsy can help differentiate between infection and Charcot. From initiation through to bone consolidation may take up to 18 months. The principle of treatment throughout is to maintain a foot-shaped foot to prevent late pressure ulcers. The acute Charcot foot requires appropriate splintage in a Charcot retaining orthotic walker (CROW) or a total contact cast (TCC), but many surgeons offer an aggressive early surgical approach if bony prominence/ulceration is thought to be inevitable. Surgical excision of a bony prominence dramatically reduces ulceration and amputation risk and reconstruction in the early phases of Charcot is now becoming more mainstream, but surgical risks are high. Long-segment fixation with implants and intramedullary nailing is now regularly undertaken. Failure of non-operative or operative treatment results in ulceration and amputation.

Summary box 41.9

Diabetes

- Patients with diabetes are prone to infection because of:
  - Peripheral neuropathy
  - Peripheral vascular disease
  - Impaired resistance to infection
- A Charcot foot is often misdiagnosed but is a surgical emergency and requires urgent admission and management
- An ulcer in a diabetic foot is a surgical emergency and requires urgent admission and management

Entrapment neuropathies

Any nerve supplying the foot can become entrapped and result in pain, and treatment often requires surgical decompression. Tarsal tunnel syndrome is much rarer than carpal tunnel syndrome and is confirmed with nerve conduction. A high proportion of patients retain neurology and pain despite release.

Heel pain

The commonest cause of heel pain is plantar fasciitis. Pain is located inferomedially within the heel and is worst first thing in the morning and after periods of rest. The majority of cases settle within 18 months and surgery is rarely required or successful. Ultrasound-guided injection or shockwave forms the mainstay of treatment for the non-resolving cases. The differential diagnosis list includes calcaneal stress fracture, tarsal tunnel syndrome, seronegative arthropathy and Ledderhose's disease.

CHAPTER

42 Musculoskeletal tumours

Learning objectives

- List the symptoms and signs associated with a musculoskeletal tumour
- Understand why a patient with a suspected musculoskeletal tumour should be referred to a specialist centre for staging, biopsy and multidisciplinary management
- Understand why staging should be completed before biopsy
- Explain why a diagnosis is required before treatment
- Understand the principles of biopsy
- Describe the principles of surgical treatment of musculoskeletal tumours
- List the aims of surgical treatment for metastatic bone disease
- Understand how to manage patients with an impending or completed pathological fracture
- Evaluate the risk of pathological fracture

INTRODUCTION

Musculoskeletal tumours include primary and secondary benign and malignant tumours of bone and soft tissue. The most common malignant tumours in bone are metastatic carcinomas (*Figure 42.1*). Advances in oncological treatment mean that the number of patients living with metastatic bone disease is increasing. The most common carcinomas that metastasise to bone originate in the breast, prostate, lung, kidney, thyroid and colon (*Figure 42.2*).

Haematopoietic tumours may also arise in bone: multiple myeloma (*Figure 42.3*) is a malignant neoplasm arising from plasma cells in the bone marrow, leading to multiple lesions in the skeleton. When solitary, this type of tumour is called a plasmacytoma.

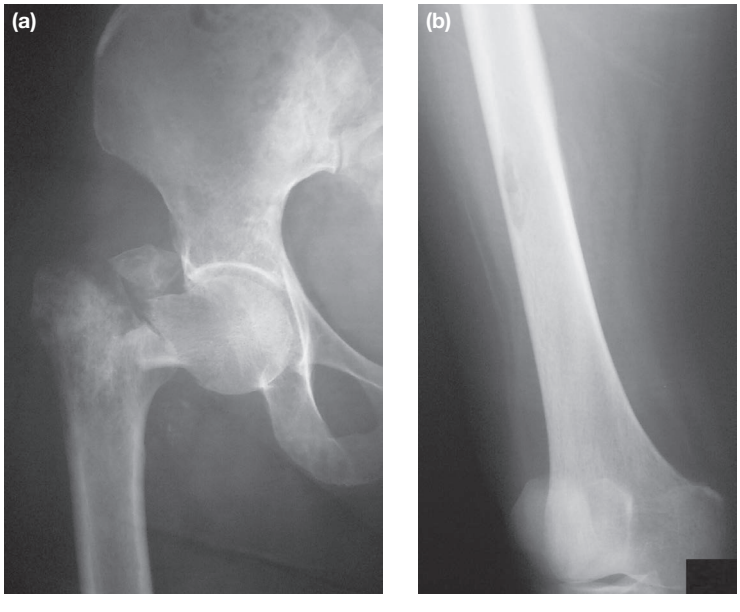

Figure 42.1 (a) Pathological fracture of the proximal femur through metastatic breast carcinoma. **(b)** Radiographs of the whole femur show a further, more distal metastatic deposit.

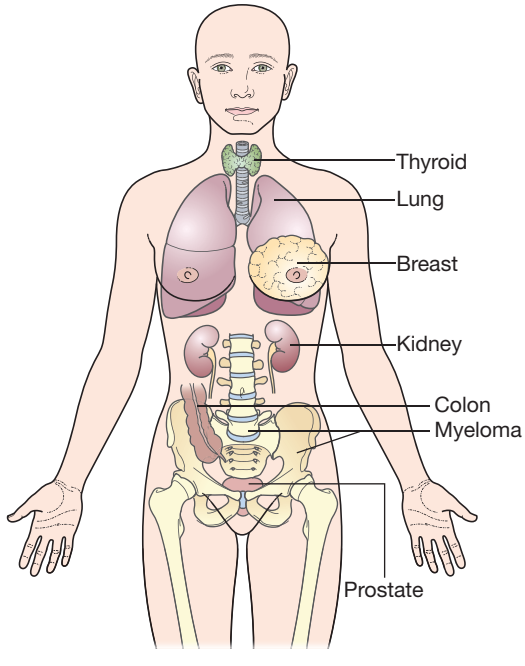

Figure 42.2 Common malignant tumours involving bone (courtesy of Mr Andy Biggs, The Robert Jones and Agnes Hunt Orthopaedic Hospital NHS Foundation Trust).

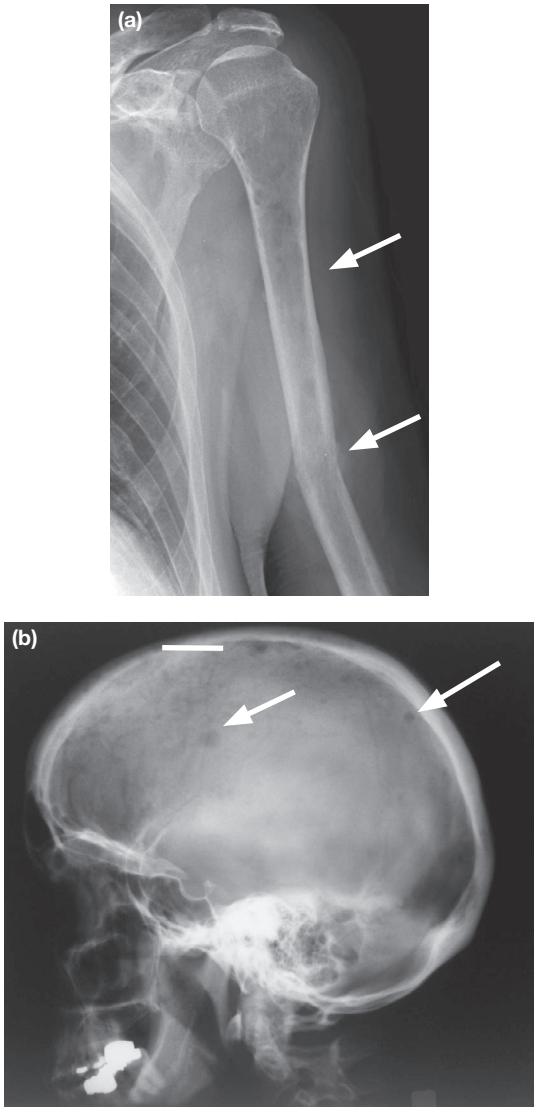

Figure 42.3 (a) Multiple myeloma affecting the left humerus with a pathological fracture (arrows). (b) Multiple myeloma with multiple deposits in the skull (arrows).

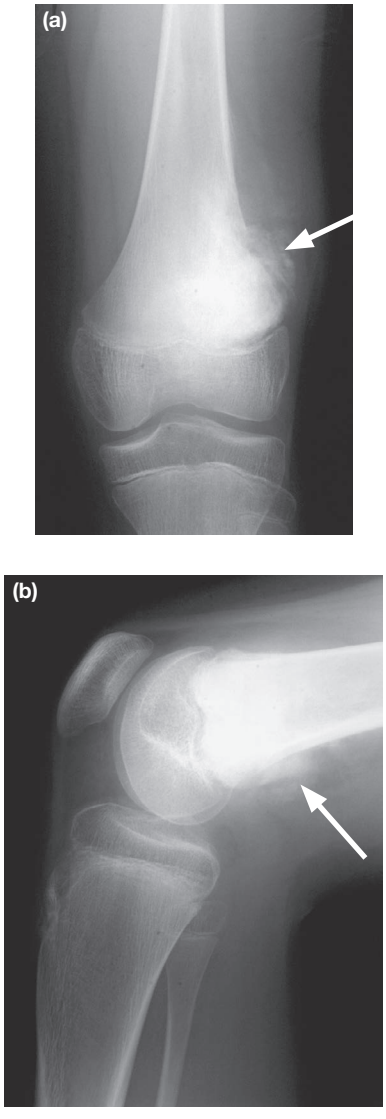

Figure 42.4 (a, b) Sclerotic osteosarcoma of the distal femur in a child (arrows).

Malignant primary bone tumours (sarcomas) are very rare, but notably can occur in children and young adults. The most common malignant primary bone tumours are osteosarcoma (*Figure 42.4*), chondrosarcoma (*Figures 42.5, 42.6 and 42.7*) and Ewing's sarcoma (*Figure 42.8*).

Soft-tissue tumours are common. However, only one in a 100 is malignant (*Figure 42.9*).

BONE TUMOURS

Tumours found in bone are classified according to their morphological appearances. These include:

- metastatic carcinomas; may show histological features of their tissue of origin;
- haematopoietic tumours; e.g. myeloma;
- osteogenic tumours; e.g. osteosarcoma;
- chondrogenic tumours; e.g. chondrosarcoma;
- others; e.g. Ewing's sarcoma.

Osteosarcoma has two age incidence peaks: one in adolescence and the other later in life. Osteosarcomas in older patients usually arise in association with Paget's disease, osteonecrosis or after radiotherapy treatment. Ewing's sarcoma occurs in adolescence, whereas the incidence of chondrosarcoma increases from middle age onwards.

Some conditions are associated with an increased likelihood of developing malignant tumours in bone and/or cartilage (*Table 42.1*).

James Ewing, 1866–1943, Professor of Pathology, Cornell University Medical College, New York, NY, USA, described this type of sarcoma in 1921.
Sir James Paget, 1814–1899, surgeon, St Bartholomew's Hospital, London, UK, described osteitis deformans in 1877.

TABLE 42.1 Conditions associated with an increased risk of malignant disease in bone and cartilage.

High risk	Moderate risk	Low risk
Maffucci syndrome (enchondromatosis and angiomas of soft tissue)	Hereditary multiple exostoses	Chronic osteomyelitis
Ollier's disease (enchondromatosis)	Polyostotic Paget's disease	Osteonecrosis
Familial retinoblastoma syndrome	Radiation osteitis	Fibrous dysplasia, osteogenesis imperfecta, osteoblastoma and chondroblastoma

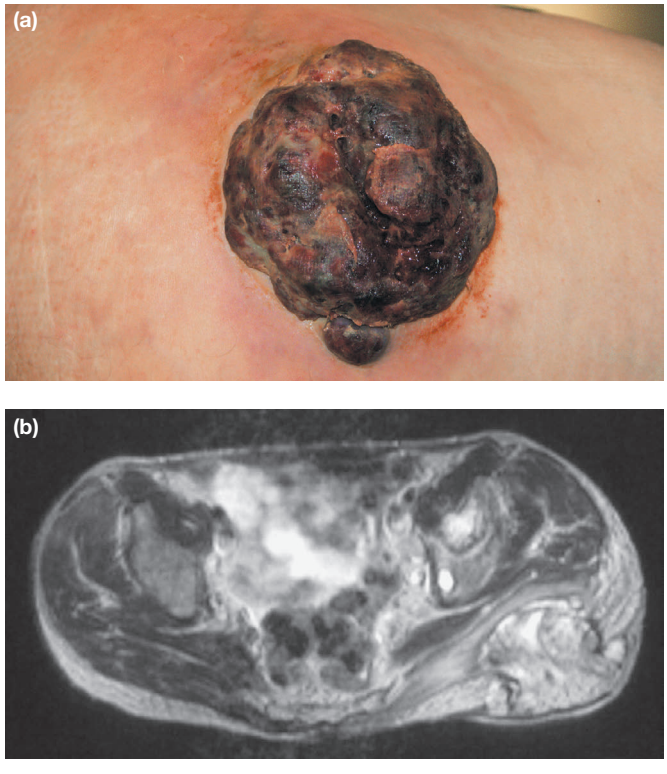

Figure 42.9 (a) Large fungating soft-tissue sarcoma of the buttock. (b) Magnetic resonance imaging scan from the same patient showing a large fungating sarcoma of the buttock.

Metastatic bone disease

Most tumours that metastasise to bone are carcinomas. Sometimes, despite further investigations, the primary tumour is never found: these patients are described as having 'carcinoma of unknown primary'. However, with advanced diagnostics and laboratory investigations the origin of most bone metastases can be identified.

Carcinomas usually spread to bone by the haematogenous route: the spine is the third most common site for metastases, after the lung and liver. Although most patients with metastatic cancer will have bone metastases in the spine before they die, only 10% are symptomatic.

Tumour cells metastasise to the spine via Batson's venous plexus. These retroperitoneal veins have no valves and allow retrograde embolic spread to the spine and proximal long bones (*Figure 42.10*).

Bone metastases can be lytic, sclerotic or mixed. Lytic metastases are usually highly vascular or locally aggressive such that there is no healing response from the bone. Metastases from prostate cancer may appear sclerotic.

Metastases are rare in children, but bone metastases can occur from neuroblastoma, rhabdomyosarcoma and clear cell carcinoma of the kidney.

Angelo Maffucci, 1847–1903, Professor of Pathological Anatomy, Pisa, Italy, described enchondromatosis in association with soft tissue haemangiomas in 1881.
Louis Xavier Edouard Léopold Ollier, 1830–1900, Professor of Surgery, Lyons, France, described enchondromatosis in 1899.
Oscar V Batson, 1894–1979, American otolaryngologist.

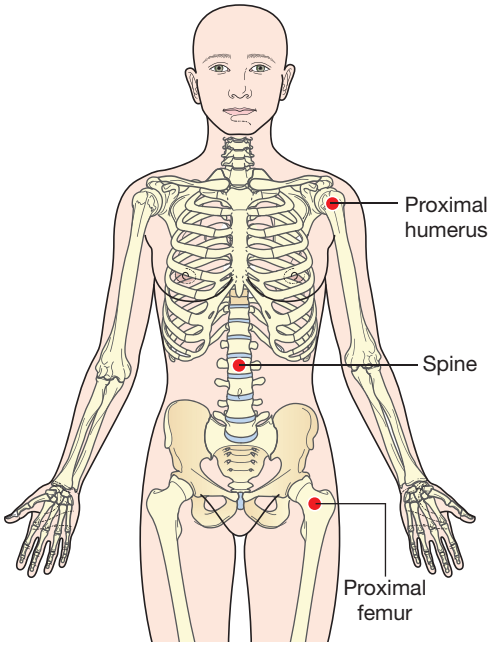

Figure 42.10 Common sites of metastatic bone disease (courtesy of Mr Andy Biggs, The Robert Jones and Agnes Hunt Orthopaedic Hospital NHS Foundation Trust).

Summary box 42.1

Most common tumours metastasising to bone (93%)

- Breast
- Prostate
- Lung
- Renal
- Thyroid
- Colon

Summary box 42.2

Most common sites of bone metastases

- Spine
- Proximal femur and pelvis
- Proximal humerus

Haematopoietic tumours

Malignant haematopoietic tumours that commonly present in orthopaedic clinics are either solitary plasmacytoma/multiple myeloma (arising from plasma cells; ***Figure 42.2***) or lymphomas (arising from lymphoid cells).

Osteogenic tumours

These tumours characteristically produce osteoid or bony matrix, which may be seen on imaging studies or on histological examination.

Osteoid osteoma (***Figures 42.11 and 42.12***) is a benign bone-forming lesion that is small but very painful. Usually, pain occurs at night and is typically relieved by non-steroidal anti-inflammatory medication. Osteoid osteomas usually occur in children and adolescents. They can arise in any bone, particularly the proximal femur, and cause a dense cortical reaction in the centre of which is a nidus (***Figure 42.12***).

Figure 42.11 Radiograph showing an osteoid osteoma of the tibial diaphysis with reactive bone formation (arrow).

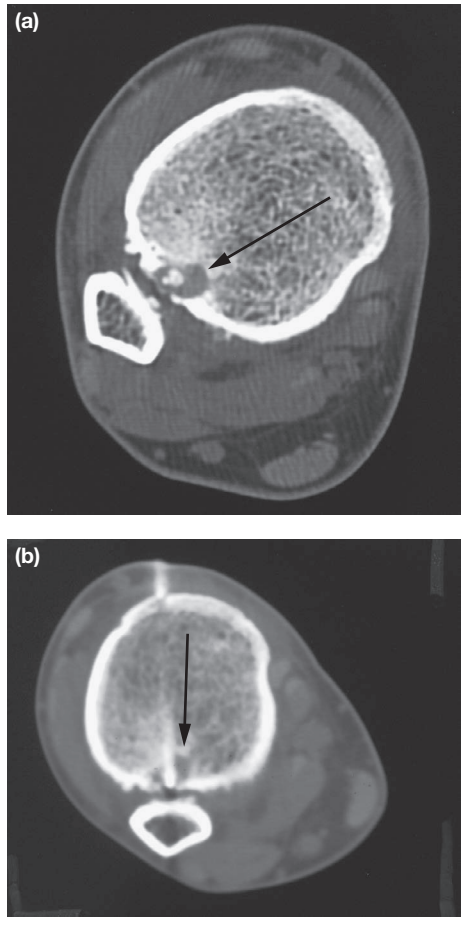

Figure 42.12 **(a)** Axial computed tomography (CT) scan showing an osteoid osteoma nidus in the distal tibia (arrow). **(b)** CT-guided radiofrequency thermocoagulation of an osteoid osteoma of the distal tibia. The scan shows the electrode *in situ* (arrow).

Summary box 42.3

Malignant bone tumours

- Plasmacytoma – solitary form of multiple myeloma
- Osteosarcoma – usually secondary to Paget's disease and radiotherapy in older patients
- Chondrosarcoma
- Ewing's sarcoma

Osteoid osteomas can cause irritation and effusions if they occur close to a joint.

Osteoblastoma is the larger (>2 cm), more aggressive counterpart of osteoid osteoma and more typically occurs in the spine.

Osteosarcoma (***Figure 42.4***) is a malignant bone-forming tumour, most common in the distal femur, followed by the proximal tibia, proximal humerus and distal tibia. The radiological and histological classification of osteosarcomas includes sclerotic (***Figure 42.4***), chondroblastic, telangiectatic and other more unusual forms. Usually, osteosarcomas are intraosseous, but they can also arise from the surface of bones. Parosteal osteosarcoma (***Figure 42.13***) is a low-grade osteosarcoma that arises from the surface of the bone, typically of the distal femur or proximal tibia. Symptoms are often mild and longstanding.

Summary box 42.4

Tumours producing bone

- Osteoid osteoma – small, painful; produce dense cortical reaction
- Osteoblastoma – larger and more aggressive than osteoid osteoma
- Osteosarcoma – malignant; commonest in lower femur and upper tibia

Chondrogenic tumours

These tumours produce chondroid matrix and include a wide range of benign and malignant tumours.

Osteochondroma (***Figures 42.14 and 42.15***) is a benign cartilage-capped bony projection, thought to originate from the physis. The bony projection always grows away from the joint towards the diaphyseal region of the bone. It has no structures attached to it. Osteochondromas can be pedunculated (with a stalk) or sessile (without a stalk). The stalk or base is always continuous with the intramedullary cavity of the bone, and the continuity of the cortex of the bone into an osteochondroma is a characteristic radiological feature. They are usually solitary, but some patients have multiple osteochondromas (hereditary multiple exostoses, autosomal dominant inheritance) (***Figure 42.16***). Osteochondromas can cause local irritation and complications include mechanical symptoms, nerve impingement, vascular pseudoaneurysm, fracture and infarction. Increasing size or pain, particularly after skeletal maturity, is concerning and may indicate malignant transformation. The incidence of malignant transformation is less than 1% in solitary osteochondromas and 1–3% in patients with multiple osteochondromas.

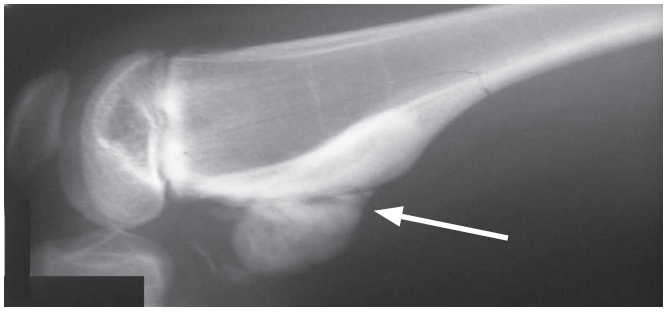

Figure 42.13 Parosteal osteosarcoma of the distal femur in an unusually young patient. There is no continuity between the tumour and the intramedullary cavity of the femur (arrow).

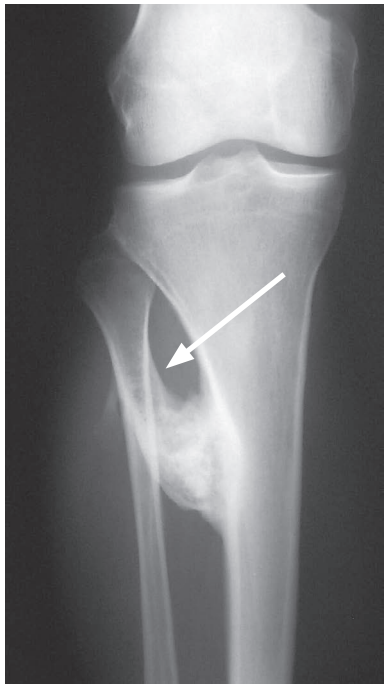

Figure 42.14 Pedunculated osteochondromas (arrow) of the proximal fibula with pseudarthrosis. Osteochondromas always grow away from the physis and are in continuity with the intramedullary cavity of the bone they arise from.

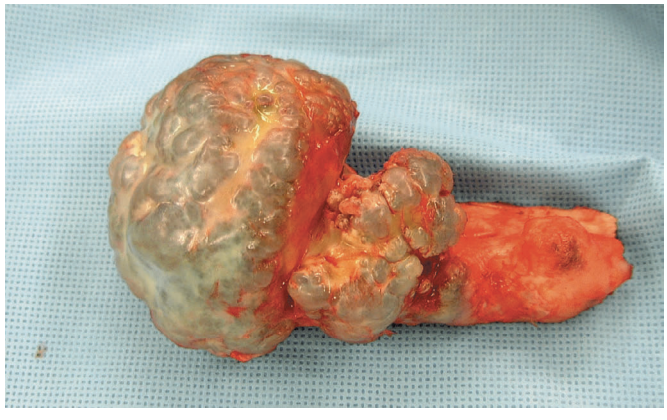

Figure 42.15 Excised pedunculated osteochondroma showing a cartilage cap.

Figure 42.16 Multiple osteochondromas in hereditary multiple exostoses. Note the multiple bone involvement and the flask-shaped femoral metaphyses.

Figure 42.17 (a, b) Calcification and pathological fracture in a benign enchondroma of the proximal phalanx of the ring finger (arrows).

Enchondroma (*Figure 42.17*) is a benign cartilaginous neoplasm within the intramedullary cavity of bone. Approximately 50% are in the hands and feet: enchondromas are the most common bone tumours in the hand. Although they can present with pain, swelling or pathological fracture, many are entirely asymptomatic and are detected incidentally. Patchy calcification, expansion and scalloping can be visible on radiographs, but some are only diagnosed on magnetic resonance imaging (MRI) scan.

Ollier's disease is a developmental condition characterised by multiple enchondromas. In Maffucci syndrome, multiple enchondromas are associated with multiple angiomas. Malignant transformation to chondrosarcoma can occur in approximately 20% of patients with Ollier's disease and is almost inevitable in patients with Maffucci syndrome.

Chondroblastoma (*Figure 42.18*) is a benign cartilage-producing tumour that occurs in the epiphyses of bones in children. It is most common around the knee. Pain is often severe, with associated inflammation and possibly joint effusion. On plain radiographs, there is an often barely visible lytic lesion in the centre of the epiphysis. Previously, the diagnosis was often missed, but this has become less frequent with MRI scanning, which usually identifies the lesion with an intense inflammatory response.

Chondrosarcoma (*Figures 42.5, 42.6 and 42.7*) is a malignant tumour with cartilage differentiation. The biological behaviour ranges from very low-grade lesions to highly aggressive dedifferentiated tumours. Patients usually present with pain and/or swelling and symptoms may be longstanding. Many chondrosarcomas arise in pre-existing lesions such as osteochondromas or enchondromas. Diagnosis of a chondrosarcoma requires clinical, radiological and pathological correlation. Clear cell chondrosarcoma is a rare form of chondrosarcoma that occurs in the epiphysis (*Figure 42.19*).

Summary box 42.5

Tumours producing cartilage

- Osteochondroma – cartilage capped; grows away from physis
- Enchondroma – inside bone; commonest in hands and feet
- Chondroblastoma – in epiphyses of adolescents
- Chondrosarcoma – of varying malignancy

Others

Simple (unicameral) bone cyst (*Figure 42.20*) is a membrane-lined cavity filled with serous fluid within a bone. It usually occurs in the proximal long bones of children. Associated thinning of the cortex of the bone can lead to fracture. Such fractures usually heal with conservative treatment, but the cyst may only partially resolve.

Aneurysmal bone cyst (*Figure 42.21*) is a benign cystic lesion of bone consisting of blood-filled spaces separated by fibrous septa. The lesion is more aggressive than a simple bone cyst and often presents with pain and swelling. Plain radiographs commonly show aggressive features with eccentric expansion of the cortex and an open physis. Scans often show multiple fluid levels (*Figure 42.21b*).

Giant cell tumour of bone (*Figure 42.22*) is a locally aggressive tumour with large osteoclast-like giant cells. It usually occurs between the ages of 20 and 45, after the physes have closed. Giant cell tumour of bone typically extends into the epiphysis of long bones and erodes bone under the articular cartilage, especially around the knee, proximal humerus and distal radius. 'Benign' metastases are rare.

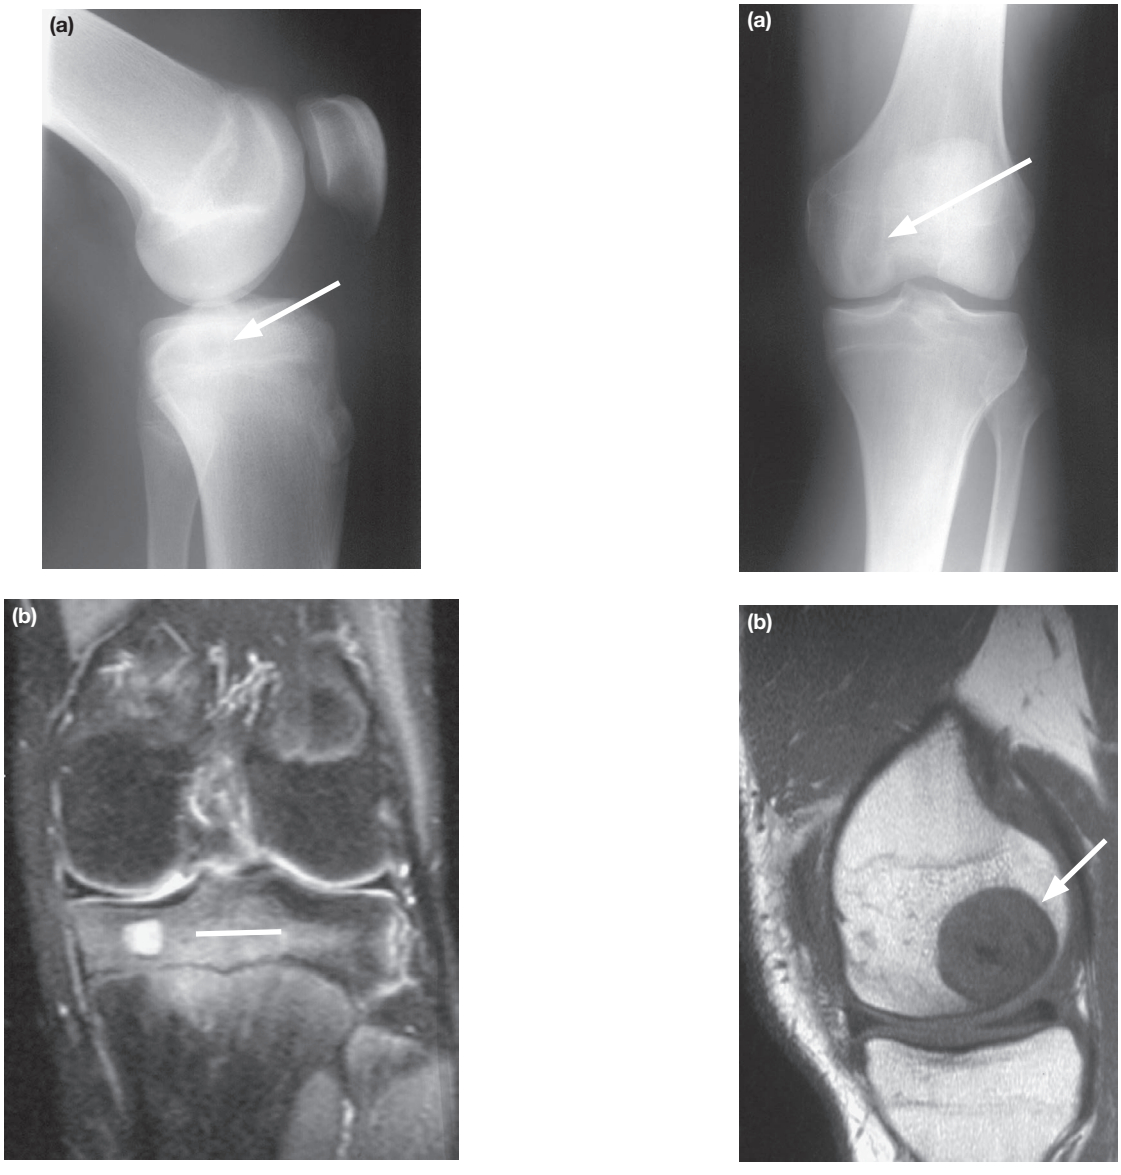

Figure 42.18 (a) Lateral radiograph with a barely visible chondroblastoma in the epiphysis of the proximal tibia (arrow). (b) Coronal T2-weighted magnetic resonance imaging scan showing a chondroblastoma (arrow) in the epiphysis of the proximal tibia with surrounding oedema. (c) Sagittal computed tomography reconstruction showing calcification within a chondroblastoma (arrow) of the proximal tibial epiphysis.

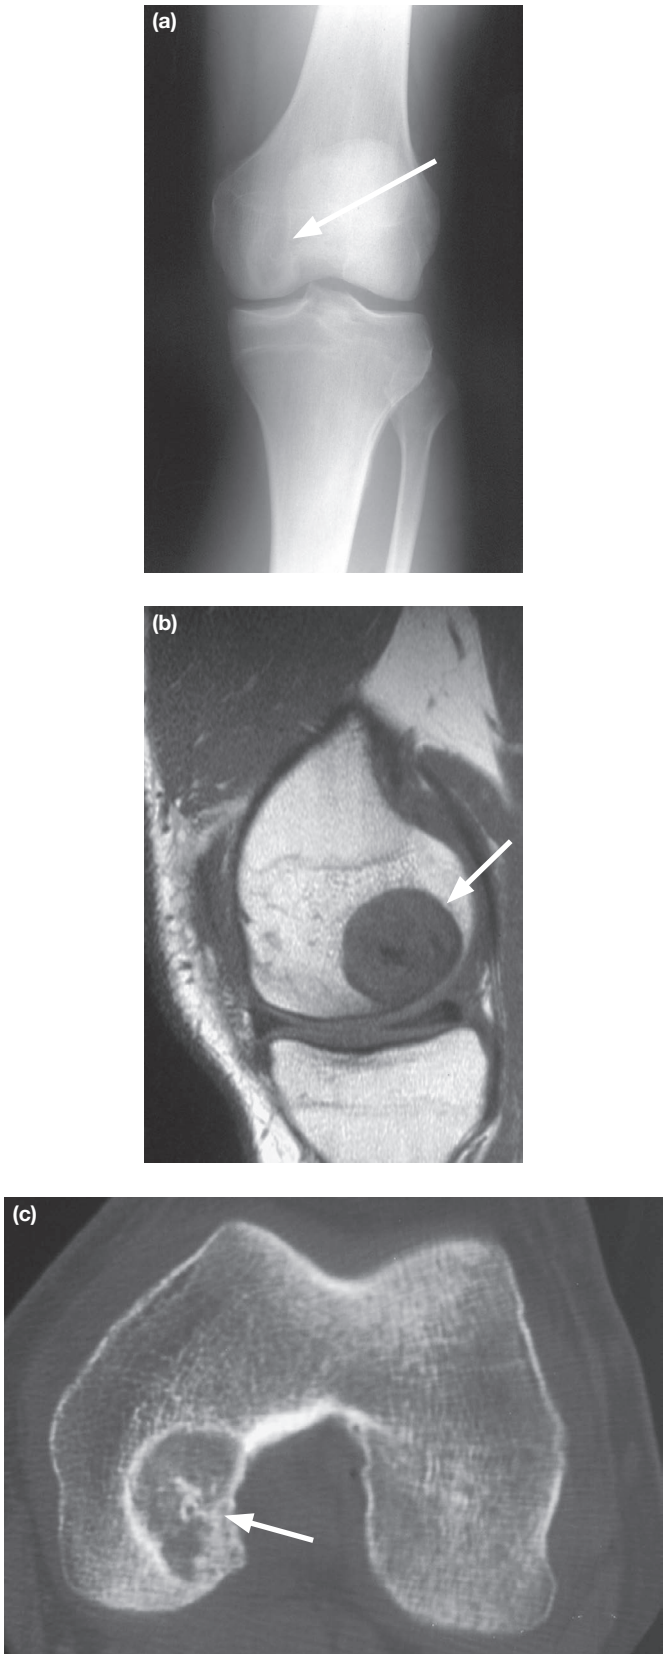

Figure 42.19 (a) Clear cell chondrosarcoma of the medial femoral condyle (arrow). (b) Sagittal T1-weighted magnetic resonance imaging scan showing a clear cell chondrosarcoma (arrow) in the medial femoral condyle. (c) Computed tomography scan reconstruction shows calcification (arrow) within the lesion.

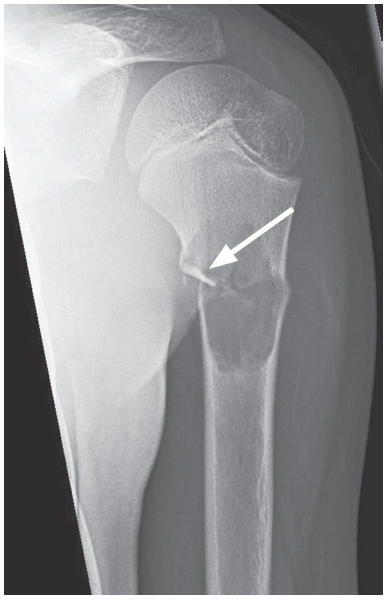

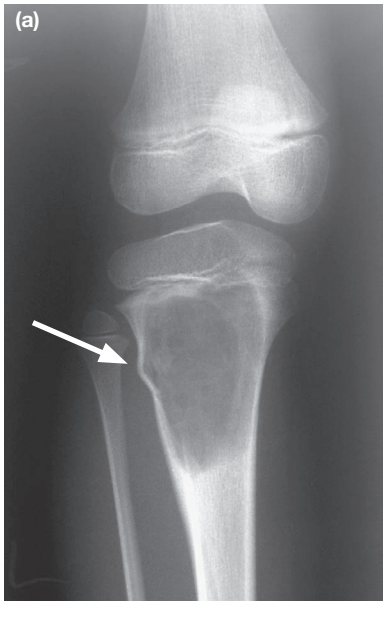

Figure 42.20 Pathological fracture through a simple bone cyst (arrow) with the pathognomonic fallen leaf sign. The fracture healed and the cyst consolidated without operative intervention.

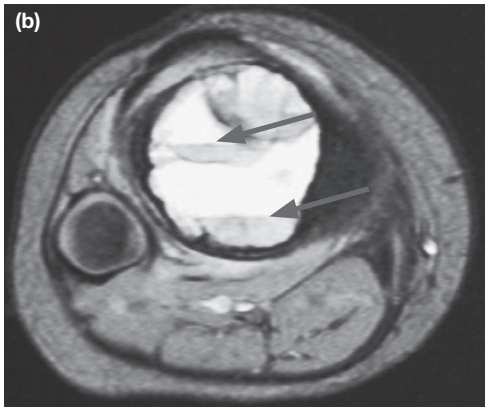
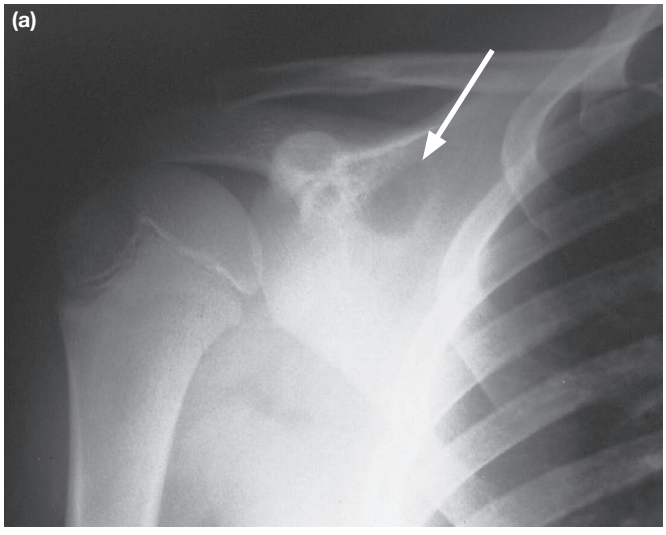
Eosinophilic granuloma is a rare neoplasm of Langerhans cells (*Figure 42.23*). It can be unifocal (eosinophilic granuloma), multifocal (Hand–Schüller–Christian disease) or disseminated (Letterer–Siwe disease). There is a predilection for the skull and the diaphyses of long bones. In the spine it can present with collapse, known as vertebra plana. The radiographic appearance can be aggressive and similar to Ewing's sarcoma.

Fibrous dysplasia (*Figure 42.24*) is a benign, developmental, fibro-osseous lesion that can be mono- or polyostotic. It usually affects the long bones, ribs and skull. Patients can present with pain, swelling and/or fracture, but many lesions are detected incidentally. Hip fractures can produce a 'shepherd's crook' deformity of the proximal femur. Radiologically there is often expansion and a ground-glass appearance, sometimes with cystic change.

Ewing's sarcoma (*Figure 42.8*) is a malignant round cell sarcoma of bone in which cells usually have a characteristic 11:22 translocation. However, other mutations have been described. It tends to arise in the diaphysis of a long bone, pelvis or scapula. Patients usually present with a painful mass and may have systemic symptoms, including fever, anaemia and increased erythrocyte sedimentation rate (ESR). Radiologically the bone appears moth-eaten and may show an 'onion skin' periosteal reaction. MRI may show a large extraosseous soft-tissue mass as well as significant inflammation with oedema.

Bone tumours usually occur in characteristic anatomical locations (*Table 42.2*), and epiphyseal tumours are likely to be benign (*Table 42.3*).





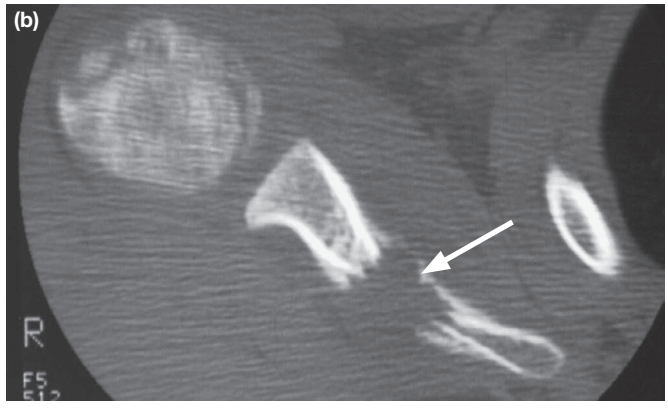


Figure 42.21 (a) Aneurysmal bone cyst with pathological fracture (arrow) of the proximal tibia. (b) Magnetic resonance imaging scan shows multiple fluid levels (arrows).

Figure 42.22 Giant cell tumour of the distal radius (arrow). Note the classic epiphyseal/metaphyseal location with subarticular involvement, as well as a permeative margin proximally in the radius indicating locally aggressive behaviour.

Paul Langerhans, 1847–1888, Professor of Pathological Anatomy, Freiberg, Germany.
Alfred Hand Jr, 1868–1949, American pediatrician, described the eponymous disease in 1893.
Artur Schüller, 1874–1957, Austrian neuroradiologist, described the eponymous disease in 1915.
Henry A Christian, 1876–1951, American physician, described the eponymous disease in 1919.
Erich Letterer, 1895–1982, German pathologist.
Sture A Siwe, 1897–1966, Swedish paediatrician.

TABLE 42.2 Classification of bone tumours by site.

Site	Tumour
Diaphyseal	• Eosinophilic granuloma • Osteoid osteoma • Fibrous dysplasia • Adamantinoma • Ewing's sarcoma
Metaphyseal	• Most
Epiphyseal	• Chondroblastoma • Intra-articular osteoid osteoma • Giant cell tumour (physis closed) • Clear cell chondrosarcoma

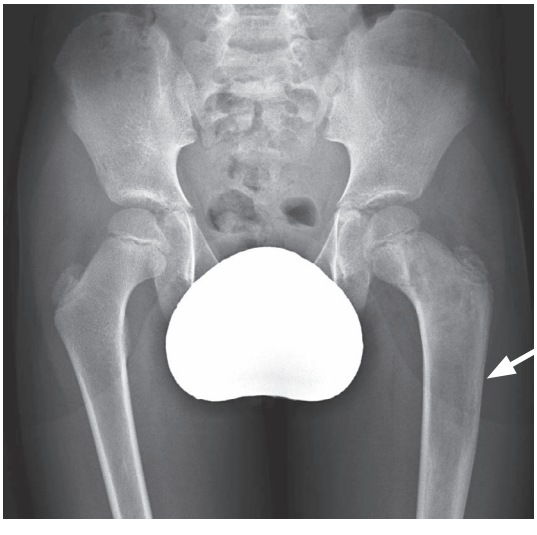

Figure 42.24 Fibrous dysplasia affecting the left proximal femur (arrow). There is expansion of the bone with a ground-glass appearance.

TABLE 42.3 Common diaphyseal bone tumours according to age.

Age	Most common diaphyseal tumour
<10 years	Eosinophilic granuloma
Teenage	Ewing's sarcoma
Adult	Lymphoma
>60 years	Metastasis/myeloma

Summary box 42.6

Other bone tumours

- Simple bone cyst – proximal long bones of children
- Aneurysmal bone cyst – more aggressive, expanding
- Giant cell tumour – found in epiphyses around the knee
- Fibrous dysplasia – may be multiple; long bones, ribs and skull
- Ewing's – round cell sarcoma; patients may have fever and anaemia

Staging of primary bone tumours

In the Enneking system, benign tumours are staged as:

- latent (e.g. osteochondroma);
- active (e.g. osteoid osteoma);
- aggressive (e.g. giant cell tumour).

William F Enneking, 1926–2014, American orthopedic oncologist.

Latent lesions are usually asymptomatic and often discovered incidentally. Active lesions, such as osteoid osteoma, present with mild symptoms and continue to grow. Aggressive lesions tend to grow rapidly and destroy bone.

The Enneking staging system for malignant tumours combines the local extent of the tumour and the histological grade (***Table 42.4***). The compartment is the bone in which the tumour arises. A tumour is extracompartmental when it has breached the cortex of the bone. Most primary malignant bone tumours are Enneking stage 2B at diagnosis, meaning they have extended outside the bone of origin but metastases are not detectable. The American Joint Committee on Cancer (AJCC)/Union for International Cancer Control (UICC) staging system is also widely used.

TABLE 42.4 The Enneking staging system for bone tumours.

Low grade	Intracompartmental	1A
	Extracompartmental	1B
High grade	Intracompartmental	2A
	Extracompartmental	2B
Any grade	Metastases	3

Summary box 42.7

Warning signs – bone tumour

- Non-mechanical bone pain
- Especially around the knee in young adolescents
- Concerning radiographs

SOFT-TISSUE TUMOURS

Soft-tissue tumours have also historically been classified according to their morphological appearance and presumed cell of origin. The range of biological behaviour is wide and most morphological types have a benign and malignant counterpart, for example lipoma (***Figure 42.25***) and liposarcoma. Other more frequent types include undifferentiated pleomorphic sarcoma and synovial sarcoma. Patients with suspected or confirmed soft-tissue sarcomas should be assessed and managed in a specialist centre.

Summary box 42.8

Warning signs – soft-tissue tumour

- Larger than 5 cm
- Increasing in size
- Painful
- Deep to the fascia
- Recurrence after previous excision

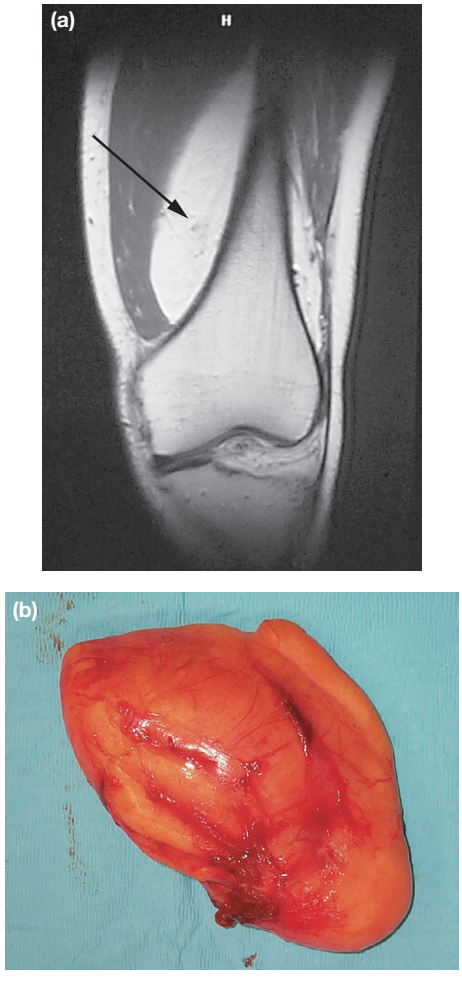

Figure 42.25 (a) Coronal T1-weighted magnetic resonance imaging scan showing a benign lipoma deep to the quadriceps muscle (arrow). **(b)** Excised benign lipoma.

The Trojani system, based on tumour differentiation, mitotic count and tumour necrosis, is the standard for grading malignant soft tissue tumours. The AJCC / UICC system is used to stage malignant soft tissue tumours.

EVALUATION AND INVESTIGATION OF THE PATIENT WITH A SUSPECTED BONE OR SOFT-TISSUE TUMOUR

The diagnosis and treatment of patients with primary bone and/or soft-tissue tumours requires a high index of suspicion, appropriate and prompt investigation, and early referral to a specialist multidisciplinary team for diagnosis, biopsy and appropriate treatment. When a musculoskeletal tumour is suspected, clinicians should:

- stop;
- think;
- investigate.

Monique Trojani, contemporary, described the histopathological grading system in 1984.

The assessment and investigation of any patient with a bone or soft-tissue tumour can be divided into three phases. The first two phases can be performed at the referring hospital, but the third phase may be best done in a specialist centre (*Table 42.5*).

TABLE 42.5 The three phases of assessment of lesions.

Phase 1 (within 24 hours)	Phase 2 (within first week)	Phase 3 (at specialist centre)
• History and examination • Blood tests • Radiograph whole bone • Chest radiograph	• Bone scan • Ultrasound scan abdomen • CT scan chest	• CT scan lesion • MRI scan lesion • Biopsy

CT, computed tomography; MRI, magnetic resonance imaging.

History and examination

It is important to take a thorough history, including a pain history. Non-mechanical and/or night pain, particularly in the young adolescent, is a concerning symptom and a primary bone tumour should be suspected. Relief with non-steroidal anti-inflammatory drugs may suggest an osteoid osteoma.

Patients with a history of malignancy who present with back pain should be considered to have metastatic bone disease until proven otherwise. Plain radiographs of the spine and routine blood tests are the minimum that is required. An MRI of the spine is a more sensitive test for the detection of a malignant tumour and may demonstrate soft-tissue extension into the spinal canal. Multiple myeloma (*Figure 42.3*) is the most common primary malignancy of bone in adults and should be considered in all patients over 65 years of age with back pain. Back pain associated with an ESR >100 mm/h indicates multiple myeloma until proven otherwise. Monoclonal gammopathy or elevated urinary and serum Bence Jones proteins are diagnostic. All patients with suspected cancer in the spine should be examined for signs of spinal cord compression, a potential surgical emergency.

Great care should be taken when managing a patient with an apparently 'solitary' bone metastasis. This could be a primary bone tumour, and further investigation including biopsy is required.

Soft-tissue tumours are common and the vast majority are benign. However, a soft-tissue mass meeting any of the following criteria may be malignant and the patient should be referred to a specialist centre:

- painful;
- increasing in size;
- more than 5 cm in diameter.

In addition, tumours that have recurred after previous excision and tumours located deep to the fascia are more likely to be malignant. It is important to note that tumours that appear mostly superficial but involve the deep fascia are classified as deep tumours.

Investigation

The investigation of a patient with a suspected primary bone or soft-tissue tumour should include the following.

- Local investigations:
  - ultrasound scan (for soft-tissue tumours);
  - plain radiographs of the whole affected bone or soft-tissue lesion (*Figure 42.1*);
  - MRI of the whole affected bone or soft-tissue mass;
  - computed tomography (CT) scan may be helpful in addition to an MRI scan.
- Distant:
  - blood tests, including full blood count, ESR, urea and electrolytes, bone profile and protein electrophoresis;
  - plain radiographs or CT scan of the chest (more sensitive);
  - whole-body isotope bone scan (for suspected primary or metastatic bone tumours);
  - ultrasound or CT scan of the abdomen (if renal metastasis is a possibility).

Plain radiographs are usually the most useful imaging investigations in determining the diagnosis of a primary bone tumour, but further appropriate scans are usually required for confirmation and staging. Imaging should always include the whole of the affected bone to look for satellite lesions and skip metastases. Satellite lesions occur within, whereas skip lesions occur beyond, the reactive zone of the tumour, which is the layer of compressed tissues, inflammatory cells and tumour infiltration that surrounds the tumour.

Both primary bone and soft-tissue sarcomas metastasise to the lungs, and a CT scan of the chest is an essential part of staging.

Patients who present with a lytic bone lesion could have a primary renal carcinoma and an ultrasound or CT scan of the abdomen is advised. Surgery to a renal metastasis can lead to significant blood loss.

Summary box 42.9

Staging

- Plain radiography is most informative for bone tumours
- Always image the whole bone in the case of skip lesions
- CT of the lung detects lung metastases
- Lytic lesions require imaging of the abdomen to check for a primary renal carcinoma

Biopsy

A biopsy is performed only when local staging investigations have been completed. Because removal of the biopsy track is an important principle in the treatment of sarcomas, and specialist pathology is required, biopsies should be performed either in, or after consultation with, the specialist centre where the definitive surgical procedure will be performed.

Henry Bence Jones, 1813–1873, physician, St George's Hospital, London, UK.

Image-guided biopsies (usually ultrasound- or CT-guided) have a higher diagnostic accuracy because areas of radiological concern can be targeted. If image-guided biopsy is performed, close discussion between radiologist and surgeon is required to ensure an appropriate biopsy route is used (***Figures 42.26 and 42.27***).

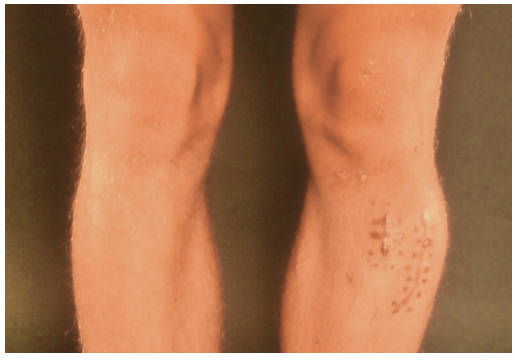

Figure 42.26 Poorly placed biopsies can make subsequent surgical excision of the track difficult or not possible.

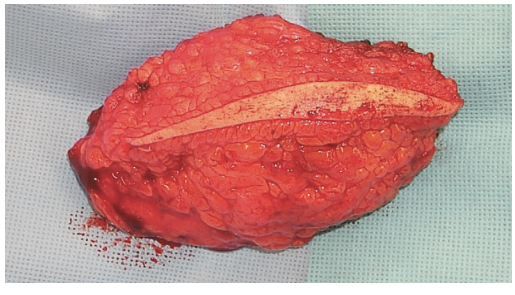

Figure 42.27 *En bloc* excised tumour and biopsy track.

Summary box 42.10

Biopsy

- Only biopsy once local staging is completed
- Biopsy should be performed at, or after discussion with, the specialist centre
- Image-guided biopsy is more reliable
- The biopsy track should be excised at definitive surgery
- Jamshidi needles for bone; Trucut needles for soft tissues

Biopsies for bone tumours are usually taken using a Jamshidi or other hollow needle (***Figure 42.28***), while Trucut needles are preferred for soft-tissue tumours.

Although most biopsies are performed with a needle, sometimes an open biopsy is required, which should be performed according to the following principles.

- A tourniquet can be used; but exsanguination by compression should be avoided as this may disseminate the tumour.

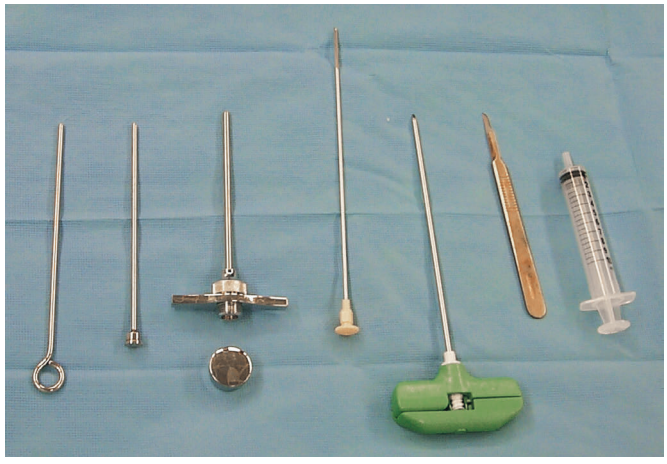

Figure 42.28 Bone biopsy instruments.

- Use longitudinal incisions that are part of an extensile approach.
- Do not cross anatomical compartments or contaminate critical anatomical structures (e.g. nerves or blood vessels).
- Use a biopsy track that can be excised at the time of definitive surgery.
- Ensure specimens are sent for microbiology as well as histopathology.
- Some specimens should be sent fresh to the laboratory for genetic studies.

PRINCIPLES OF TREATMENT

Primary bone tumours

Benign

Most latent and active benign bone tumours that need treatment are treated by intralesional curettage. Packing of the cavity with a graft or bone substitutes is usually not required.

Simple bone cysts can heal following pathological fracture and an initial conservative approach following fracture is best. If the cyst persists following union of the fracture, and the risk of further fracture is deemed to be high, then a variety of treatments, including injection with steroid or bone marrow and surgical curettage, have been described.

Osteoid osteomas can resolve spontaneously. However, symptoms are often pronounced, and most patients are treated by CT-guided thermocoagulation. Surgical removal (which usually requires burring down onto the surface of the nidus and removing it) is seldom required.

Large or more rapidly growing benign bone tumours may require more extensive surgical excision and reconstruction. Giant cell tumours of bone are associated with a high local recurrence rate and are usually treated with thorough curettage or, when very extensive, surgical resection of the affected bone. The RANK-ligand (receptor activator of nuclear factor ligand) antibody denosumab has an evolving role in treating these tumours.

En bloc is French for 'in a block'.
Khosrow Jamshidi, contemporary, Iranian haematologist.

Malignant tumours

Malignant primary bone tumours require a multidisciplinary approach that may include chemotherapy and radiotherapy as well as surgery. Osteosarcoma and Ewing's sarcoma are treated with neoadjuvant (before surgery) chemotherapy and surgery. Chondrosarcomas are not sensitive to chemotherapy or radiotherapy and treatment is surgical excision where possible.

The aim of surgery for a primary malignant bone tumour is to remove it completely (usually with a layer of normal tissue around it that includes the biopsy track) and then to reconstruct the limb to maximise physical function.

Following excision the surgical margins can be classified as shown in *Table 42.6*.

TABLE 42.6 Classification of surgical resection margins.

Intralesional	Resection through the tumour
Marginal	Resection through the reactive zone of the tumour
Wide	Resection outside the reactive zone of the tumour
Radical	Resection of the whole anatomical compartment

In most cases, limb salvage with excision and reconstruction is possible (*Figure 42.29*). Only a minority of patients (10–15%) require primary amputation, either because of neurovascular invasion or because the reconstructed limb may be less functional than an amputation (e.g. for some tumours in the foot and ankle). Limb salvage is associated with a slightly higher rate of local recurrence than amputation. However, no difference in overall survival has been demonstrated. The surgical options for malignant primary bone tumours include:

- amputation or van Nes rotationplasty;
- excision alone (for dispensable bones, e.g. the fibula, or areas where reconstruction is difficult, e.g. in parts of the pelvis);
- excision and reconstruction with a structural graft or massive endoprosthesis.

The complications of massive endoprosthetic reconstruction of a limb include infection, instability and wear or loosening of the prosthesis.

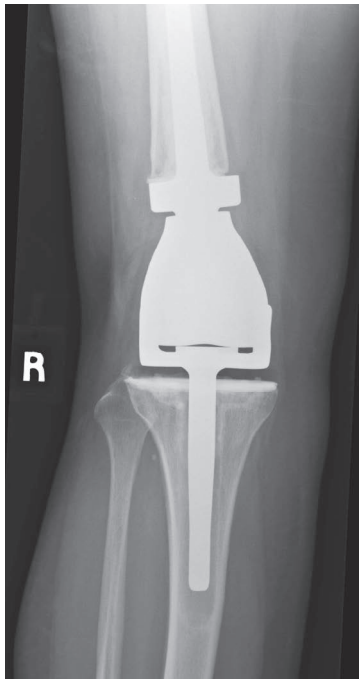

Figure 42.29 Endoprosthetic replacement of the distal femur.

Summary box 42.11

Treatment of benign bone tumours

- Benign lesions can usually be simply curetted
- CT-guided thermocoagulation is used for osteoid osteoma
- Large benign tumours may require reconstruction

Summary box 42.12

Treatment of malignant bone tumours

- Osteosarcomas and Ewing's sarcoma require neoadjuvant chemotherapy
- Chondrosarcomas are insensitive to radiotherapy or chemotherapy
- Most malignant tumours can be treated with limb salvage
- There is no difference in survival between amputation and limb salvage

Metastatic bone disease

Patients with confirmed metastatic bone disease may require resuscitation for electrolyte imbalance, anaemia, cardiorespiratory problems or hypercalcaemia before surgical treatment can be considered. Hypercalcaemia can be treated effectively with fluid resuscitation and bisphosphonate infusion.

Surgical treatment in patients with metastatic bone disease is usually palliative; although complete resection of solitary metastases in selected patients may confer some survival benefit, the evidence for this is not strong.

Surgery of the spine may be required for stabilisation and/or decompression when tumour extension puts the spinal cord at risk. Surgery in the peripheral skeleton is mainly for treatment of pain and (impending) pathological fracture.

Renal metastases tend to be very vascular and massive blood loss can be encountered during surgery. Therefore, preoperative embolisation should be considered just before surgery to prevent blood loss (*Figure 42.30*).

Treatment of myeloma is mainly haematological. Non-surgical treatments including radiotherapy can lead to healing

Cornelis Pieter van Nes, 1897–1972, Dutch orthopaedic surgeon, who practised in Leiden and described rotationplasty in 1950.

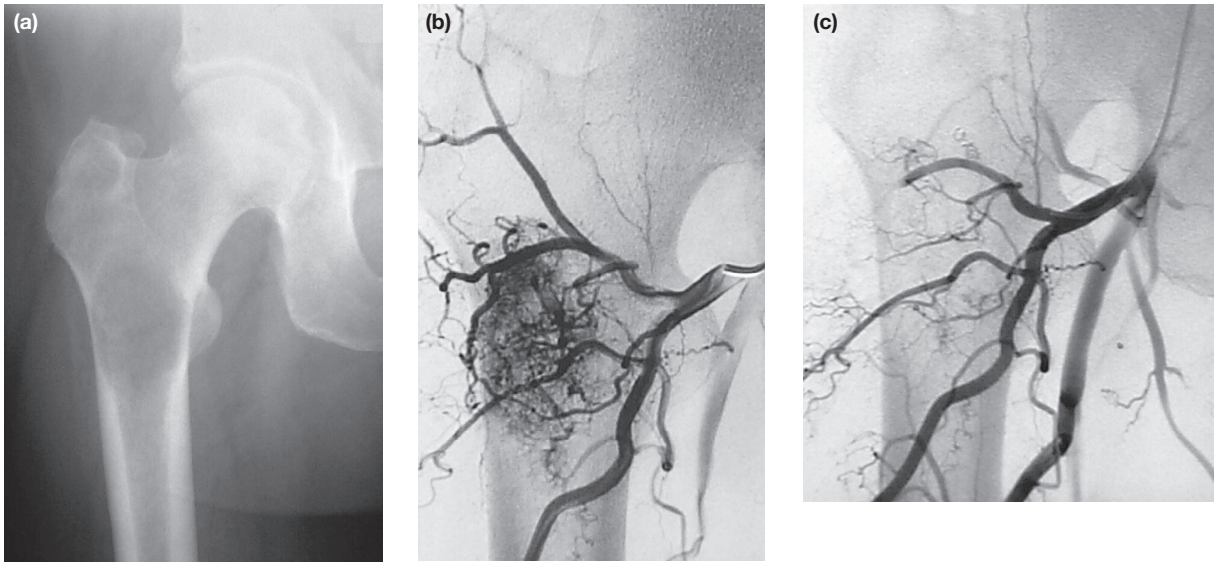

Figure 42.30 (a) Lytic metastasis of renal cell carcinoma. **(b)** Angiogram shows increased vascularity. **(c)** Following embolisation.

of bone lesions in some cases. Surgical treatment is often required for complications such as fracture and spinal cord compression.

The following factors should be considered when contemplating surgical treatment for patients with metastatic bone disease:

- likely survival (*Figure 42.31*) – consider the primary diagnosis and performance status;
- quality of life;
- fitness for anaesthesia and surgery;
- fracture risk;
- single or multiple bone lesions;
- response to adjuvant treatment such as radiotherapy and hormonal treatment;
- radiotherapy can be administered pre- or postoperatively.

The risk of pathological fracture can be assessed using the Mirels score (*Table 42.7*). However, this scoring system is prone to inter- and intraobserver variation.

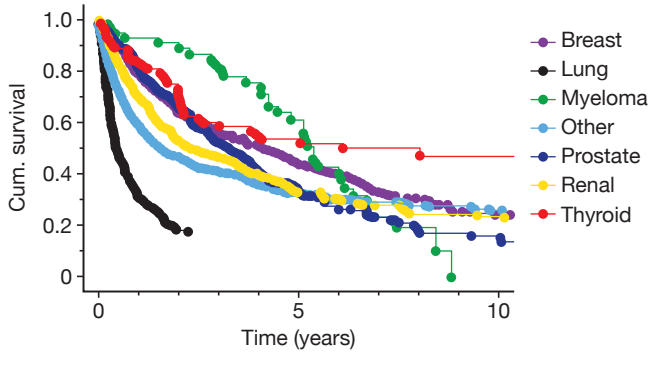

Figure 42.31 Cumulative survival curves of patients who present with bony metastasis.

TABLE 42.7 The Mirels scoring system for risk of pathological fracture.

	Score		
	1	2	3
Site	Upper limb	Lower limb	Peritrochanteric
Pain	Mild	Moderate	Functional
Size	<1/3	1/3–2/3	>2/3
Lesion	Blastic	Mixed	Lytic

Score >8, high risk of fracture – urgent prophylactic fixation should be considered; score <8, low risk of fracture – orthopaedic intervention may not be required.

Bone healing following a fracture through a metastasis is unpredictable and there can be local recurrence of the tumour after treatment. The approach is therefore different from the treatment of other fractures. The aim of surgery should be to improve pain and maintain mobility. Approaches that require prolonged protected weight-bearing to allow healing are not appropriate in this group of patients with reduced life expectancy. Therefore, as a general rule, prosthetic replacement of bones is preferred, particularly for epiphyseal and metaphyseal lesions. Metastases in the diaphysis may be most appropriately treated with an intramedullary nail. In the shoulder, prosthetic replacements have a poor function and internal fixation may give better physical functioning. However, for hip lesions, the best treatment is often replacement surgery.

Patients with solitary breast and renal metastases can have prolonged disease-free survival, so excision and replacement rather than fixation should be considered.

Hilton Mirels, contemporary, South African orthopaedic surgeon who now practises in the USA.

Summary box 42.13

Treatment of bone metastases

- Surgery cannot lengthen life but may shorten it
- The spine may need to be stabilised and nerves or the cord decompressing
- Long bones will need to be stabilised if a pathological fracture is imminent
- Patients who have a possibility of long-term survival may need excision and prosthetic reconstruction
- Radiotherapy often relieves pain

Soft-tissue tumours

The treatment of soft-tissue tumours should take account of tumour type and the response to other treatments including radiotherapy. Large low-grade or benign lipomatous tumours may be excised in a deliberately marginal or close but complete fashion. Soft-tissue sarcomas should however be excised with a margin of normal tissue around them, which includes the biopsy track, wherever possible (***Figure 42.27***). Skin involvement may require resection of the skin and reconstruction with a split-skin graft or skin flap.

Following surgical excision of high-grade soft-tissue sarcomas, adjuvant radiotherapy should be considered. Preoperative radiotherapy can also have good results, but there is a risk of wound-healing problems following surgery. Chemotherapy has a limited role in the treatment of soft-tissue sarcomas.

PART 5 | Elective orthopaedics

CHAPTER 43

Infection of the bones and joints

Learning objectives

To understand:

- Characteristic features of septic arthritis, acute and chronic osteomyelitis and implant infections
- Diagnostic principles in bone and joint infection
- Treatment of infection of native bones and joints
- Treatment of fracture-related and prosthetic joint infections

INTRODUCTION

Osteomyelitis is an old disease, identified in dinosaur bones, early hominids and skeletons from ancient civilisations. It is named from the components of the disease (*osteo*, bone; *myelos*, marrow; *itis*, inflammation; Greek) and is caused by bacterial invasion of the bone. Worldwide, acute infection of bones and joints remains common in children. In adults, open fractures and orthopaedic implant surgery produce a large number of severe infections each year.

Orthopaedic infection can present acutely, with major systemic upset, local inflammation and purulence, or insidiously, with gradual bone destruction leading to loss of function and slowly evolving local symptoms, with or without systemic features.

Bone and joint infections cause a substantial burden of complex morbidity. Acute infections can be life- or limb-threatening, while chronic disease may produce prolonged disability, pain and ill-health. This has major implications for patient mental health and social interactions.

EPIDEMIOLOGY

The pattern of bone infection is changing, and the incidence is increasing. Bone and joint infection affects around 1 per 10 000 children across the world. Inadequate initial treatment generates chronic infections in up to one-third of cases. In the developed world, bone infection is frequently seen after injury or surgery (contiguous focus osteomyelitis) and is often implant related (***Figure 43.1***). Increasing life expectancy, obesity, medical comorbidities (diabetes, peripheral vascular disease, immunocompromise) and increased rates of bone surgery contribute to a group of patients with increased susceptibility to infection. Prosthetic joint replacement is a highly successful therapy for joint disease but is complicated by infection in at least 1% of cases. It was estimated that joint replacement generated more than 70 000 new cases of prosthetic joint infection (PJI) in the USA in 2020. These are difficult and expensive to treat,

Figure 43.1 This open fracture of the tibia was treated with internal fixation using a plate. An early fracture-related infection developed, with skin breakdown and exposure of the metalwork.

costing over US$1.5 billion. The incidence of infection after fracture has decreased but increased use of internal fixation has increased the prevalence of post-traumatic bone infection overall. This will produce a significant economic burden for healthcare providers in the future.

Summary box 43.1

Epidemiology of bone infection

- Bone and joint infections from haematogenous spread remain common worldwide
- The increased use of implants for joint replacement and fracture fixation are an important source of new infections
- Immunocompromised patients are another increasing source (e.g. diabetes, cancer treatment)

GENERAL PRINCIPLES OF ORTHOPAEDIC INFECTION

Pathology

Bone infection has all the elements of any inflammatory condition but bone produces some specific pathological features. Acute osteomyelitis occurs when pathogenic organisms cause infection, leading to inflammation in the bone and surrounding tissues. The medullary bone may form abscesses and pus may track through the cortex to form periosteal elevation and soft-tissue extension. This process will devascularise the cortical bone, causing bone death – the characteristic feature of chronic osteomyelitis.

Bacteria can adhere to dead bone or implant surfaces, forming a complex community enveloped in a polysaccharide matrix, known as a biofilm. These bacteria alter their metabolic state, making them more resistant both to the host immune system and to antibiotics. Toxins and lytic enzymes from bacteria cause early damage to articular cartilage.

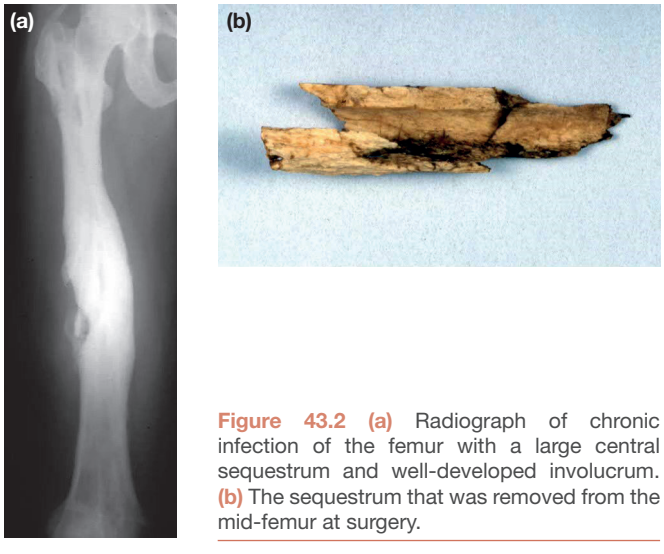

Figure 43.2 (a) Radiograph of chronic infection of the femur with a large central sequestrum and well-developed involucrum. **(b)** The sequestrum that was removed from the mid-femur at surgery.

The infected bone reacts to the infection by separating dead fragments of bone (sequestration) and forming sinuses to drain pus and discharge small bone fragments. New bone is laid down around the infection from the periosteum (involucrum) (***Figure 43.2***).

In septic arthritis, infection may follow direct ingress of bacteria after injury or surgery, or may result from discharge of an adjacent acute osteomyelitis into the joint. Particularly in neonates or the elderly, bacteraemia may infect a previously normal joint.

Summary box 43.2

Pathology of bone infection

- Bacteria infecting bone form a resistant biofilm on dead bone and implant surfaces
- Infected bone dies and forms a sequestrum
- The periosteum around lays down new bone – an involucrum

Microbiology

Virulent Gram-positive organisms, particularly *Staphylococcus aureus*, are the most common cause of bone or joint infection in native tissue. However, once prosthetic material is implanted, a wide range of organisms can be involved. This includes organisms with low virulence that are usually considered skin commensals, such as coagulase-negative staphylococci, α-haemolytic streptococci and *Cutibacterium acnes* (***Table 43.1***).

Diagnosis

Clinical

Diagnosis is predominantly clinical with confirmation using other tests, as outlined below.

Biomarkers

Raised inflammatory markers (erythrocyte sedimentation rate [ESR], C-reactive protein [CRP] and white cell count [WCC]) are characteristic of acute infection, but they are neither sufficiently sensitive nor sufficiently specific to rule infection in or out. Recently, new synovial fluid markers (α-defensin and calprotectin) have shown high accuracy in diagnosis of PJI.

Imaging

Plain radiographs can demonstrate dead bone, periosteal reaction, involucrum formation and loosening of implants. However, they are often normal in the first few days of infection. A normal radiograph does not exclude infection. Over time, radiographs will show progressive implant loosening, bone lysis or sequestration in chronic osteomyelitis.

Ultrasonography is ideal for identifying soft-tissue collections and joint effusions and can be used to guide bone biopsy and aspiration.

Computed tomography (CT) scans are helpful in assessing bone union of infected fractures. Small sequestra and cortical

Hans Christian Joachim Gram, 1853–1938, Professor of Medicine, Copenhagen, Denmark.

TABLE 43.1 Organisms most commonly involved in bone and joint infection.

Classification of infection	Group(s) of organisms	Examples of specific organisms and context in which infection occurs
Gram positive	Staphylococci	*Staphylococcus aureus* (commonest across all settings) Coagulase-negative staphylococci (common in implant-associated infection)
	Streptococci	α-Haemolytic streptococci, including *Streptococcus pneumoniae, Streptococcus milleri* group and *Streptococcus viridans* (in implant-associated infection)
		β-Haemolytic streptococci (e.g. *Streptococcus pyogenes, Streptococcus agalactiae*)
	Cutibacteria	Increasingly recognised in implant-associated infection and septic arthritis of the shoulder
	Enterococci	Common in diabetic foot infection and chronic osteomyelitis
Gram negative	Enterobacteriaceae	*Escherichia coli* (especially at extremes of age)
		Klebsiella spp.
		Salmonella spp. (particularly associated with sickle cell disease)
	Pseudomonas spp.	Associated with diabetic foot infections, osteomyelitis underlying chronic wounds/ulcers, patients heavily exposed to a hospital environment and/or prior antibiotics
	Kingella kingae	Common cause of septic arthritis in children under 4 years
	Haemophilus spp.	*Haemophilus influenzae* (consider in non-immunised children)
	Neisseria spp.	*Neisseria meningitidis*
		Neisseria gonorrhoeae (consider risk factors for sexually transmitted infection)
Others	Fungi, especially *Candida* spp.	Cause infection in immunocompromised and/or heavily antibiotic-exposed hosts. Common after prolonged use of negative-pressure wound therapy
	Mycobacterium tuberculosis	Present without pulmonary disease Geographical distribution Common with HIV
	Atypical mycobacteria (*Mycobacterium marinum, Mycobacterium ulcerans*)	May be a component of disseminated infection in HIV-infected patients; also cause post-surgical infection in immunocompetent hosts
Mixed	Any combination of the above organisms	More common after trauma, recurrent surgery and with poor wound healing and sinuses, or resulting from contiguous spread from an infected source (e.g. skin, GI tract)
'Culture negative'	No growth from cultures, but diagnosis of infection made on clinical/radiological/ histopathological grounds	Most common in patients who have had recent antimicrobial exposure prior to surgical sampling

GI, gastrointestinal; HIV, human immunodeficiency virus.

erosions are best seen with CT and these scans can be used to plan surgery for excision of dead bone (***Figure 43.3a***).

Isotope bone scans are of very limited value as they are non-specific and give no information that may guide diagnosis or treatment. The combination of ^{18}F-fluorodeoxyglucose positron emission tomography (^{18}FDG-PET) with a CT scan allows localisation of active infection in chronic osteomyelitis and may facilitate planning of surgery. ^{18}FDG-PET/CT is not specific to infection and so cannot reliably distinguish infective from aseptic loosening around implants.

Magnetic resonance imaging (MRI) scanning is the investigation of choice, in the absence of metal implants. It is highly sensitive and specific, showing all components of the disease (***Figure 43.3b***). However, it can overestimate the extent of infection when there is widespread reactive oedema.

Microbiological diagnosis

Good treatment starts with a reliable microbiological diagnosis. Superficial swabs from wounds or spontaneously draining pus are unreliable. Cultures from these do not reflect the pathogens in the bone. Microbiological samples may be falsely negative if antibiotics are given first. Synovial tissue samples are particularly important in producing a higher diagnostic yield for infection with mycobacteria or fungi.

In chronic infections, particularly those involving prosthetic material, multiple biopsy samples are needed. It is recommended to take at least five tissue samples; each one with a separate, sterile instrument. Samples should be promptly transferred to the laboratory with clinical details of the infection. Culture should be maintained for at least 10 days in musculoskeletal infections to allow identification of slow-growing

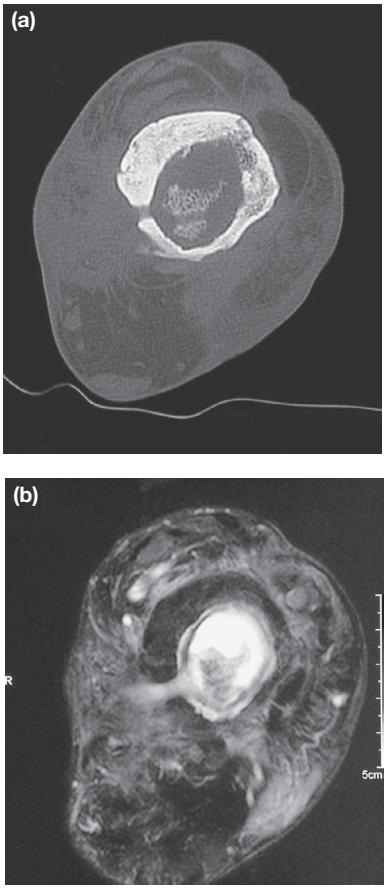

Figure 43.3 (a) Transverse computed tomography scan of the femur with a central sequestrum, sinus and cortical bone erosion. (b) Magnetic resonance imaging scan of the same femur with better resolution of the medullary infection and soft-tissue involvement.

organisms such as *C. acnes*. A positive tissue diagnosis is confirmed when phenotypically identical organisms are cultured from at least two of the five tissue samples. A single positive culture may suggest infection.

It is also possible to culture organisms from removed implants that have been subjected to ultrasonic vibration to disrupt biofilm (sonication).

Summary box 43.3

Principles of diagnosis

- ESR and CRP are neither sensitive nor specific in making a diagnosis of bone infection
- Plain radiographs may be normal in the early phase
- Ultrasonography is valuable for identifying fluid/pus collections
- MRI is usually the investigation of choice
- Superficial swabs are of no value in identifying the organism causing deep infection
- If the patient is on antibiotics, cultures may be falsely negative
- Multiple biopsy specimens should be obtained to optimise microbiological diagnosis
- A neutrophil infiltrate on histology can confirm infection

Histopathology

The histological diagnosis of infection (rather than other sources of inflammation) depends on identifying organisms on a Gram stain or the presence of a neutrophilic infiltrate. Histology can directly diagnose tuberculosis and atypical mycobacterial osteomyelitis (caseating and non-caseating granulomas), actinomycosis and fungal hyphae. The presence of five or more polymorphonuclear neutrophils per high-powered field is diagnostic in fracture-related joint infections and PJIs. Histology is valuable in confirming the presence of infection in culture-negative cases.

Management

Successful treatment requires accurate diagnosis and a multidisciplinary approach to deliver a package of care, summarised as follows:

- Preoperative:
  - patient assessment and clinical staging of disease;
  - full discussion of all treatment options with potential complications;
  - diagnostic tests for general health;
  - optimisation of patients and treatment of comorbidities.
- Operative:
  - exposure for multiple, deep bone sampling;
  - excision of all affected tissue;
  - intravenous antibiotics after sampling;
  - bone stabilisation, if necessary;
  - dead-space management;
  - soft-tissue cover, which may include plastic surgery.
- Postoperative:
  - functional rehabilitation;
  - continued antimicrobial therapy guided by culture results, with regular clinical monitoring.

The principles listed above dictate that a range of surgical and medical specialists will be needed to treat patients with bone and joint infections. If the patient is systemically well, there is often time to complete investigations, optimise patient health and plan interventions. Complex infections should be referred early to centres that specialise in these cases. Attention to diabetes control, peripheral vascular disease, nutrition and smoking cessation is essential. Many patients will benefit from psychological support or at least good counselling around the difficulties of eradicating infection and the components of treatment.

Antibiotic therapy

Patients with septic shock, or with rapidly advancing local or systemic signs of infection, should receive prompt empiric antibiotic therapy. When delay in antibiotics would be unsafe, blood cultures, local aspiration of pus or radiologically guided biopsy may give valuable culture material immediately prior to starting antibiotics.

In most cases, it is safe to delay antibiotics until definitive operative microbiological samples have been taken, particularly in chronic or implant-related infections. For patients who

have already been started on antibiotics, a clinical assessment should be made; if safe to do so, antibiotics should be stopped at least 2 weeks before biopsy or surgery.

Local guidelines should be followed, but most hospitals recommend a 'community-acquired' level of cover using an agent such as co-amoxiclav. Additional antibiotics to cover resistant Gram-positive organisms (e.g. vancomycin for methicillin-resistant *S. aureus* [MRSA]) are considered if there has been significant prior hospital exposure or if the patient is known to be colonised with these organisms. Cover for resistant Gram-negative organisms (e.g. meropenem for *Pseudomonas*) is considered in certain settings, including severe diabetic foot infection.

In the past, prolonged intravenous antibiotic courses (i.e. 4–6 weeks of treatment) were often recommended. The recent OVIVA trial has shown that oral therapy is equally effective, providing that the organism(s) is susceptible and the patient can tolerate the chosen antibiotic.

Summary box 43.4

Antibiotics for osteomyelitis

- Septic shock needs treatment without delay, with antibiotics chosen empirically based on local guidelines
- In clinically stable patients, antibiotics should be delayed until specimens have been taken
- In elective surgery for osteomyelitis, antibiotics should be stopped at least 2 weeks in advance
- Agents such as co-amoxiclav or ceftriaxone are appropriate for most community-acquired infection
- Vancomycin or meropenem may be indicated for resistant species
- Oral therapy is effective if susceptible organisms are cultured

NATIVE JOINT SEPTIC ARTHRITIS

Epidemiology

Bacterial infection of native joints occurs with an estimated incidence of 4–10 per 100 000 population per year in western Europe, with higher rates associated with socioeconomic deprivation and in developing countries. The condition most characteristically affects patients at extremes of age, usually with pre-existing arthropathy or immunocompromise (***Table 43.2***).

Joint infection may arise as a result of haematogenous dissemination of bacteria from another focus (e.g. endocarditis) or may occur as a result of direct inoculation or local extension from an infected source (e.g. traumatic wound or adjacent osteomyelitis).

Clinical features

Most patients present after an acute or subacute history with a single hot, swollen, painful joint. In children, there is often a history of recent minor trauma. The joint is held immobile in the 'position of comfort', with 'pseudoparalysis' in neonates.

TABLE 43.2 Risk factors for native joint septic arthritis.

- Extremes of age
- Underlying joint abnormality, especially rheumatoid arthritis
- Immunocompromise (e.g. diabetes mellitus, HIV infection, immunosuppressive therapy)
- Joint instrumentation (e.g. steroid injection, arthroscopy)
- Intravenous drug abuse
- Indwelling central venous catheter
- Bacteraemia (especially *Staphylococcus aureus*)

HIV, human immunodeficiency virus.

There is severe pain if any attempt is made to move the affected joint actively or passively. In children and adults, the knee joint is most frequently affected, whereas in neonates it is the hip. Fever and other systemic signs are usually present, but their absence does not rule out the diagnosis. Fever is absent in about one-third of cases.

Diagnosis

Aspiration and/or biopsy of intra-articular fluid or tissue will allow a Gram stain to be performed (although this is positive in only about one-third of infected cases). Culture of a causative organism from synovial fluid is diagnostic (positive in 80–90%) but results are delayed by the time taken to grow and identify the organism in the laboratory. A high WCC in joint fluid (e.g. 50–150 000 cells/mm^3), with a neutrophil predominance (>90%), is characteristic of infection. However, other inflammatory conditions can also cause a raised cell count, and crystals may be seen in infected joints as well as in gout or pseudogout. The limited sensitivity of direct microscopy and Gram stain and the time taken to obtain a positive culture should not delay early treatment for the infection. The decision to perform a surgical washout and give antibiotics should be based on the clinical picture.

Summary box 43.5

Presentation of septic arthritis

- Children may be toxic and febrile but adults may have only a low-grade fever
- Usually symptoms affect only one joint, often with pre-existing arthropathy
- The joint is swollen and held in a characteristic 'position of comfort'
- **Any** movement causes extreme pain

Management

Surgical management

Medical treatment alone is rarely indicated in joint sepsis. Prompt surgical drainage is a priority to avoid further damage to the cartilage. Arthroscopic washout is commonly performed but it may be difficult to remove loculated areas of infection. Washout should be with Ringer's solution or

Sidney Ringer, 1835–1910, Professor of Clinical Medicine, University College Hospital, London, UK.

0.9% sodium chloride. Antiseptics should be avoided because of the risk of chondrolysis. There should be a low threshold for open arthrotomy, particularly if a joint is not settling. A synovectomy is recommended if there is major synovial thickening, aggressive synovitis or subchondral erosions seen on radiology (Gächter stages 3 and 4). Inadequate clearance may lead to chronic infection with destruction of the joint (***Figure 43.4***). Treatment may then require joint excision, joint fusion or staged joint replacement.

Medical management

Antibiotics are usually given for 3–6 weeks (beginning with intravenous therapy). There are sparse data to guide duration. Longer courses should be considered if the infection is slow to resolve, if more than one washout is required, if the patient is bacteraemic and/or if the infection is caused by *S. aureus*. The choice of antibiotics is as given in ***Summary box 43.4***.

Summary box 43.6

Native joint septic arthritis

- Most common at extremes of age, in patients with rheumatoid arthritis and in association with immunocompromise
- Most commonly affects hips in neonates and knees in adults and children
- The commonest pathogen is *S. aureus*
- Joints should be aspirated for microbiology before starting antibiotics, if safe to do so
- Management is prompt surgical joint washout, followed by 3–6 weeks of antibiotics

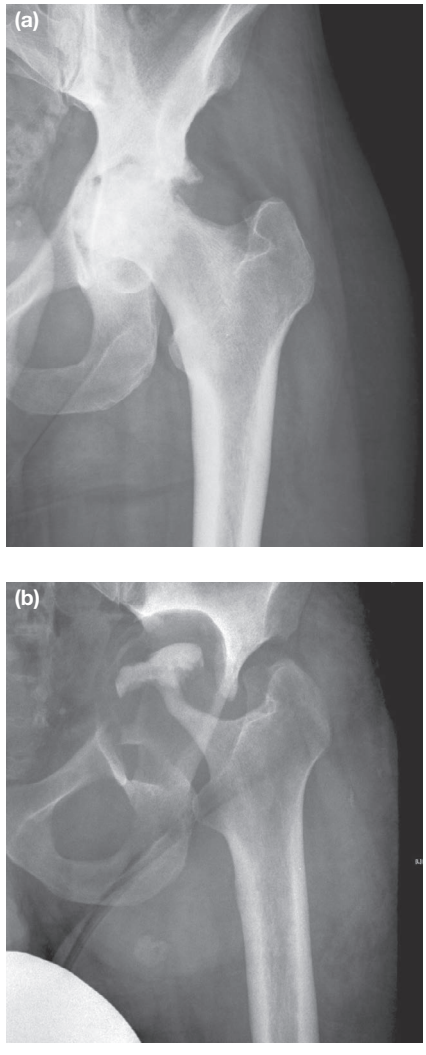

Figure 43.4 (a) Septic arthritis of the hip in a person who injects drugs. This was untreated for several weeks, resulting in destruction of the joint surface. **(b)** The same hip after 9 months without treatment. The proximal femur and acetabulum have been grossly eroded by infection.

PROSTHETIC JOINT INFECTION

Epidemiology

The incidence of PJI is around 1% per joint per year, with upper limb joints at a higher risk. Infection can be minimised with improved operative practice, prophylactic systemic antibiotics, local antibiotics in cement and the use of surgical 'care bundles'. Risk factors include obesity, skin disease, diabetes, malignancy, inflammatory arthritis, prolonged or complicated surgery, revision surgery, fracture and postoperative wound infection or haematoma.

Clinical features

PJIs may present early (within 3 months of surgery), in a delayed manner (3–24 months from surgery) or late (after 2 years).

- **Early infections** are acquired at surgery and are usually caused by virulent organisms (e.g. *S. aureus*). They present with a discharging wound, cellulitis, pain, inflammation and swelling.
- **Delayed infections** are more characteristically due to low-virulence organisms (e.g. coagulase-negative staphylococci or cutibacteria).
- **Late infections** are more likely to present with an indolent clinical syndrome of joint discomfort or mechanical dysfunction ('start-up' symptoms are particularly characteristic), with or without a discharging sinus. Late presentations are usually due to haematogenous infection of a previously uninfected joint, from bacteraemia. The source may indicate the microbiology (e.g. pneumococci from respiratory origin, *Salmonella* spp. from the gut, *Escherichia coli* from the urinary tract).

Diagnosis

Infection should be suspected in any patient with a leaking wound over an implant, unresolved pain or new pain around a previously pain-free implant. Routine blood tests may be helpful in acute infection but are often falsely reassuring.

André Gächter, contemporary, Swiss orthopaedic surgeon.

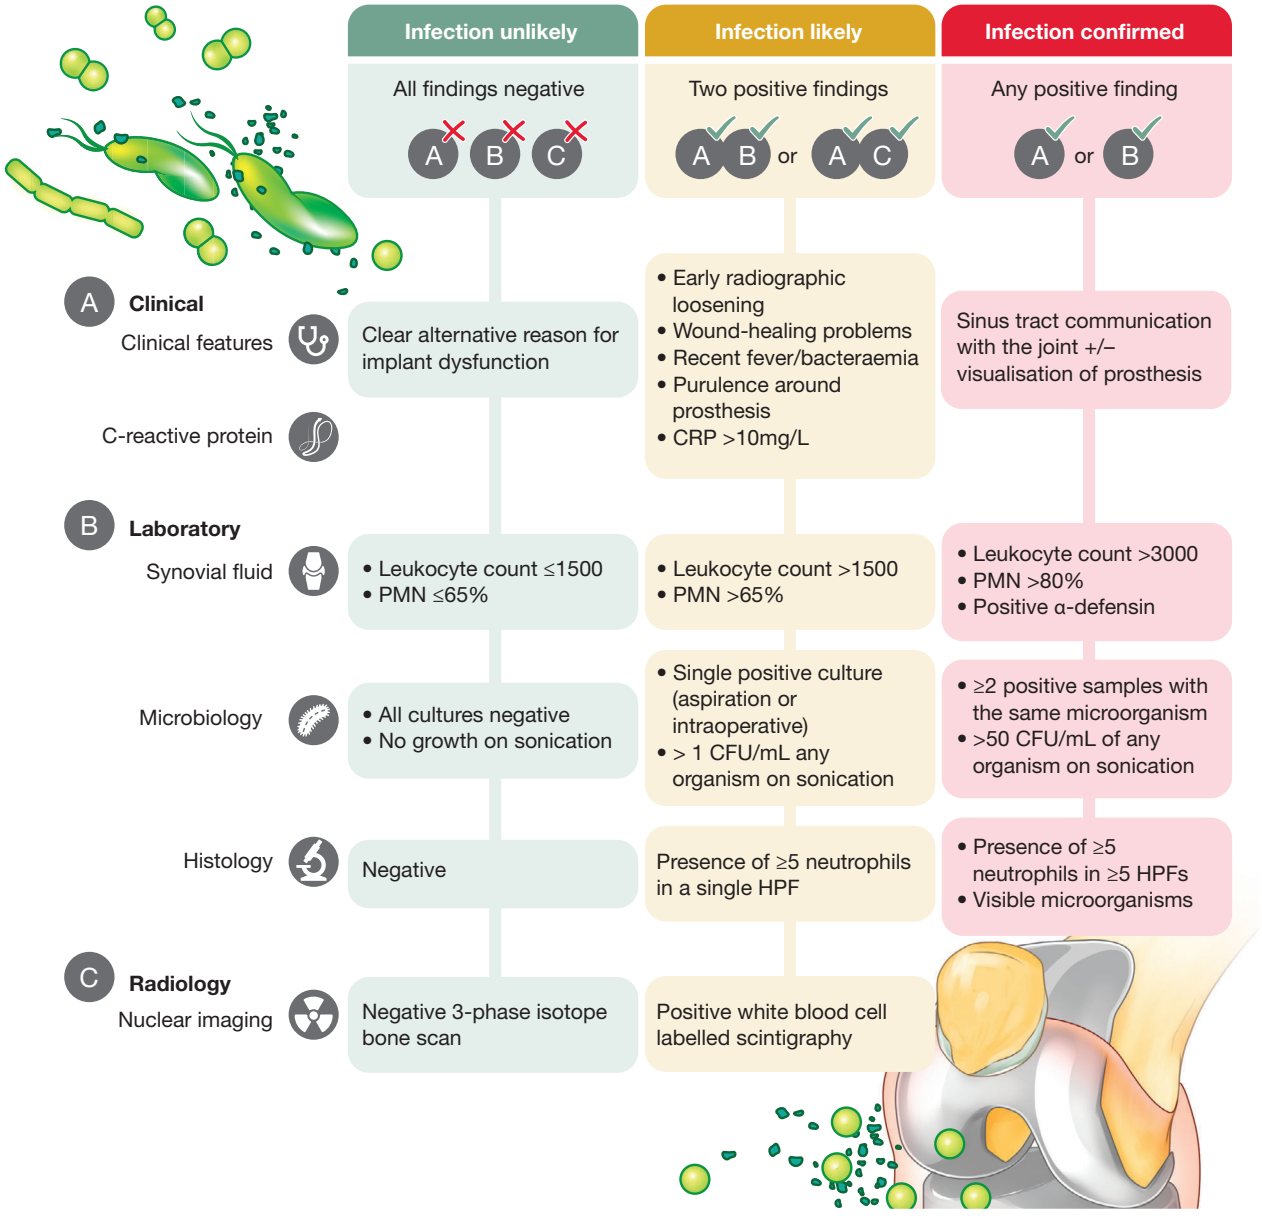

Figure 43.5 The European Bone and Joint Infection Society definition of prosthetic joint infection. CFU, colony-forming unit; CRP, C-reactive protein; HPF, high-power field; PMN, polymorphonuclear cells. (Reproduced with permission from McNally MA, Sousa R, Wouthuyzen-Bakker M *et al*. Infographic: The EBJIS definition of prosthetic joint infection: a practical guide for clinicians. *Bone Joint J* 2021; **103-B**(1): 16–17.)

The European Bone and Joint Infection Society (EBJIS) has produced diagnostic criteria for PJI. Infection is confirmed if there is a sinus communicating with the joint or there is a high synovial fluid WCC (>3000/μL), a positive microbiological culture or positive histology (more than five polymorphs per high-power field) (***Figure 43.5***) Plain radiographs may show features of loosening of a chronically infected prosthesis, and ultrasound may identify associated collections. Nuclear scans cannot reliably distinguish aseptic loosening from PJI.

Management

A multidisciplinary approach is required, including orthopaedics, plastic surgery, infectious diseases/microbiology, pharmacy, nursing, occupational therapy and physiotherapy, centred on the patient's understanding and wishes regarding their condition. Many patients have other medical comorbidities that should also be addressed and optimised. PJI can be associated with a range of emotional, psychological and mental health issues, ranging from anger about surgical complications to depression arising from chronic symptoms, lack of function and prolonged hospitalisation.

The choice of surgical strategy for prosthetic joints can be categorised as:

- salvage of an infected implant;
- removal of the infected implant with or without reimplantation.

Some groups have used the timing of presentation to determine this (i.e. salvage for early infection versus removal and revision for late infection). Others regard any firmly fixed implant as potentially salvageable, irrespective of the timing (and there are now several studies showing that this is feasible). However, it is agreed that loose infected implants should always be removed (*Figure 43.6*). Furthermore, it is essential to achieve soft-tissue cover of bone and prosthetic material. This may be difficult around the knee, requiring local muscle flaps.

Management options can be divided into the following broad approaches.

- **Debridement, antibiotics and implant retention - 'DAIR'**. This can only be undertaken if the prosthesis is well fixed. DAIR is not a form of washout as all infected soft tissue and necrotic bone must be fully excised and modular components exchanged. This cannot be achieved by arthroscopic surgery. Good soft-tissue cover is essential. Following debridement, the patient is treated with long-term antibiotics (frequently 6 weeks of intravenous therapy followed by 6 months or more of oral antibiotics). Prolonged infection-free intervals can be achieved in 80% of patients but success with this strategy may be lower in infections caused by *S. aureus* or with multiresistant organisms.
- **Two-stage joint revision surgery**. A thorough excision is undertaken and all cement and loose foreign material is removed. An antibiotic-impregnated spacer may be implanted (which may be articulating). This is a temporary measure and cannot withstand full weight-bearing. The patient is treated with oral or intravenous antibiotics, most commonly for 6 weeks. A new prosthesis is implanted after the course of antibiotics has been completed. In recent years there has been a trend towards shorter intervals between stages, often within the 6-week antimicrobial therapy.
- **Single-stage joint revision surgery**. The procedure is the same as above, but removal and reimplantation are undertaken in the same operating session. Healthy soft tissues around the new implant are essential to prevent reinfection. Some centres consider single-stage revisions when less florid signs of infection are present (i.e. absence of collections or sinus tracts), or for frail patients for whom the risk of a second operation is higher. There are no adequate trial data comparing outcomes with the two-stage approach.
- **Joint removal or fusion**. When reconstruction options are not technically possible or are ruled out by comorbid conditions, removal of the prosthesis without reimplantation may palliate symptoms. An example is the Girdlestone excision arthroplasty of the hip. In prosthetic infections of the knee, ankle or wrist, it may be possible to create a joint fusion after prosthesis removal. This is complex surgery, which may involve major bone reconstruction. Amputation may be necessary for knee or ankle implants.
- **Suppressive therapy with antibiotics**. In patients who are not medically fit for any operative intervention, or who choose to decline all surgical options, long-term treatment with antibiotics may help to suppress the symptoms of infection. There are limited data, but anecdotally the success rate of this approach is low.

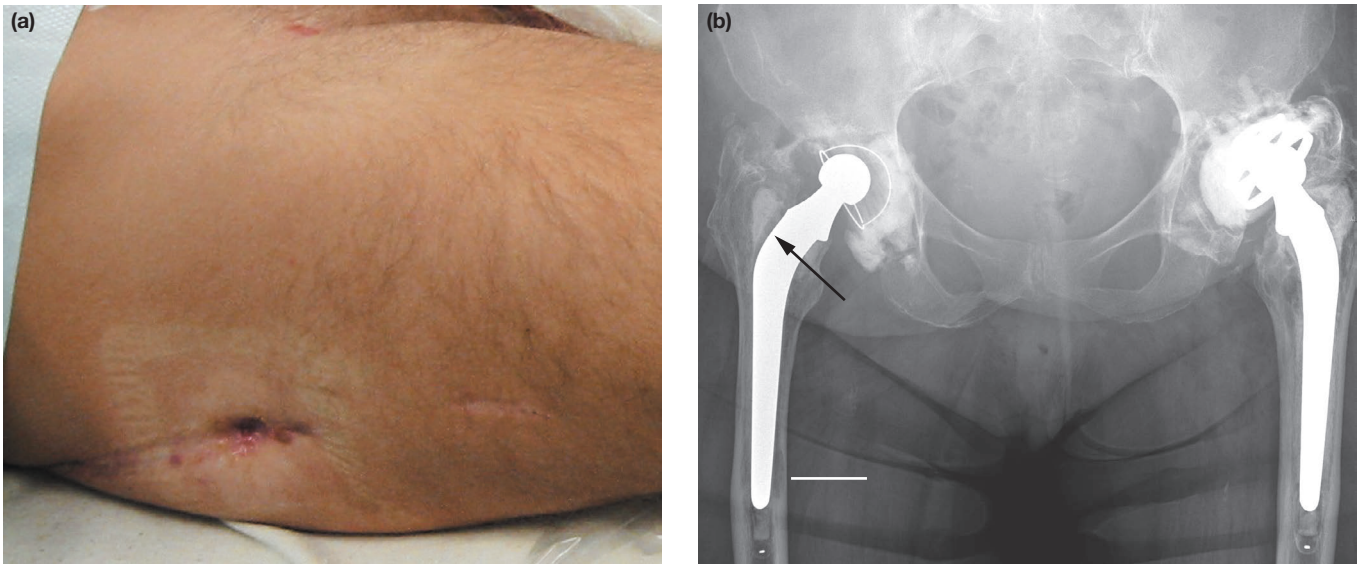

Figure 43.6 (a) Sinus draining from the scar over the lateral side of the hip. This patient had a total hip replacement 14 years before that had been complicated by a wound haematoma and infection. (b) Radiograph of both hips of same patient. Both hips are loose but only the right side has definite infection (arrows).

Gathorne Robert Girdlestone, 1881–1950, Nuffield Professor of Orthopaedics, University of Oxford, UK, described excision arthroplasty of the hip for septic arthritis.

Summary box 43.7

Prosthetic joint infection

- Well-fixed prostheses may be Debrided, treated with Antibiotics and the Implant Retained ('DAIR' approach)
- Loose prostheses must be removed
- Replacement can be made at the initial surgery (one stage) or after a delay to allow infection to be eradicated with antibiotics (two stage)
- Multiple surgical samples are crucial for identifying a pathogen
- Thorough excision of infected tissue is a key determinant of outcome
- Long-term antibiotics may be used for patients who are not suitable for major revision surgery

FRACTURE-RELATED INFECTION

Infection complicates around 3–5% of all fracture fixations. Open tibia fractures are a high-risk group with up to 25% becoming infected after fixation. Calcaneal fractures and ankle fracture fixation in the elderly also have high infection rates.

Many of the principles outlined above for PJI can be applied to infections associated with metalwork used to fix fractures.

There are several clinical scenarios which must be addressed:

- **Unhealed fracture with *stable* fixation**. This is usually seen early after fixation and can be managed with deep sampling, debridement of infected tissues and management of dead spaces (often with local antibiotic carriers) ('DAIR' approach). It is extremely important to provide good soft-tissue cover over the fracture. In the tibia, this will most often require a plastic surgical reconstruction. After debridement, systemic antibiotics must be given to suppress infection until bone union.
- **Healed fracture with infected implant**. In these cases, the implant can be removed, but there should still be a careful debridement, deep sampling, dead space management and soft-tissue cover.
- **Unhealed fracture with *unstable* fixation**. Stability is essential for bone healing and eradication of infection. If the implant is not stable, it should be removed and replaced by an external fixator. Radical excision of the infected fracture is needed and the resulting defect may present a major reconstructive challenge (***Figure 43.7***). Recently, antibiotic-coated locking nails have been used to restabilise infected fractures with some success.

ANTIMICROBIAL THERAPY FOR PROSTHETIC JOINT INFECTION AND FRACTURE-RELATED INFECTION

Following surgical sampling, empiric broad-spectrum intravenous antibiotic therapy (e.g. vancomycin and meropenem) should be given. This can be rationalised when culture results are available. In culture-negative cases, ongoing therapy to cover the most likely pathogens should be instituted.

The duration of therapy is determined according to the surgical approach, with 6 weeks for those in whom prosthetic material is completely removed versus 6 months for patients undergoing a 'DAIR' strategy, and prolonged (occasionally lifelong) treatment for patients in whom all other options are contraindicated or intolerable. In a few patients, the best therapy is no intervention, when chronic low-grade symptoms are well controlled and preferable to the risks of either surgery or long-term antibiotic therapy.

The antibiotic regimen should be planned with the advice of a microbiologist and supervised carefully to promote compliance and to detect and manage side effects. Monitoring of the joint is largely on clinical grounds; biomarkers including CRP are not predictive of treatment failure. Serial radiographs are helpful to detect progressive bone loss, which may be an indicator of recurrent active infection and can predispose to periprosthetic fracture and implant loosening.

ACUTE OSTEOMYELITIS

This presents like septic arthritis with a short history of pain, swelling, loss of function and systemic upset. In adults, the vertebral column is the commonest site; in children, long bones are most frequently affected. In young children, a fever and refusal to weight-bear may be the only clues.

Diagnosis

In the early phase (2–3 days) radiographs may be normal but MRI will show bone oedema and periosteal elevation. After 5–7 days, plain radiographs may show subtle abnormality with osteopenia and periosteal new bone formation. WCC and CRP are often elevated in the early phase. Treatment should not be delayed pending investigations.

Management

Acute osteomyelitis can be treated with antibiotics alone, when the diagnosis is made within 2–3 days of onset of symptoms, there is no dead bone on imaging and there is no adjacent septic arthritis. Culture results help to guide therapy, so blood cultures should be taken, and radiologically guided sampling should be considered. Empirical intravenous therapy against Gram-positive organisms is given (cephalosporins or flucloxacillin), adding gentamicin to cover Gram-negative organisms in children under 1 year.

The limb should be splinted and good analgesia given. Intravenous antibiotics should be converted to oral therapy, depending on clinical progress and the results of cultures, and therapy is continued for a total of 2–3 weeks. If the patient does not respond rapidly, if the limb deteriorates or if there is imaging evidence of progression of disease, surgery is indicated to prevent bone destruction and the onset of chronic osteomyelitis.

With prompt treatment, acute bone infection has a good prognosis with a 90% cure rate. Failure to treat adequately produces chronicity, with recurrent infection over many years. In children, the adjacent growth plates and joints may be affected with subsequent deformity and joint destruction.

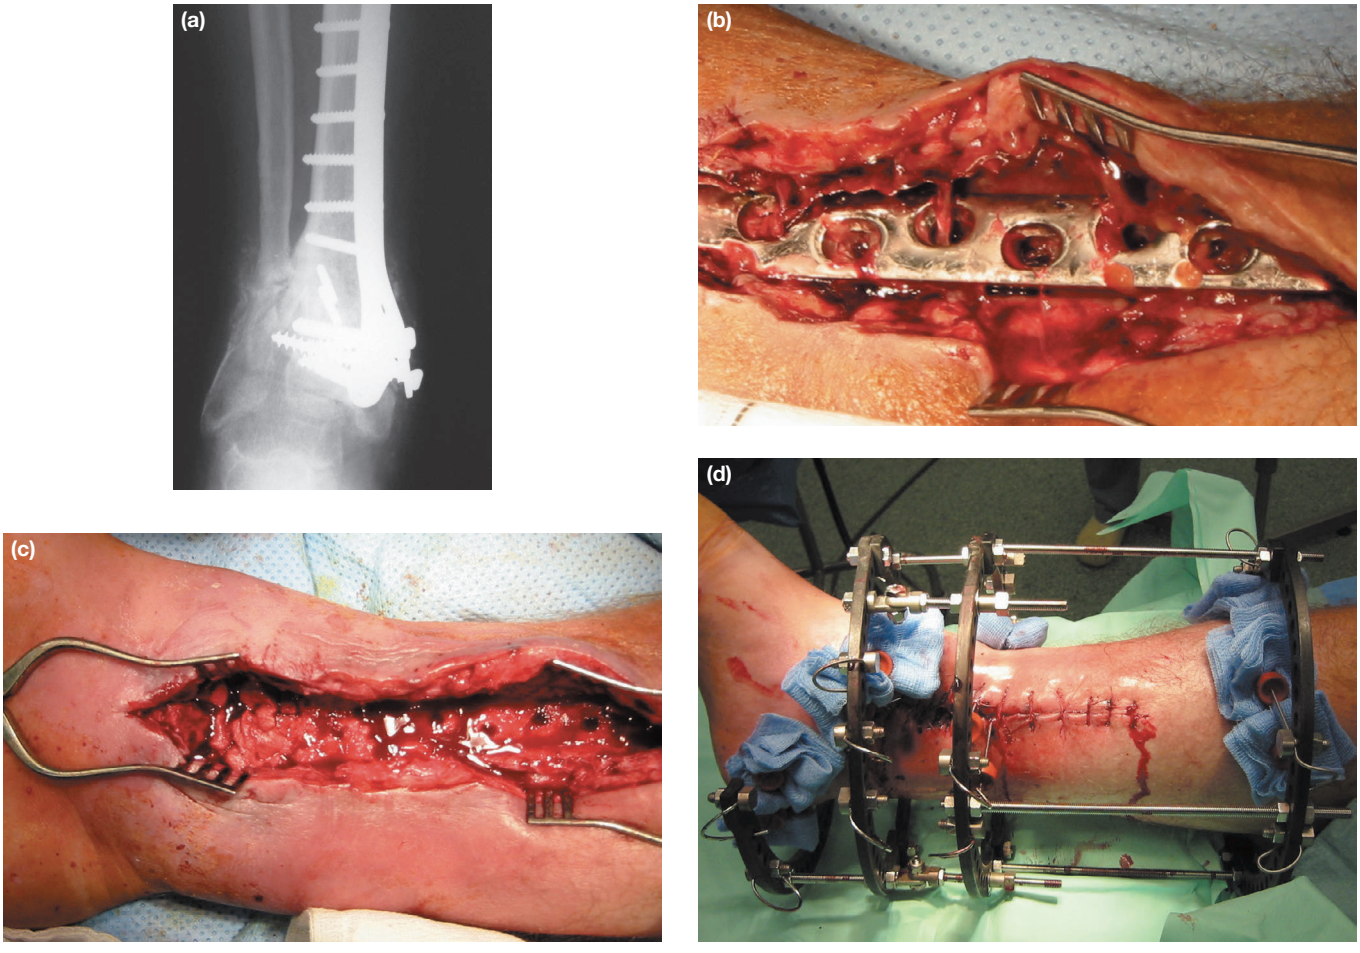

Figure 43.7 (a) Radiograph of a complex distal tibia fracture that was internally fixed but complicated by deep infection. (b) At operation, the plate was loose and grossly infected. (c) The plate and all infected tissue was excised. Deep samples were sent for microbiology and histology. The defect at the lower end was filled with an absorbable antibiotic carrier. (d) The bone was stabilised with an Ilizarov circular external fixator and the skin primarily closed.

Summary box 43.8

Acute osteomyelitis

- Presents in children with toxaemia, fever and unwillingness to move the limb
- May affect the vertebral column in adults, where back pain may be the only symptom
- Radiographs may be normal for up to 1 week so are of limited value in early diagnosis
- MRI is the investigation of choice
- WCC and CRP are usually raised
- Early diagnosis is treated with high dose intravenous antibiotics, started empirically and modified with culture results
- Late diagnosis and/or failure of medical treatment requires surgical debridement

CHRONIC OSTEOMYELITIS

This is a serious condition that may affect the patient for decades. Chronic bone infection is best treated within a dedicated multidisciplinary team that has the skills to deal with all aspects of the condition, the associated comorbidities and the range of surgical reconstructive options.

Diagnosis

Plain radiographs can delineate soft-tissue swelling, subperiosteal reaction, bone destruction and sequestra. CT scans are good for cortical bone imaging (*Figure 43.8*). MRI is the imaging test of choice (see *General principles of orthopaedic infection*). Blood tests are often normal in chronic osteomyelitis. Confirmation of the diagnosis is with culture from deep surgical samples and histology. ^{18}FDG-PET CT scanning can be helpful for surgical planning.

Gavriil Abramovich Ilizarov, 1921–1992, orthopaedic surgeon, Kurgan, Western Siberia, Russia, pioneered this eponymous approach to bone reconstruction in the 1960s for the management of osteomyelitis, fractures and limb deformities.

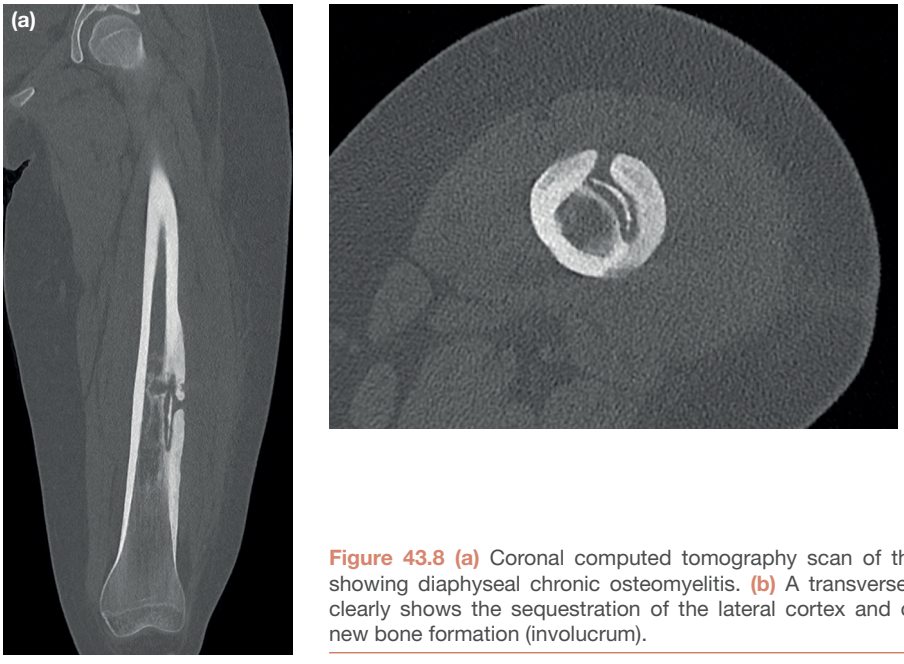

Figure 43.8 (a) Coronal computed tomography scan of the femur showing diaphyseal chronic osteomyelitis. **(b)** A transverse section clearly shows the sequestration of the lateral cortex and overlying new bone formation (involucrum).

Management

The BACH classification divides patients into 'uncomplicated', 'complex' and 'limited options available' based on the four important features of the infection (***Figure 43.9***). These are: the anatomical location in the bone (B), the antimicrobial profile (A), the need for soft-tissue cover (C) and the health of the host (H). Treatment must always address all four parts of the classification to achieve good outcomes. All infected unhealed fractures and infected non-unions are complex.

As with PJI, comorbidities should be optimised before surgery. The interaction between the patient's health status and the extent of the bone infection greatly affects the outcome after surgery. In chronic infection, it is essential to address medical conditions that may impair wound healing (e.g. smoking, peripheral vascular disease, diabetes, steroid use) prior to surgery. This approach has been shown to improve cure rates. A joint assessment by an orthopaedic surgeon, plastic surgeon and infectious disease physician will allow good preoperative planning.

	Bone involvement	**A**ntimicrobial options	**C**overage of soft tissue	**H**ost status
Uncomplicated	B1 Cavitary involvement (including medullary, cortical and non-segmental corticomedullary) 	Ax Unknown/culture negative A1 <4 resistant tests ≥80% susceptibility tests sensitive	C1 Direct closure possible Plastic surgery expertise *not required*	H1 Patient fit and well or has well-controlled disease
Complex	B2 Segmental involvement Any infection with joint involvement 	A2 >4 resistant tests <80% susceptibility tests sensitive	C1 Direct closure not possible Plastic surgery expertise *required*	H2 Patient with either poorly controlled disease, severe disease or recurrent osteomyelitis
Limited options	B3 Whole bone involvement	A3 Sensitivity to either 0 or 1 susceptibility test		H3 Unfit for anaesthetic Patient declines surgery Surgery not indicated

Figure 43.9 The BACH classification of osteomyelitis.

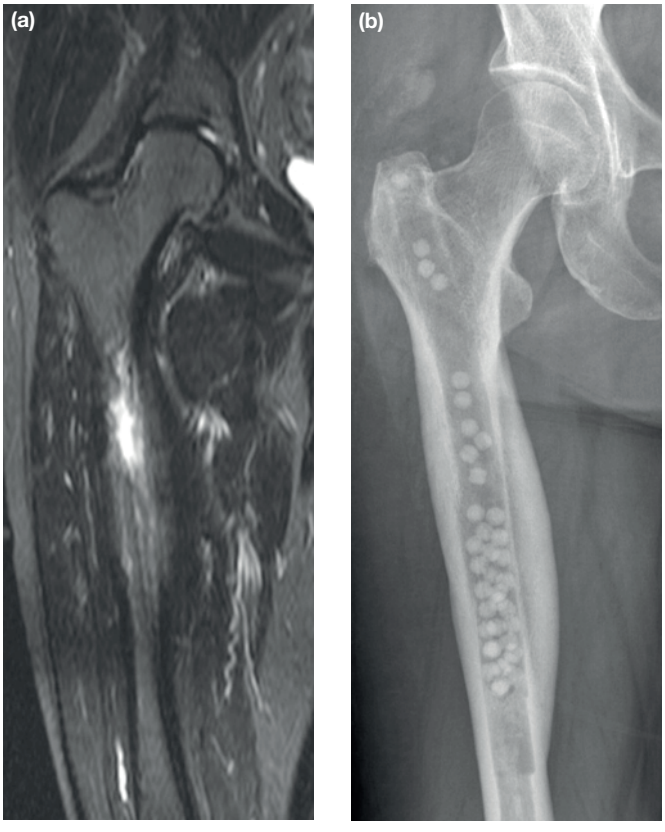

Figure 43.10 (a) This magnetic resonance imaging scan shows a BACH uncomplicated medullary osteomyelitis of the femur. (b) The infected bone has been removed by reaming and the central defect filled with absorbable calcium sulphate pellets with gentamicin.

In uncomplicated disease, excision of the dead bone, with local and systemic antibiotics and direct wound closure, is highly effective (*Figure 43.10*). If more than one-third of the cortical circumference is excised, splintage is essential, often with external fixation to prevent fracture. Secondary bone grafting may be needed.

When the infection is segmental (BACH complex), or when the soft-tissue envelope cannot be closed directly, major reconstruction will be required. Curative resection must be segmental and bone stabilisation will always be required. The Ilizarov method, which uses distraction osteogenesis to fill bone defects, is a powerful and successful technique in these cases. It can be combined with free tissue transfer. This allows reconstruction to proceed in parallel with rehabilitation.

After surgery, patients should be given antibiotics. In total segmental excision of infection a short course may be indicated, but in most chronic infections 6–12 weeks is often advised. If there is any doubt about the adequacy of removal of the dead bone, a long antibiotic course will be needed and recurrence will be more likely. In chronic fracture-related infection, antibiotics should continue until fracture union.

There is now increasing interest in the use of local antibiotic absorbable carriers. These can deliver high doses of antibiotics into the bone, without systemic effects. Some ceramic materials (with hydroxyapatite) can form new bone in the defect, avoiding the need for secondary bone grafting.

Summary box 43.9

Chronic osteomyelitis

- Chronic disease requires specialist surgery with excision, stabilisation and reconstruction
- Host status should be optimised before surgery
- Following surgery, antibiotic therapy is typically continued for at least 6 weeks

DIABETIC FOOT INFECTION

The global prevalence of diabetes has increased exponentially in recent years. Foot infections are a leading cause of hospital admissions in this group, with an annual incidence of foot complications of 1–2% per year owing to the combined influence of macro- and microvascular insufficiency, mechanical disruption, peripheral and autonomic neuropathy, immune defects and impaired tissue healing. Ulceration of the calcaneum and bones of the forefoot is common (*Figure 43.11*) and will result in amputation in up to one-fifth of cases.

Infection begins as invasion of bacteria into the compromised tissues and will rapidly spread to deep structures. Diagnosis is made on the clinical signs and symptoms of local inflammation and systemic upset. The presence of a wound/ulcer, spreading cellulitis, fevers or critical ischaemia indicate a more severe infection and the need for urgent treatment.

Blood tests are frequently unhelpful, as inflammatory markers may be normal or only mildly raised. Plain radiographs may show evidence of osteomyelitis but can be normal (particularly early in infection). MRI is the most sensitive imaging modality for diagnosis of bone involvement. Superficial swabs

Figure 43.11 A severe diabetic foot infection, with marked infection, necrosis and tissue loss. The patient was neuropathic and had ankle and hindfoot deformity. The foot was salvaged with a corrective triple fusion of the hindfoot, excision of the infected ulcer, antibiotic therapy and primary closure of the lateral soft tissues.

or cultures from ulcers or sinus tracts are not reliable in determining the organisms responsible for underlying deep-seated infection. A combination of the 'probe-to-bone' test with elevated inflammatory markers and abnormal plain radiographs confirms the diagnosis.

The aetiological agents of diabetic foot infection are the same as for bone infection in non-diabetic individuals, namely *S. aureus*, β-haemolytic streptococci and aerobic Gram-negative bacilli. *Pseudomonas* is over-represented, and empirical therapy for severe infections should include cover for this organism. Anaerobes may also be present and addition of metronidazole (particularly for abscesses and/or devitalised tissue) should be considered.

Surgical debridement is required for collections, necrotic areas or more extensive osteomyelitis. Thought should be given to distinguishing superficial osteitis, resulting from loss of soft-tissue cover (often in association with vascular compromise), from more extensive bone involvement. In the former, biopsy and antibiotic therapy may be of limited importance and optimising glycaemic control, improving vascular supply and relieving pressure, with appropriate footwear, much more important. This approach may avoid more extensive tissue loss or later amputation.

Many patients with diabetes with foot infection have significant vascular compromise and neuropathy, which makes healing after surgery unreliable. A full vascular assessment is mandatory in those with poor peripheral pulses. Proximal angioplasty or bypass surgery may improve distal vascularity to a level where infection surgery in the foot may be more successful.

Amputation is not an easy option in diabetic foot disease and wound healing can be problematic. In general, excision should be adequate to remove all infected material and excess bone may need to be resected to allow tension-free skin closure. If there is extensive peripheral neuropathy, a below-knee amputation in an area with better sensation may be more appropriate.

Summary box 43.10

Diabetic foot infection

- The most important risk factor for osteomyelitis is the presence of a foot ulcer
- Ulcer swabs are not reliable in determining the pathogens responsible for osteomyelitis
- Bone biopsy for culture should be considered in extensive/complex infection but may not be necessary in mild disease
- In severe disease, surgical debridement of collections and/or necrotic tissue is required, followed by antibiotics tailored according to culture results

MUSCULOSKELETAL INFECTION CAUSED BY MYCOBACTERIA

Tuberculous arthritis/osteomyelitis remains prevalent in low- and middle-income countries. There is now a resurgence across the world as a consequence of migration and immunocompromise (including human immunodeficiency virus [HIV]). The most common organism is *Mycobacterium tuberculosis*. Around half of all cases affect the spine, typically manifesting as para-discal infection but also causing discitis and vertebral osteomyelitis. Native joint infection typically presents with monoarticular pain in a weight-bearing joint.

For optimal management of tuberculosis, the patient must be referred to a specialist multidisciplinary team for input that includes the following components.

- Baseline screening for HIV and other blood-borne viruses.
- Assessment for other sites of mycobacterial infection.
- Measurement of baseline renal and liver function, to be repeated at intervals throughout treatment. Drug-induced hepatitis is the commonest serious side effect that may require temporary withdrawal or alteration of therapy.
- Baseline and follow-up testing of hearing (if injectable agents to be used) and colour vision (if ethambutol to be used).
- Consideration of any potential drug interactions (rifampicin is a potent inducer of the cytochrome P450 system; it can interact with many classes of drug, including anticonvulsants, antiretroviral therapy, anticoagulants, antibiotics and antifungals).
- Institution of appropriate infection control precautions and contact tracing.
- Appropriate education and support to optimise adherence to therapy.
- Prescription of an appropriate combination of drug therapy.
  - For fully sensitive *M. tuberculosis*, the preferred regimen is oral rifampicin, isoniazid, pyrazinamide and ethambutol for 2 months, followed by rifampicin and isoniazid for a further 4 months.
  - Worldwide, there is an increase in the prevalence of drug-resistant tuberculosis, classified as multidrug resistant (MDR) and extensively drug resistant (XDR). Infection with these organisms requires a treatment regimen that includes an injectable agent (typically amikacin, kanamycin or capreomycin) together with oral agents selected according to the susceptibility profile of the isolate (these may include cycloserine, ethionamide, para-aminosalicylic acid [PAS], fluoroquinolones and linezolid). Prolongation of therapy is required, and side effects/toxicity are common.
- Surgery is only recommended to decompress or stabilise the spine and occasionally to confirm the diagnosis by tissue biopsy.

Non-tuberculous mycobacteria are ubiquitous environmental organisms. They are best recognised as agents of disease in patients with underlying immunocompromise (including HIV, diabetes and organ transplantation) or other risk factors for introduction of infection (such as penetrating trauma or the presence of a prosthesis). However, they may occasionally also cause infection in hosts without obvious risk factors.

Treatment can be difficult; these organisms are resistant to the standard agents used for first line antituberculous therapy; surgery to debride and drain sites of infection can therefore be particularly important to reduce the bacterial burden. There is no single standardised drug regimen or duration, so choice of

therapy depends on the *in vitro* susceptibility of the organism and length of treatment depends on the location of disease; extent of surgical debridement; the identification and phenotypic characteristics of the organism; and the patient's underlying condition, presence of immunocompromise and response to therapy. As for treatment of *M. tuberculosis*, expert medical oversight is crucial throughout treatment.

ACKNOWLEDGEMENTS

Dr Philip Bejon and Dr Philipa Matthews contributed to earlier versions of this chapter, and I remain grateful for their input.

PART 5 | Elective orthopaedics

CHAPTER 44

Paediatric orthopaedics

Learning objectives

To be familiar with:

- Physiological versus pathological development of the musculoskeletal system
- Diagnosis and treatment of developmental dysplasia of the hip
- Presentation and management of other childhood hip conditions
- Management of club foot
- Problems associated with musculoskeletal infection in childhood

INTRODUCTION

Immature skeletons heal rapidly and can remodel with growth but physeal injury or muscle imbalance may lead to progressive deformity. The conservative treatment of common conditions, such as developmental dysplasia of the hip (DDH), considers remodelling ability with an understanding of the Hueter–Volkmann principle and Wolff's law (*Table 44.1*): improving the biomechanical environment may reverse abnormal growth. In contrast, in conditions such as Blount's disease, a poorly functioning growth plate leads to asymmetrical growth and deformity. Advances in genetics and molecular science have improved our understanding of certain conditions and may lead to new treatments.

TABLE 44.1 Laws governing the remodelling of bone.

Hueter–Volkmann principle
• Compressive forces inhibit growth
• Tensile forces stimulate growth
Wolff's law
• Bone deposition and resorption depend on the stresses applied

DEVELOPMENT OF THE MUSCULOSKELETAL SYSTEM

The upper limb bud forms on the lateral wall of the 4-week embryo, followed promptly by the lower limb bud. By 2 months, differentiation of the limb elements is complete. Most congenital limb anomalies arise during this period.

Three coordinated signalling centres control limb development. The **apical ectodermal ridge** (AER) guides mesodermal differentiation in a proximal-to-distal direction, controlling digit formation via the production of fibroblast growth factors (FGFs). The mesodermal **zone of polarising activity** (ZPA) directs anteroposterior development via the sonic hedgehog protein, which is itself sustained by FGFs. The ectodermal driven **wingless-type** (Wnt) signalling centre develops dorsoventral axis configuration and limb alignment.

Certain limb anomalies are directly related to alterations in these centres. Experimentally, removal of the AER leads to a truncated limb, similar to a congenital amputation, and prevents interdigital necrosis resulting in syndactyly. An additional ZPA results in a mirror duplication of the distal limb.

Factors causing fetal limb anomalies may also influence other organ formation, resulting in potentially life-threatening disorders.

Summary box 44.1

Development of the musculoskeletal system

- Occurs 4–8 weeks after fertilisation
- AER controls proximal-to-distal differentiation and interdigital necrosis
- ZPA directs posterior-to-anterior differentiation
- Wnt influences dorsal-to-ventral differentiation

NORMAL VARIANTS

Many normal variants of growth and development cause parental concern. The common problems relate to tripping and falling, an intoeing gait, bowlegs, knock knees and flat feet. In general, if they are symmetrical, symptom-free and in an otherwise normal child, they require no intervention. If the

Carl Hueter, 1838–1882, Professor of Surgery, University of Greifswald, Germany.
Richard von Volkmann, 1830–1889, Professor of Surgery, Halle, Germany.
Julius Wolff, 1836–1902, Professor of Orthopaedic Surgery, Berlin, Germany.

child fails to achieve their developmental milestones or there are functional problems, further investigation may be required.

Intoeing gait

Intoeing is defined as a negative foot progression angle and results from one or more lower limb torsional anomalies (*Figure 44.1 and Table 44.2*).

Persistent femoral neck anteversion presents clinically with excessive internal rotation at the hip joint, which is best assessed with the patient prone (*Figure 44.2a*). All femurs are anteverted at birth but as the femur lengthens it rotates with spontaneous improvement in the anteversion. If, by 10–12 years, a persistent deformity is associated with functional difficulties, corrective osteotomy may be justified. In such cases, the child has no ability to externally rotate the extended hip. In others, compensatory external tibial torsion may develop, in which case the foot progression angle will be normal but the child may have symptoms of the miserable malalignment syndrome, including knee pain and feelings of instability.

TABLE 44.2 Common sites and causes of intoeing gait in childhood.

Site	Cause
Femur/hip	Persistent femoral neck anteversion
Tibia	Internal tibial torsion
Foot	Metatarsus adductus

Internal tibial torsion is assessed by the thigh–foot angle and is commonly associated with physiological tibia vara in infants (*Figure 44.2b*). Spontaneous correction occurs by age 4, as the tibia rotates with growth.

Metatarsus adductus (*Figure 44.2c*) is usually flexible and corrects by age 2–4 years. For the more rigid foot, stretching, with or without plaster casts or straight-last shoes, may help. Surgical release is rarely indicated.

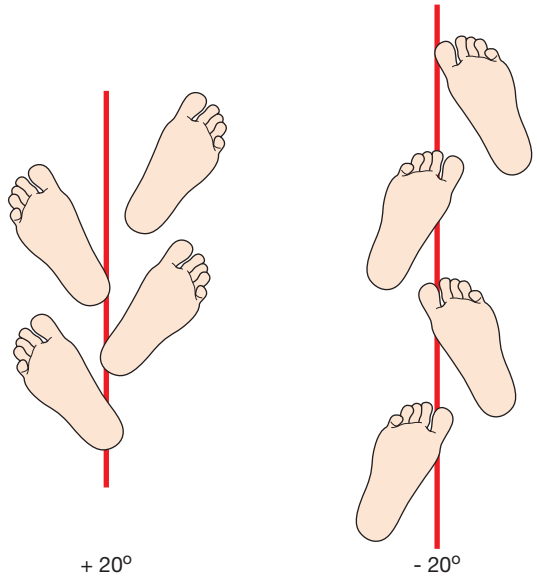

Figure 44.1 Foot progression angle: a positive angle represents an extoeing gait; a negative angle, an intoeing gait.

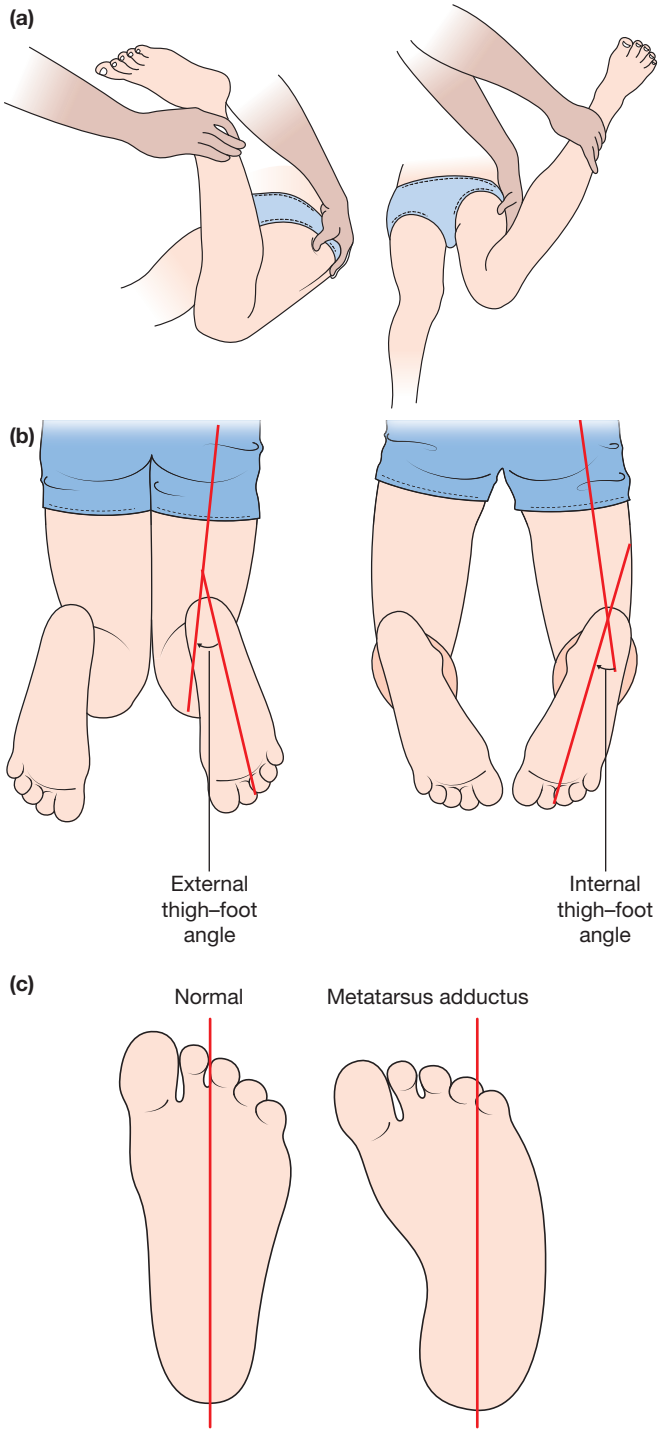

Figure 44.2 Assessment of the torsional profile: all assessments are done with the child prone. **(a)** Femoral neck anteversion measured as the range of internal hip rotation with the hip extended and the knee flexed. Craig's test measures the degree of internal rotation present when the greater trochanter is at its most prominent (also called the trochanteric prominence test). **(b)** The thigh–foot angle measures the angle between the relaxed hindfoot and the thigh. **(c)** The bean-shaped foot of metatarsus adductus viewed from above: a curved lateral border with/without a medial crease.

Other abnormalities of gait

Extoeing is less common but results from relative femoral retroversion, external tibial torsion or flexible flat feet. The child may walk late because of poor balance associated with the foot posture and overall alignment. Gait improves with growth/time.

Toe walking is a phase in normal gait development. If the gait does not mature to a heel–toe pattern by 3 years, physiotherapy may help, and older children benefit from surgical lengthening of a contracted gastrocsoleus complex, if it is present. If toe walking starts after walking age, a spinal or neuromuscular aetiology such as a tethered cord or a muscular dystrophy must be considered; in the unilateral case, an orthopaedic cause for a short leg, such as a dislocated hip, must be excluded.

Knock knees and bowlegs

All children start life with bowlegs, often accompanied by internal tibial torsion. By the age of 2–3 years they have developed knock knees, which regress towards the normal adult tibiofemoral angle of 7° valgus by age 7 (*Figure 44.3*).

The intercondylar or intermalleolar distance is often used to quantify the deformity but radiographs are needed when the deformity is severe, asymmetrical or symptomatic. The most common pathological causes are previous trauma, rickets or a skeletal dysplasia.

Flat foot

All children (<3 years) have flat feet with a fat pad obscuring the arch. Over time, the longitudinal arch develops but 15% of adults have flat feet influenced by familial and racial factors.

All flat feet have a flattened medial arch with a valgus heel but two types are distinguishable (*Table 44.3*). The painless, flexible flat foot needs no treatment. Orthoses **do not** alter the natural history but can alleviate symptoms **if** they are present.

The symptomatic, rigid flat foot is due to inflammation or a tarsal coalition and requires investigation and medical or surgical management (*Figure 44.4*).

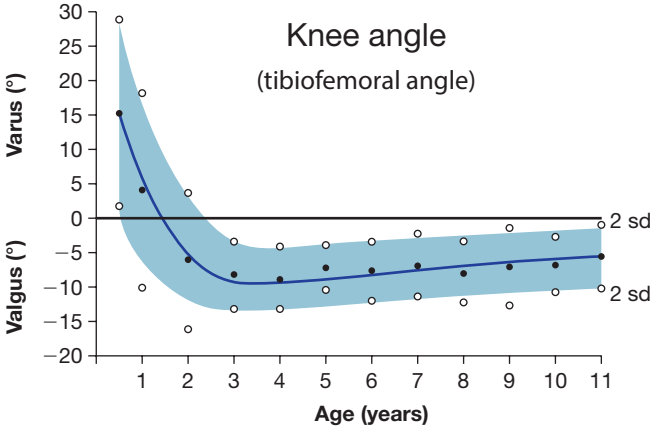

Figure 44.3 Graph to show the normal tendency of limb alignment to change from varus to valgus with growth; normal is slight valgus after the age of 7–8 years.

TABLE 44.3 Flat feet.

Type	Characteristics
Flexible	• On tiptoe the arch returns and the heel corrects into varus • Subtalar joint movements are full and pain free
Rigid	• On tiptoe the arch fails to return and the heel remains in valgus • Subtalar joint movements are restricted and often painful

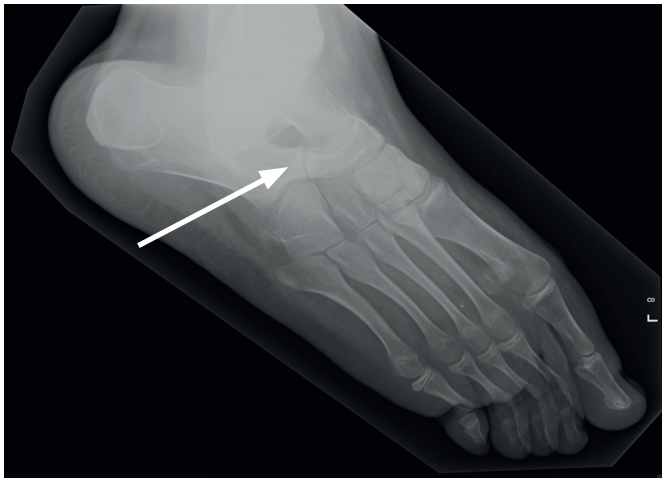

Figure 44.4 Oblique radiograph of the foot that shows the most common form of tarsal coalition: an incomplete calcaneonavicular bar (arrow).

Summary box 44.2

Normal variants

- Legs are often bowed until age 2 years and then knock-kneed until age 6–7 years
- Neuromuscular pathology must be excluded in toe walkers, particularly when the onset is late
- Intoeing or extoeing is associated with excessive femoral or tibial torsion or foot deformity
- Flexible, pain-free flat feet require no treatment

Postural abnormalities

Many babies are subjected to moulding pressures *in utero*. At birth they exhibit 'postural abnormalities', such as torticollis, calcaneovalgus feet and plagiocephaly, which improve with time and/or stretching exercises.

CONGENITAL AND DEVELOPMENTAL ABNORMALITIES OF THE SKELETON

Although many skeletal abnormalities are identified antenatally or at birth, others become apparent with growth. Skeletal disorders are often linked to focal or generalised soft-tissue abnormalities; the presence of a skin dimple or a

vascular malformation should be a 'red flag', as should the 'featureless' limbs of a child with arthrogryposis multiplex congenita (AMC) (*Table 44.4 and Figure 44.5*).

TABLE 44.4 Classification of congenital limb malformations.

Category	Example
Failure of formation of parts	
• Transverse	• Congenital amputation of the forearm/lower limb
• Longitudinal	• Fibula hemimelia
Failure of differentiation	Radioulnar synostosis; vertebral body fusion
Duplication	Extra digits
Overgrowth	Gigantism; macrodactyly
Undergrowth	
Congenital constriction band syndrome	Often affects hands/feet with poor formation of the digits distally
Generalised skeletal abnormalities	Skeletal dysplasia, e.g. achondroplasia

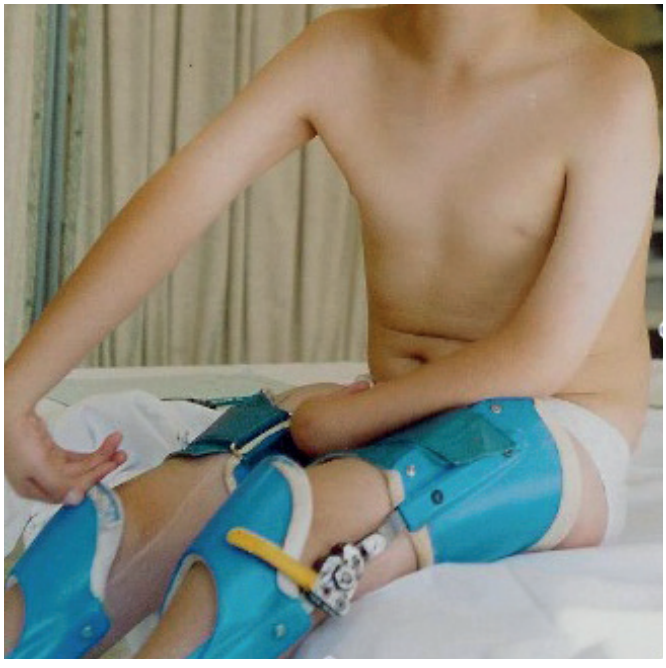

Figure 44.5 A child with arthrogryposis multiplex congenita and featureless upper limbs (no skin creases or muscle definition). He mobilises with the help of knee–ankle–foot orthoses.

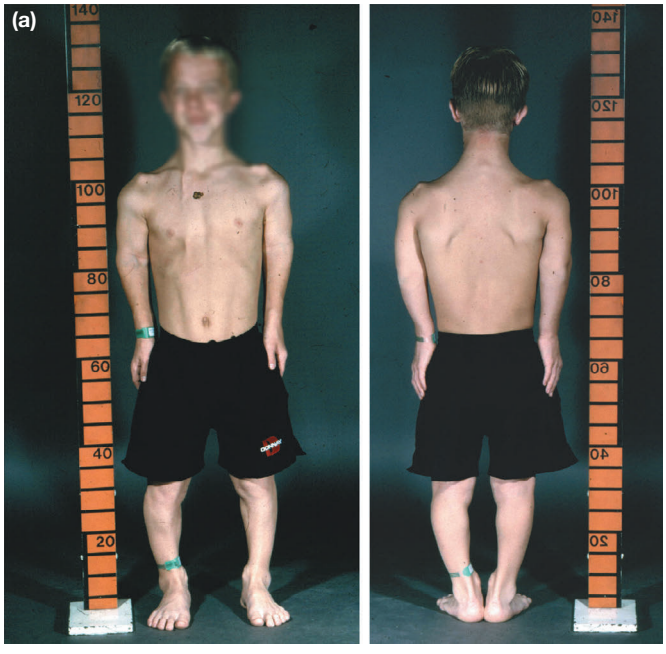
Many anomalies require little treatment and cause minimal functional disability whereas others, such as proximal femoral focal deficiency (PFFD), pose considerable challenges to both the patient and their doctors. In these cases the functional and cosmetic needs of the child and family must be balanced against available resources and expertise (*Figure 44.6*). Despite advances in limb reconstruction techniques there are few high-quality data from skeletally mature patients to support their widespread use. Concurrently, significant advances are occurring with amputation prosthetics, which may result in better patient-reported outcome scores (PROMSs), particularly in certain regions.

Generalised skeletal dysplasias

Achondroplasia

Achondroplasia is caused by a gain-in-function mutation in the FGFR3 (fibroblast growth factor receptor 3) gene, located on the short arm of chromosome (Chr) 4, which affects enchondral bone formation. It is autosomal dominant. Patients present with disproportionate short stature where the limbs are shorter than the trunk, together with classical clinical and radiographic features (*Figure 44.7*).

Underdevelopment of the foramen magnum and spinal stenosis can cause neurological difficulties. Correction of limb alignment may be necessary and limb-lengthening techniques are used in some countries.



Hereditary multiple exostoses

An autosomal dominant condition related to a loss-of-function mutation in either the *EXT1* (Chr 8q) or *EXT2* gene (Chr 11p), leads to dysregulated growth and exostosis formation. Exostoses consisting of a cartilaginous cap on a bony stalk may be sessile or pedunculated. They grow as the child grows and may cause cosmetic or functional difficulties,

Figure 44.6 Radiograph of a child born with proximal femoral focal deficiency. A proximal femoral osteotomy improved her hip mechanics and stability (a screw has come loose from the plate). She opted to keep her foot and not to undergo leg lengthening. She functions well with an extension prosthesis.

justifying excision. Differential growth between the paired bones of the forearm and lower leg can lead to joint deformity and dislocation of the radial head, exacerbated by the effects of altered mechanical forces on growth. Treatment aims to prevent deformity (***Figure 44.8***). Continued growth after skeletal maturity may represent malignant transformation of a benign osteochondroma: a rare occurrence (see ***Chapter 42***).

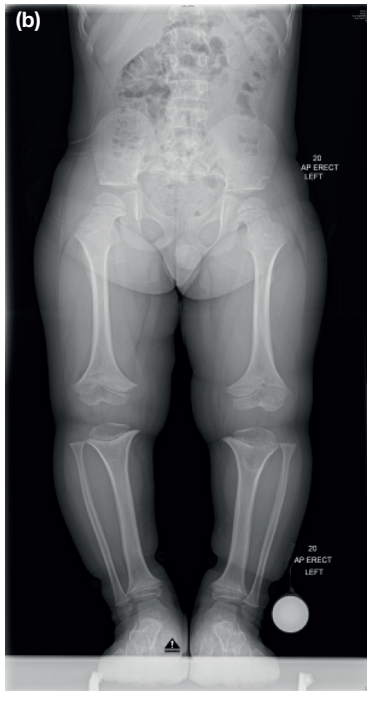


Figure 44.7 Achondroplasia. **(a)** A child with achondroplasia: his upper limbs are short and his hands do not reach midthigh. **(b)** Standing leg length/alignment radiograph of a different child demonstrating short limbs, widened metaphysis, an overlong fibula and slight bowing. The acetabulum is horizontal and the pelvic wings seem square: classical features of achondroplasia.

Enchondromatosis (Ollier's disease)

Enchondromas arise from chondrocyte rests within the medullary canal of tubular bones: they consist of mature hyaline cartilage (***Figure 44.9***). Larger lesions may show calcification on radiographs and vertical lucent streaks (representing cartilage columns) in the metaphysis. Pathological fractures are common. In Maffucci's syndrome there are also soft-tissue haemangiomas and lymphangiomas (see ***Chapter 42***).

Fibrous dysplasia

This common disorder is often a chance radiographic finding, particularly in its monostotic form. It is a localised defect in osteoblastic differentiation and maturation in which normal bone is replaced by fibrous stroma. With polyostotic fibrous dysplasia, limb deformity and pathological fractures are common. In patients with precocious puberty and Coast of Maine café-au-lait spots, the diagnosis is McCune–Albright syndrome (***Figure 44.10***).

Summary box 44.3

Congenital and developmental abnormalities of the skeleton

- Achondroplasia affects enchondral ossification and presents with disproportionate short stature
- Exostoses may cause functional and/or cosmetic problems
- Patients with Ollier's disease (multiple enchondromatosis) often have lesions in the hands and feet

Figure 44.8 Radiograph of the knee showing multiple broad-based osteochondromas.

Louis Xavier Edouard Léopold Ollier, 1830–1900, Professor of Surgery, Lyons, France, described enchondromatosis in 1899.
Angelo Maffucci, 1845–1903, Professor of Pathological Anatomy, Pisa, Italy, described enchondromatosis in association with soft-tissue haemangiomas in 1881.
Donovan James McCune, 1902–1976, American paediatrician.
Fuller Albright, 1900–1969, physician, Massachusetts General Hospital, Boston, MA, USA.

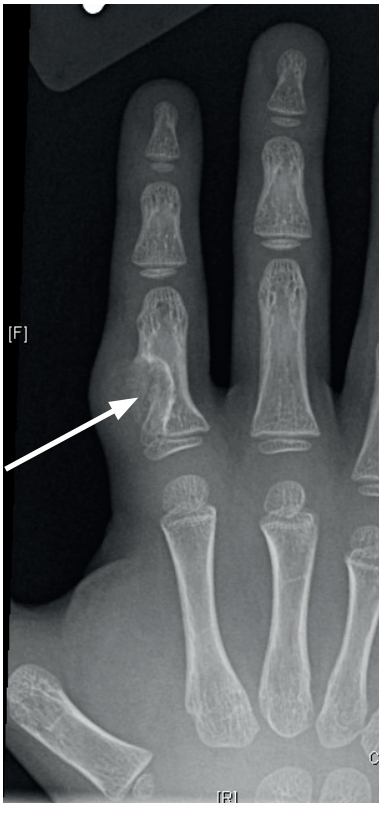

Figure 44.9 Anteroposterior radiograph of the index finger of a child showing a solitary enchondroma (arrow): note the opacity in the soft tissues, which represents the extent of the cartilaginous lesion.

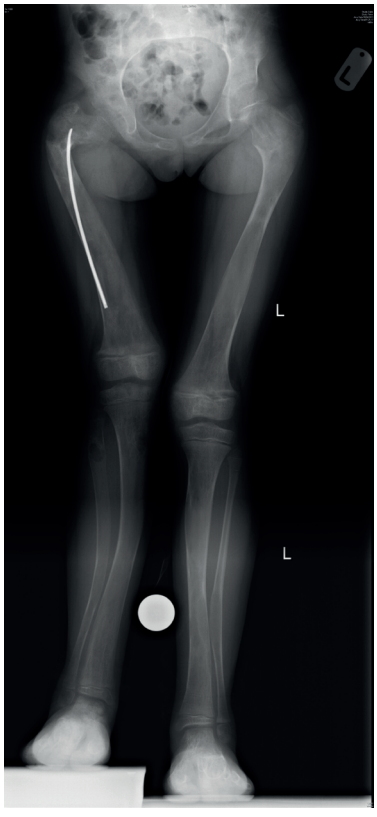

Figure 44.10 Standing leg length/alignment radiograph of a child with polyostotic fibrous dysplasia. The diaphyseal lesions have a 'ground-glass' appearance. The bones are often deformed and the limb may be short, as seen on the right. The femur has fractured previously and one intramedullary nail remains in place.

METABOLIC BONE DISEASE

Rickets

In rickets, the primary problem is inadequate mineralisation of growing bone (*Table 44.5*). In severe cases the classic radiographic features are seen at all physes with significant deformity (*Figure 44.11*). Medical treatment improves mineralisation and deformity corrects with growth. Once the medical condition has stabilised, surgery may be indicated to treat residual limb deformity. Guided growth techniques are often used in preference to osteotomies.

TABLE 44.5 Common causes of rickets.

Nutritional	Reduced intake of vitamin D and calcium
Environmental	Inadequate exposure to sunlight
Gastrointestinal disease	Crohn's disease, gluten-sensitive enteropathy
Genetic	X-linked hypophosphataemia (excess FGF23 production)
Renal disease	End-stage renal failure, renal tubular anomalies Secondary hyperparathyroidism may be present

Figure 44.11 Radiographs in cases of rickets demonstrate widened physes with cupped, flared metaphyses.

Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932.

Osteogenesis imperfecta (brittle bone disease)

Osteogenesis imperfecta (OI) represents a spectrum of conditions linked by a qualitative and/or quantitative abnormality of collagen production. Most identified mutations affect the collagen genes. The bone may break easily but it heals promptly and well. All structures containing collagen may be affected, accounting for the ligamentous laxity, blue sclerae and poor teeth in some phenotypes.

Cyclical bisphosphonate treatment decreases bone resorption and turnover. This reduces bone pain and the fracture rate, promoting weight-bearing mobility and bone strength (*Figure 44.12*).

Following fracture, treatment options range from simple casting techniques to more specialised surgical procedures to correct/maintain bony alignment while allowing growth. Intramedullary techniques for stabilisation of fractures or osteotomies are preferred to plate fixation. Rehabilitation should start promptly.

Summary box 44.4

Metabolic bone disease

- Rickets, from nutritional or other causes, is characterised by a failure of bone mineralisation
  - X-linked hypophosphataemic rickets is a dominant condition, affecting boys and girls; in some countries, treatment is with monoclonal FGF23 antibodies
- In OI:
  - There is defective type I collagen production
  - In severe forms frequent fractures lead to progressive deformity, which in turn increases fracture risk
  - Systemic treatment with bisphosphonates reduces the fracture rate

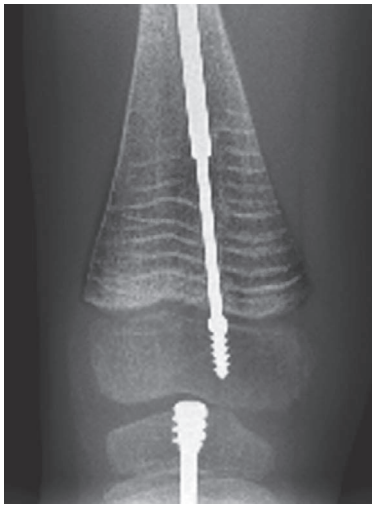

Figure 44.12 Radiograph of a child with osteogenesis imperfecta who has been treated with cyclical bisphosphonates. Multiple growth lines are visible in addition to intramedullary devices in both the femur and tibia.

ABNORMALITIES OF THE HIP

Developmental dysplasia of the hip

DDH defines the spectrum of hip instability, ranging from the hip that is in joint but has a shallow (dysplastic) acetabulum and may be 'pushed out' (Barlow positive) to the dislocated hip that is irreducible (Ortolani negative). The clinical picture varies with the pathology and the age at presentation: neonatal hips may be unstable, a toddler may limp, adolescents may experience exercise-induced pain and an adult may have pain secondary to degenerative arthritis.

Incidence

The incidence of neonatal instability is approximately 20 per 1000 live births, whereas that of true dislocation is approximately 2 per 1000 live births; many hips stabilise spontaneously.

Aetiology of developmental dysplasia of the hip

- **Gender**. Four to five times more common in girls, possibly related to hormonal factors causing temporary joint laxity in the peripartum period.
- **Breech presentation**. More common in breech babies, particularly with the extended breech position.
- **Birth order**. More common in firstborns and in the left hip because of the common fetal position (left occipito-anterior) in a tight primigravid uterus where movement is restricted.
- **Oligohydramnios**. Restricts fetal movement. The presence of other postural deformities (torticollis and metatarsus adductus) raises the possibility of DDH.
- **Family history**. A positive family history significantly increases the risk of DDH.
- **Regional and racial variation**. More common in certain regions and in certain races because of a combination of genetic, environmental and cultural factors.
  - Swaddling the legs together exacerbates hip instability, whereas carrying the baby astride the carer's hip or back encourages hip flexion and abduction that improve stability.

Hip dislocation is often found in association with generalised syndromes or neuromuscular conditions. These teratological hips are often resistant to the simpler treatments and a holistic approach to the child's overall condition and prognosis must be taken.

Diagnosis

Neonate

- **Clinical assessment and screening**. In many countries, neonates are screened for limitation of hip abduction and hip joint instability. In the UK, as part of the newborn and infant physical examination (NIPE) guidelines, the hips are examined again at 6 weeks. The knees and hips are flexed and the thigh held by the examiner with the thumb

Thomas Geoffrey Barlow, 1915–1975, orthopaedic surgeon, Salford Royal Hospital, Salford, UK.
Marius Ortolani, 1904–1987, orthopaedic surgeon, Instituto Provinciale Per L'Infanzia di Ferrara, Italy, described this test in 1937.

along the medial aspect and a finger behind the greater trochanter. The hips are abducted gently: if abduction is limited, the hip may be dislocated. The examiner's finger then lifts the greater trochanter upwards; a soft clunk – the **Ortolani test** – with improved hip abduction signifies hip reduction (*Figure 44.13a*). If the hip does abduct fully, then the flexed hip is brought back to neutral and then adducted while downward pressure is applied to the knee with the examiner's thumb and palm: an unstable hip may dislocate or sublux – the **Barlow test** (*Figure 44.13b*). With an irreducible hip there is no clunk of reduction but there will be limitation of abduction. Bilateral dislocation may be missed because abduction is symmetrical and abduction may be normal when there is low muscle tone and joint laxity. In a dislocated hip, the femoral head may be palpable in the buttock.

- **Ultrasonographic assessment**. Ultrasonography defines the anatomy and the stability of the hip joint. It is used as a screening tool (universally or selectively for 'at-risk' patients) (*Figure 44.14*). Screening scans should be performed between 4 and 6 weeks of age and treatment, when necessary, started by 6 weeks. The sonographic appearance of most hips improves (in terms of both hip stability and acetabular dysplasia) spontaneously as the baby grows.
- **Radiography**. Plain radiographs are used from 4–5 months of age, when the relationship of the femoral ossific nucleus to the acetabulum can be assessed; late ossification of the nucleus is common in DDH (*Figure 44.15*).

Infant

Hip checks, looking for limitation of abduction in more than 90° of flexion and limb shortening, are part of developmental monitoring.

Child

Children present with a Trendelenburg gait and/or unilateral tiptoeing, as the affected leg is short. Abduction in flexion is limited and there may be an extra thigh crease. The signs may be subtle and easily missed in an unsteady toddler. If both hips are affected there will be a waddling gait and a lumbar lordosis.

Adolescent

Discomfort after exercise is common but the pain may be in the knee.

In all age groups, radiographs may show dysplasia, subluxation or dislocation.

Summary box 44.5

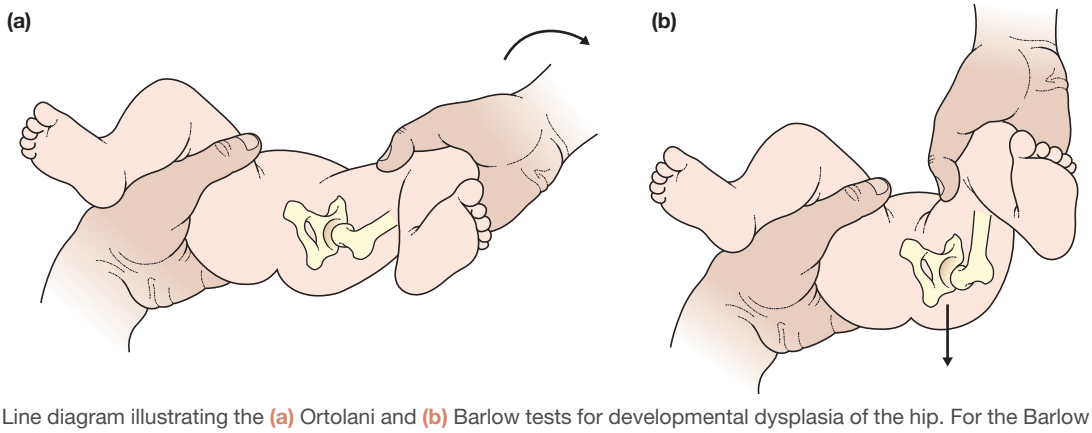
The neonatal clinical examination must ask and answer the following questions:

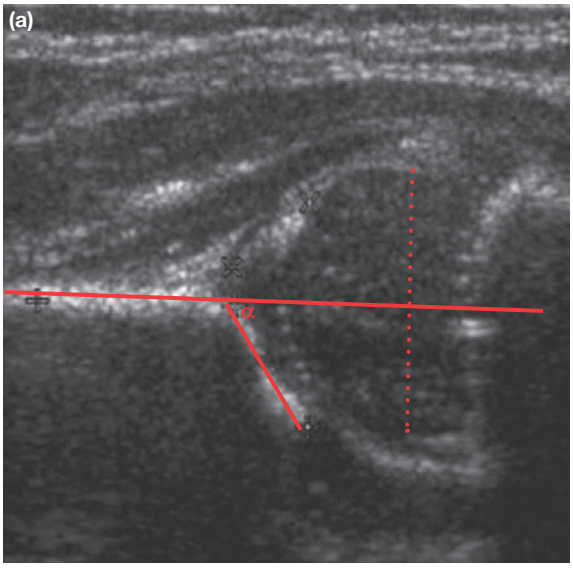
- Is the hip dislocated?
  - If so, is it reducible (Ortolani positive) or not (Ortolani negative)?
- If the hip is not dislocated, is it dislocatable (or subluxable)?
  - If so, it is Barlow positive
- If the hip is not dislocated or dislocatable, is it clinically normal?
  - If so, do the risk factors in the history still demand further assessment with an ultrasound scan or plain radiograph?

Summary box 44.6

Diagnosis of DDH

- Based on the history and clinical examination and confirmed by appropriate investigations
- All neonates are screened clinically (Barlow and Ortolani tests) at birth and at 6 weeks
- Ultrasound is used as a selective screening test in 'at-risk' babies
- Radiography is useful from 4 months onwards
- Older children present with a limp and/or tiptoeing and a lumbar lordosis in bilateral cases





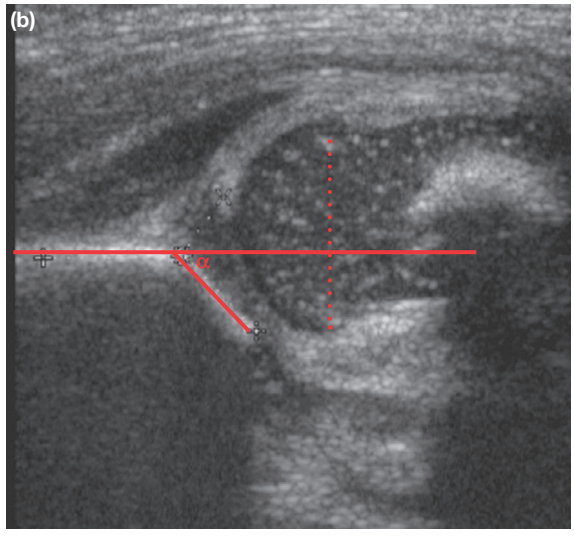


Figure 44.13 Line diagram illustrating the (a) Ortolani and (b) Barlow tests for developmental dysplasia of the hip. For the Barlow test the femur must be at 90° to the bed.

Friedrich Trendelenburg, 1844–1924, successively Professor of Surgery at Rostock (1875–1882), Bonn (1822–1895) and Leipzig (1895–1911), Germany.

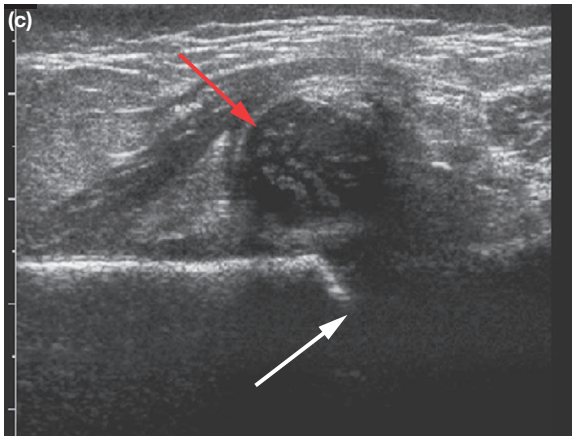

Figure 44.14 Ultrasound images of an infant hip. **(a)** Normal hip with a high α angle and a Morin index of 50% (defined as the percentage of the femoral head covered by the acetabulum, i.e. the portion lying below the horizontal red line). **(b)** Grossly dysplastic hip with a low α angle and a Morin index of <50%. This hip is likely to be unstable on dynamic ultrasound scanning, i.e. Barlow positive. **(c)** A dislocated hip joint (dislocated femoral head, red arrow; 'empty' acetabulum, white arrow).

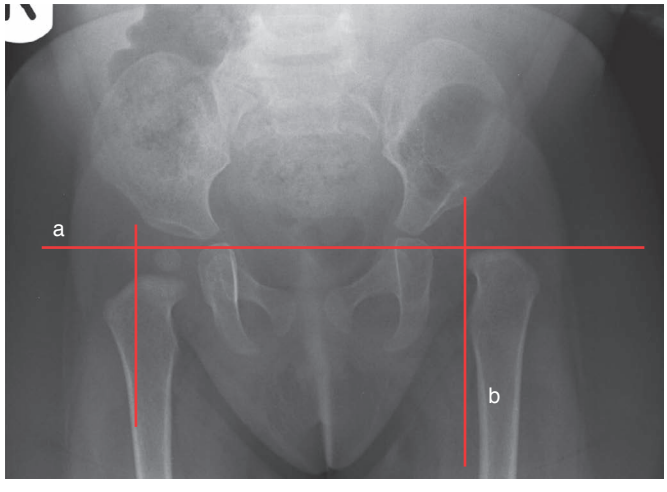

Figure 44.15 Anteroposterior pelvic radiograph showing Hilgenreiner's line (a) and Perkins' line (b). The femoral head (ossific nucleus) of a normal hip lies in the inner lower quadrant. The right hip is normal; the left hip has developmental dysplasia of the hip.

Management

The objective is to obtain a stable, congruous reduction of the femoral head within the acetabulum while avoiding damage to the capital epiphysis (avascular necrosis [AVN]), which causes stiffness and proximal femoral deformity.

Neonate

Owing to the peripartum hormonal effects many neonatal hips are unstable. Most stabilise spontaneously by 6 weeks.

Hips that remain unstable or that are dislocated at rest are treated with harnesses or splints that obtain and maintain reduction with the hip abducted and flexed. Joint stability is monitored with ultrasound scanning. Most harnesses (***Figure 44.16***) allow controlled movement while splints hold the hips more rigidly and may carry a greater risk of AVN and femoral nerve palsy. If the hips fail to relocate or stabilise, treatment should be discontinued.

Infant

Successful harness treatment is unusual after the age of 4–6 months. For the late-presenting hip or one that fails conservative treatment, an examination under anaesthetic may achieve a closed reduction. A psoas/adductor release can

Christian Morin, contemporary, French paediatric orthopaedic surgeon.
Heinrich Hilgenreiner, 1870–1954, German surgeon and orthopaedist.
George Perkins, 1892–1980, Professor of Surgery, St Thomas' Hospital, London, UK, described signs by which to diagnose congenital dislocation of the hip in 1928.

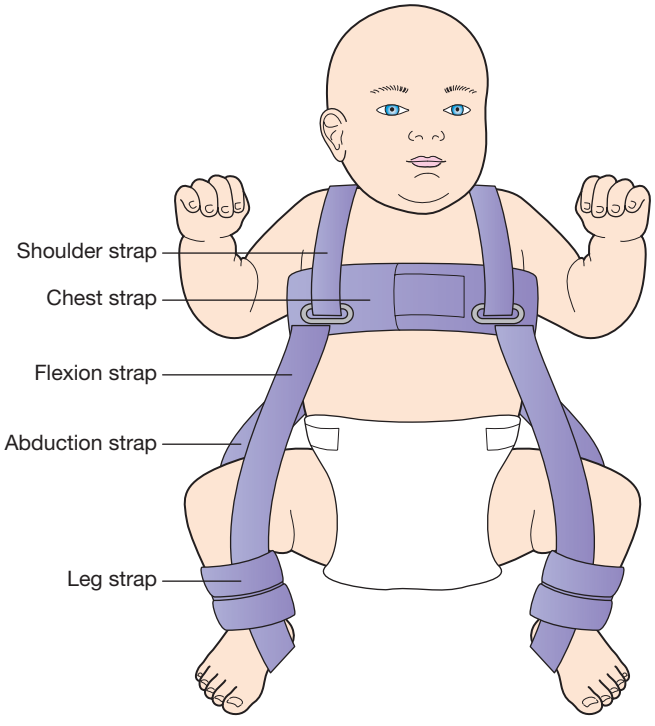

Figure 44.16 The anterior strap of the Pavlik harness controls hip flexion, whereas the posterior strap limits adduction and encourages abduction.

be performed if the arthrogram suggests they are blocking reduction or limiting stability. Postoperatively, a spica cast maintains hip reduction.

If the hip is irreducible or can only be held reduced in an extreme position then treatment should be abandoned and an open reduction considered via a medial or anterior approach.

Summary box 44.7

Management of early DDH

- Many hips that are unstable in the first 2–3 weeks of life require no treatment as they improve spontaneously
- Up to age 4–6 months, a harness or splint is effective treatment
- In older babies, closed reduction is often possible
- For failed closed treatment, open surgical reduction is required

Child

A medial approach open reduction can be performed between 6 and 24 months of age. An anterior approach to the hip (from 9–12 months of age) allows for a simultaneous capsulorrhaphy. In the older child, a pelvic osteotomy may be required to reorientate the acetabulum, and femoral shortening or derotation osteotomies will improve stability (***Figure 44.17***).

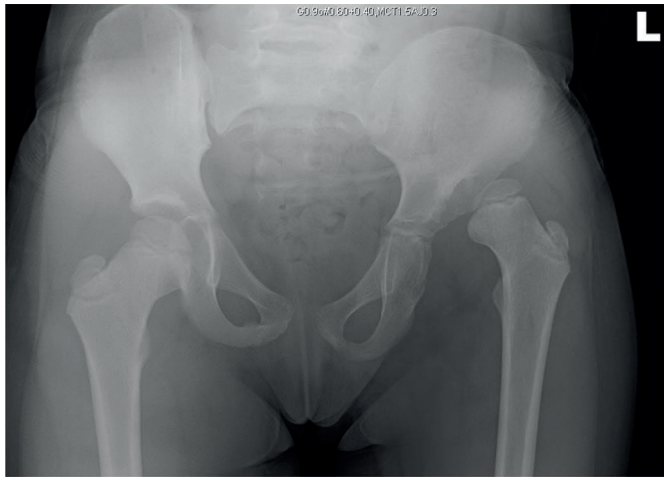

Figure 44.17 Anteroposterior pelvic radiograph showing acetabular dysplasia with subluxation (developmental dysplasia of the hip) of the left hip. This child presented at age 7 years.

Surgery is contraindicated in children over the age of 6–8 years in bilateral cases and the age of 8–10 years in unilateral cases (***Figure 44.18***).

Adolescent

Hips are often dysplastic and subluxated. If the hip is reducible, the joint can be reconstructed with a combination of pelvic and femoral osteotomies. For the irreducible hip, acetabular augmentation may reduce symptoms and delay the onset of degenerative change.

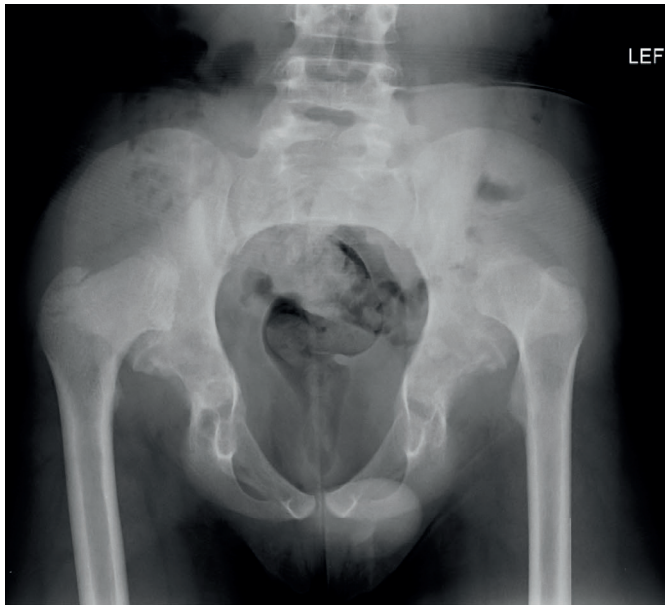

Figure 44.18 Anteroposterior pelvic radiograph showing bilateral true dislocations in a 9-year-old child; the decision was made not to offer an operation. The pathology in these hips is different from that shown in ***Figure 44.17***.

Arnold Pavlik, 1902–1962, Czech orthopaedic surgeon, became famous mainly for the development of a functional, active method of treating developmental dysplasia of the hip.

Summary box 44.8

Management of late-presenting DDH

- The older the child, the more likely it is that they will require surgery
- Femoral osteotomy improves hip stability
- Pelvic osteotomy redirects or reshapes the acetabulum
- The potential for acetabular remodelling decreases after the age of 3–4 years
- Avascular necrosis is a risk with all DDH treatment

Secondary procedures and complications

At follow-up, acetabular remodelling is assessed with the acetabular index or the centre–edge angle (***Figure 44.19***). Surgery may be required for residual dysplasia or subluxation. AVN with trochanteric overgrowth causes a Trendelenburg limp: the outcome is poor (***Figure 44.20***). Occasionally, a leg length difference needs treatment. There is an increased risk of osteoarthritis and hip arthroplasty later in life.

Legg-Calvé-Perthes disease

Incidence and aetiology

This rare condition, characterised by the development of AVN of the proximal femoral epiphysis, predominantly affects boys aged 4–7 years; 10% develop bilateral disease. Although the aetiology is unclear, factors such as socioeconomic deprivation and passive smoking have been implicated. Other causes of femoral head AVN must be considered, particularly in bilateral cases (***Table 44.6***).

TABLE 44.6 Causes of avascular necrosis of the femoral head.

- Steroids
- Infection/surgery/previous injury
- Perthes' disease
- Sickle cell disease
- Hypothyroidism
- Multiple epiphyseal dysplasia will show AVN-like appearances in both femoral heads

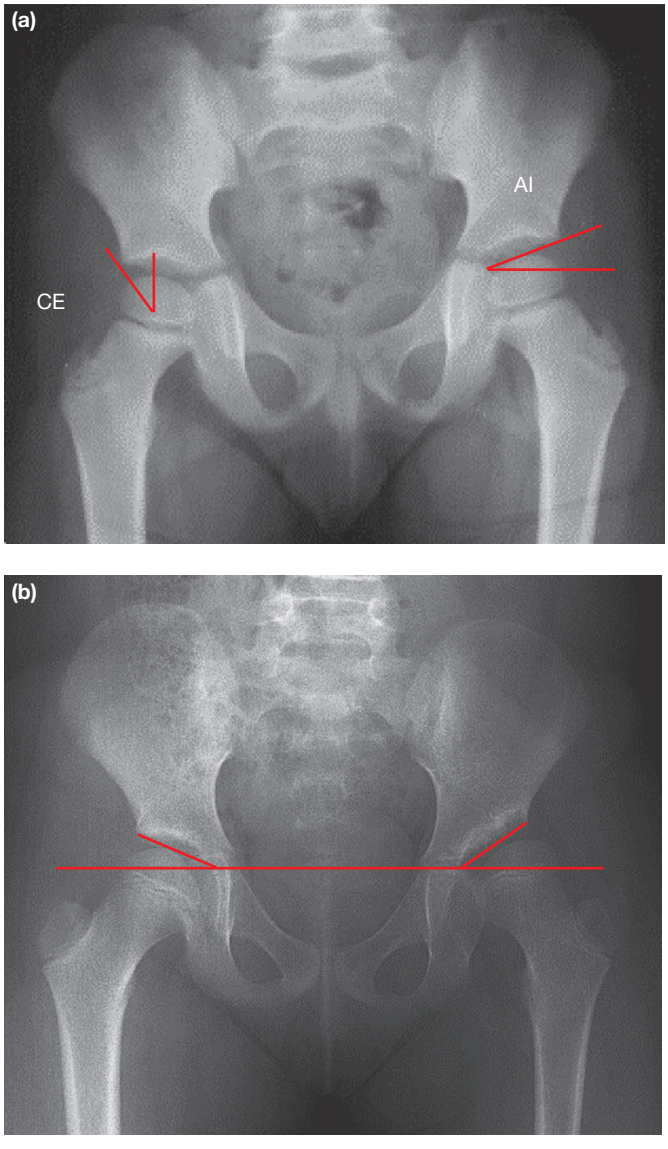

Figure 44.19 Anteroposterior pelvic radiographs demonstrating the acetabular index (AI) and the centre–edge (CE) angle: **(a)** normal hips; **(b)** the left hip shows residual dysplasia. The AI is increased when compared with the normal right hip. The left CE angle would be smaller too, but it has not been measured on this radiograph.

Pathology

Once established the process follows a well-described course. The avascular change may affect all or part of the femoral epiphysis. If the avascular bone collapses, this is followed by revascularisation, resorption and fragmentation of the dead ossific nucleus within the cartilaginous femoral head, and finally by reossification and regeneration ('healing') of the bony epiphysis. In this respect, Perthes' disease is a self-limiting condition but, during the collapse and fragmentation phases, femoral head deformity occurs as the cartilage 'follows' the shape of the reossifying epiphysis. This change in shape is irreversible and has a permanent effect on hip function.

Diagnosis

The history, clinical examination and anteroposterior and 'frog' lateral pelvic radiographs make the diagnosis. An intermittently painful hip (or knee) with a limp and irritability or restriction of hip movements requires investigation. The radiographic features vary with the disease stage and may not correlate with the clinical condition (***Figure 44.21***).

Legg, Calvé and Perthes all described osteochondritis of the head of the femur independently in 1910.
Arthur Thornton Legg, 1874–1939, orthopaedic surgeon, The Children's Hospital, Boston, MA, USA.
Jacques Calvé, 1875–1927, orthopaedic surgeon, La Fondation Franco-Americaine, Berck Plage, Pas-de-Calais, France.
Georg Clemens Perthes, 1869–1927, Professor of Surgery, Tübingen, Germany.

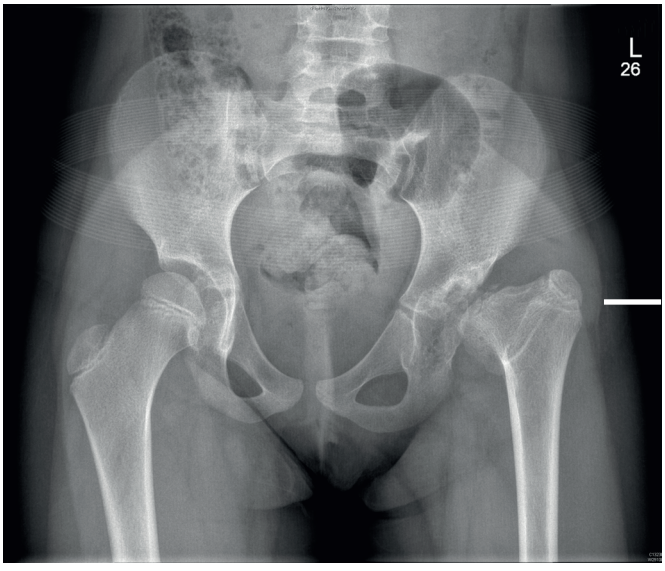

Figure 44.20 Anteroposterior pelvic radiograph of a 7-year-old girl who developed avascular necrosis secondary to a postoperative wound infection following a closed reduction of her dislocated left hip. Note the destruction of the femoral head and the proximal femoral physis, so that the femoral neck is short and the greater trochanter relatively high (arrow).

Management

The prognosis, and hence the management, is influenced by the extent of AVN and the degree of collapse. The Herring classification is popular but can only be applied when the head is in the fragmentation phase. If the anterolateral portion of the head is preserved, the prognosis is good.

Treatment aims to minimise femoral head deformity and the risk of secondary acetabular dysplasia by maintaining a good range of joint movement with analgesia and physiotherapy. The use of crutches and/or wheelchairs is discouraged because they promote a flexion/adduction posture. Brace management does not alter the natural history.

The role of operative treatment is controversial. Surgery can be performed early to prevent deformity secondary to femoral head collapse or late to 'salvage' a poor mechanical situation when deformity is limiting movement (*Table 44.7*).

Summary box 44.9

Legg-Calvé-Perthes disease

- Most common in boys aged 4–7 years
- AVN leads to femoral head collapse; the return of the blood supply heralds the resorption and reossification phases that allow the femoral head to 'heal'
- The prognosis is better in younger children (and in boys), who have more remodelling potential before skeletal maturity
- Management aims to maintain femoral head sphericity
- Treatment may be non-surgical (to maximise range of movement) or surgical (early for containment or late for 'salvage')

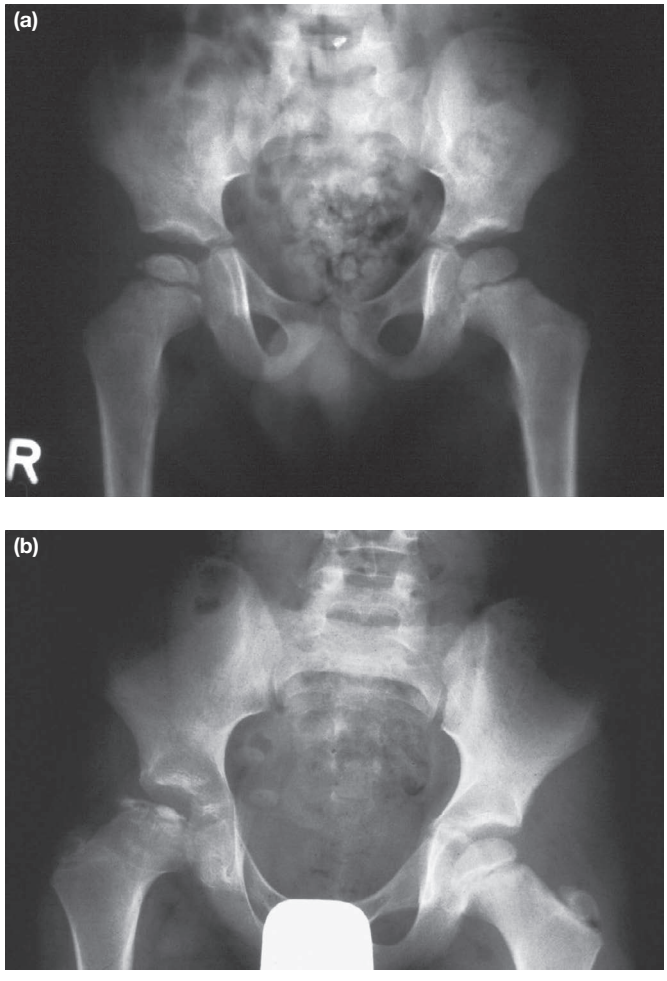

Figure 44.21 Anteroposterior pelvic radiographs of Perthes' disease demonstrating whole head involvement: (a) right-sided disease; the process is in an early phase and the area of dense necrotic bone is visible; (b) there has been collapse and fragmentation. The Herring classification relates to the height of the lateral pillar (lateral portion of the epiphysis) in the fragmentation phase of the disease.

Not all hips with deformity require 'salvage' surgery: young children, with more time to remodel, have a better prognosis as the acetabular changes (in response to the altered femoral head shape) result in an aspherical but congruent joint. Degenerative change may occur in adult life.

Slip of the capital (upper) femoral epiphysis (SCFE/SUFE)

The physis connects the proximal femoral epiphysis (the femoral head) to the metaphysis (femoral neck). In certain physiological or pathological conditions a 'stress fracture' through the physis allows the epiphysis to displace as it would with an intracapsular femoral neck fracture, so the leg lies short and externally

John A Herring, contemporary, pediatric orthopedic surgeon, chief of staff emeritus, Texas Scottish Rite Hospital for Children, and professor, UT Southwestern Medical Center, Dallas, TX, USA.

TABLE 44.7 A guide to some of the surgical options available for the management of Perthes' disease.

Timing	Type of procedure	Comments	Aim
Early	Femoral osteotomy	• Varus and derotation • Consider an opening wedge osteotomy to maintain length	To cover ('contain') the vulnerable femoral head
	Innominate osteotomy		
	Shelf acetabuloplasty		
Intermediate	Arthrodiastasis	Hinged distraction to allow movement, primarily flexion/extension	To reduce deforming pressures on the femoral head
Late	Femoral osteotomy	• Valgus • With extension to undo a fixed flexion deformity or flexion to remove the anterior bump from impinging on the acetabulum	To improve joint congruity and hence function; to improve joint mechanics
	Arthrotomy	To remove osteochondral fragments	
	Head–neck osteoplasty	After physeal closure	To improve head shape by reducing femoroacetabular impingement and increasing head/neck offset
	Trochanteric epiphysiodesis or distal transfer	Epiphysiodesis not effective after age 7–8 years	To improve lever arm function
Contralateral limb	Distal femoral epiphysiodesis		To reduce leg length discrepancy and effects on hip joint mechanics

rotated. There is painful limitation of hip movement. Hilton's law, which states that a joint is supplied by the same nerves as the muscles that move the joint, explains why many children present with knee pain although the pathology is in the hip.

Incidence and aetiology

SCFE is rare, with an incidence of approximately 5 per 100 000 population. Boys are affected most commonly. The peak incidence is related to the start of puberty and hence is earlier in girls. As a result of hormonally stimulated growth, the strength of the physis, its resistance to shear and its orientation are reduced. The hip is therefore 'at risk' and normal forces, exacerbated by obesity and repetitive minor trauma, precipitate a slip. Other conditions such as hypothyroidism, renal failure and previous radiotherapy treatment (local or to the pituitary) also increase the risk.

Diagnosis

The diagnosis is suggested by the history and examination and confirmed on plain radiographs (*Figure 44.22*). Displacement is often more obvious on a lateral view and the diagnosis can be missed if only the anteroposterior radiograph is checked.

Classification

A SCFE can be classified according to three parameters: timing, severity and stability. The onset of symptoms divides slips into those that are acute, chronic or acute on chronic. Slip severity is assessed on the lateral radiograph in terms of percentage uncovering of the metaphysis (*Table 44.8*) or by measuring the slip angle of Southwick (*Figure 44.23*). An unstable slip is defined by Loder as one in which the patient cannot bear weight on the limb.

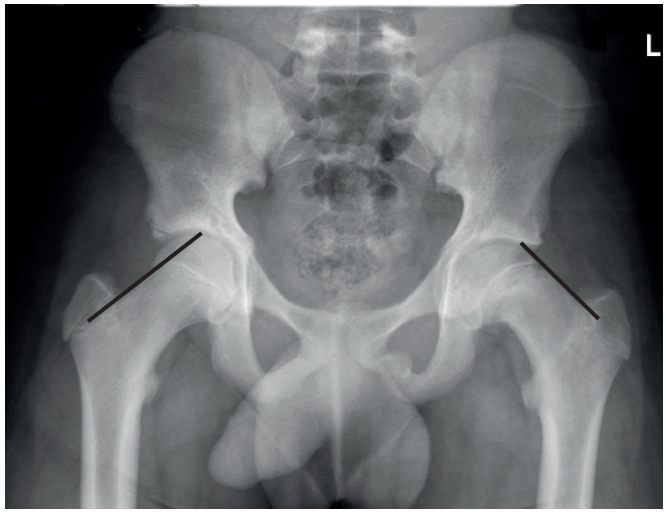

Figure 44.22 Anteroposterior pelvic radiograph demonstrating a mild slip of the upper (capital) femoral epiphysis on the left side. A line drawn along the upper margin of the femoral neck should transect the femoral head (right side); if it does not do so (left side) a slip is present. There are many other radiographic features that help to confirm the diagnosis but the changes are often subtle and may be seen first on the frog lateral view.

John Hilton, 1805–1878, surgeon, Guy's Hospital, London, UK.
Wayne O Southwick, 1923–2016, American surgeon and academic, first chairman of the Department of Orthopaedics and Rehabilitation, Yale University, New Haven, CT, USA, from 1958 to 1979.
Randall Loder, contemporary, Professor of Orthopaedic Surgery, Philadelphia, PA, USA.

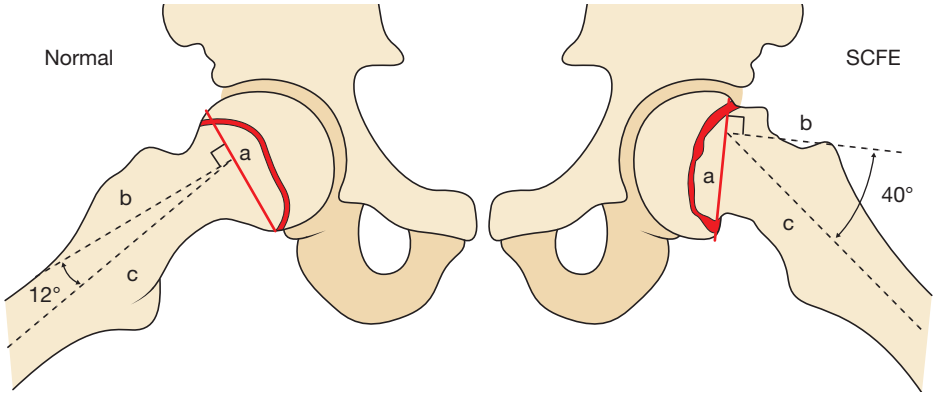

Figure 44.23 The Southwick slip angle is measured on a lateral radiograph and denotes how far the epiphysis has slipped off the metaphysis. The value on the normal side must be subtracted from the value on the abnormal side to get the true value. SCFE, slip of the capital femoral epiphysis.

Management

Following an acute episode the patient is often unable to weight bear and the slip is considered to be **unstable**.

TABLE 44.8 Grading of the severity of slip of the capital femoral epiphysis.

Slip severity	Metaphysis uncovered (%)
Mild	<33
Moderate	33–66
Severe	>66

Displacement is often moderate or severe. This situation is equivalent to a displaced intracapsular femoral neck fracture. This means that an acute unstable SCFE is an emergency. The AVN risk is considerable (*Figure 44.24*).

With the reduction in muscle spasm that accompanies a general anaesthetic, a gentle repositioning of the femoral epiphysis occurs as the externally rotated limb is lifted into the neutral position using no force. A capsulotomy reduces the tamponade effect on the epiphyseal vessels. To be effective such treatment should take place within 24 hours of injury. If delayed, the AVN rate may increase.

With **chronic** slips the patient is able to weight bear, albeit with pain, and the slip is stable. Screw or pin fixation *in situ* relieves pain and movement improves but there will be permanent reduction in abduction, flexion and internal rotation (*Figure 44.25*). The leg will be slightly short.

In the **chronic severe** slip it may be impossible to place a screw in a satisfactory position centrally within the epiphysis. Once healed, there may be significant, persistent deformity leading to restriction of joint movement. In these cases a realignment osteotomy may be considered. As with all osteotomies, the closer the correction is to the site of deformity, the better the outcome. However, in this situation the centre of rotation of angulation (CORA) for the deformity is at the level of the physis; the risk of AVN or chondrolysis may be unacceptably high with an osteotomy at this level, and so an intertrochanteric osteotomy could be considered. The slipped epiphysis is associated with a 'cam' type of femoroacetabular impingement and this may require treatment with a head–neck osteoplasty to restore the offset between the head and neck.

Bilateral slips do occur and prophylactic pinning of the normal but 'at-risk' hip may be indicated.

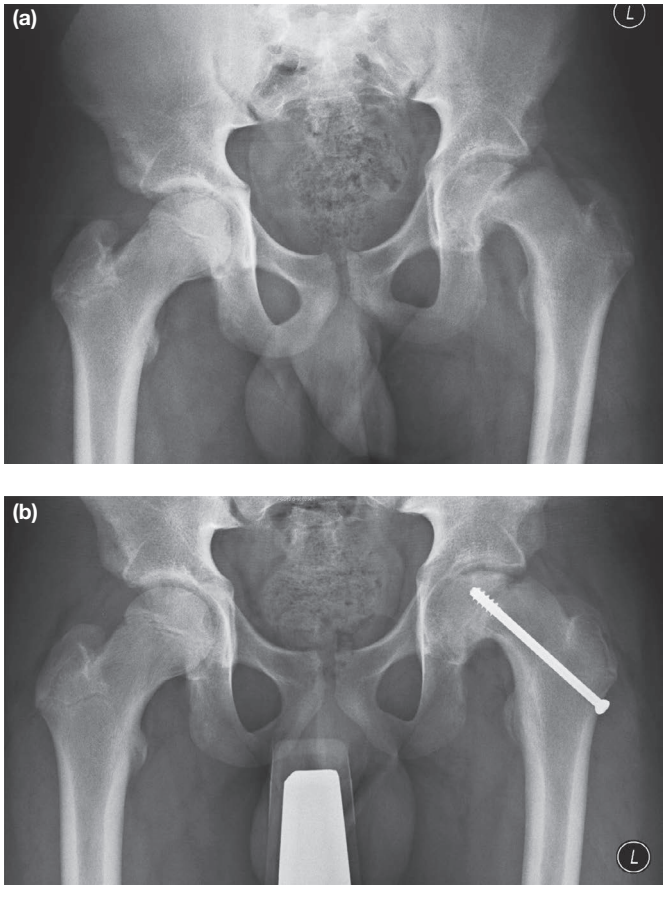

Figure 44.24 Anteroposterior pelvic radiograph showing a left-sided acute severe unstable slip of the capital femoral epiphysis: **(a)** at presentation; **(b)** following partial repositioning and fixation with a cannulated screw. When this heals, because of the incomplete reduction it is likely that the metaphysis will impinge on the acetabulum (femoroacetabular impingement) during movement, causing pain and leading to degenerative change.

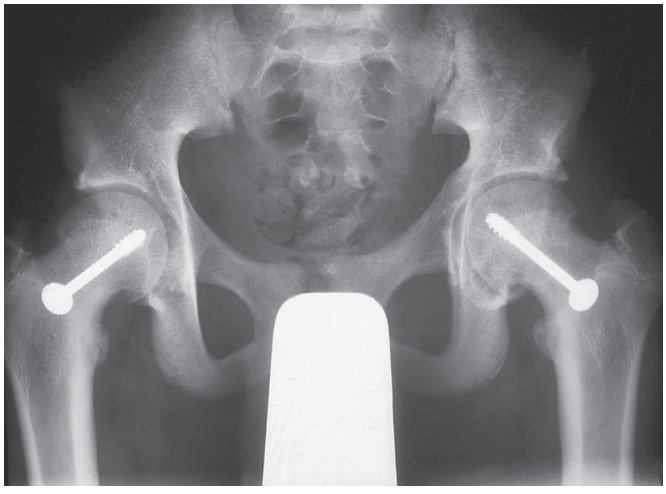

Figure 44.25 Anteroposterior radiograph showing screw fixation in situ of a case of bilateral chronic slip of the capital femoral epiphysis. Note the position of the screw: the more severe the slip, the more proximal and more anterior the screw entry point must be on the femoral neck.

Summary box 44.10

Slip of the upper (capital) femoral epiphysis

- Occurs in prepubertal children, boys more commonly than girls
- Often presents with knee pain, and a short and externally rotated leg
- Classification systems relate to timing, severity and stability – all affect the prognosis
- Most slips are pinned *in situ* with a single screw into the centre of the epiphysis
- AVN is a feared complication of both the condition and its treatment

ABNORMALITIES OF THE KNEE AND LOWER LEG

Many knee problems in children or adolescents are self-limiting. Others require surgical consideration to reduce the risk of later degenerative change.

Osteochondritis dissecans

Osteochondritis dissecans (OCD) affects the lateral aspect of the medial femoral condyle of the distal femur (but also the talus and the humerus). An osteochondral fragment becomes partially or completely separated from the joint surface. Magnetic resonance imaging (MRI) is the best method for demonstrating the site, extent and stability of the lesion. In mild cases, the osteochondral fragment remains attached and heals, particularly if treated early with activity modification. If it detaches, partially or completely, mechanical symptoms necessitate treatment either to encourage bone healing via fixation of the fragment or to remove a loose body. Younger children have a better prognosis.

Discoid meniscus

This invariably affects the lateral meniscus, which is abnormally thick and covers most of the tibial plateau. The child presents with a painful clunk on knee extension. MRI is usually diagnostic. Surgery is indicated for relief of pain or mechanical symptoms.

Anterior knee pain

In adolescents the extensor mechanism of the knee is a common site of knee pain.

Osgood–Schlatter disease is a traction apophysitis of the patellar tendon insertion. Pain, tenderness and swelling at the tibial tubercle, exacerbated by exercise, are diagnostic and radiographs are unnecessary (although, in unilateral cases, it may be important to exclude other diagnoses such as a malignancy). Treatment is relative rest and analgesia, and the condition resolves once the apophysis has fused.

Patellofemoral pain is common and often attributed to an adolescent growth spurt: symptoms are exacerbated either by activity or by resting with the knee flexed. Alterations to activity levels and sitting position and physiotherapy to stretch and strengthen both the hamstrings and the quadriceps muscles usually result in a return to normal within a few months.

Patellofemoral pain may be associated with patellar maltracking and/or instability. Physiotherapy develops the quadriceps muscles, particularly the vastus medialis oblique (VMO), and counteracts wasting secondary to the pain. Many operations improve patellar tracking and these include options for realignment of the extensor mechanism both proximally and distally.

Fibular hemimelia

In fibular hemimelia there is a congenital failure of formation of the lateral 'column' of the lower leg (*Figure 44.26* and *Table 44.9*).

TABLE 44.9 Classical radiographic features of fibular hemimelia.

Foot and ankle	Absent lateral rays; tarsal coalition; ball-and-socket ankle joint
Lower leg	Absent or deficient fibula; short, bowed tibia
Knee	Absent tibial spine (no cruciate ligament); deficient lateral femoral condyle
Femur	Relative hypoplasia
Limb length and alignment	Short; external rotation with/without valgus

Robert Bailey Osgood, 1873–1956, Professor of Orthopaedic Surgery, Harvard University Medical School, Boston, MA, USA.
Carl Schlatter, 1864–1934, Professor of Surgery, Zurich, Switzerland. Osgood and Schlatter described osteochondritis of the tibial tubercle independently in 1903.

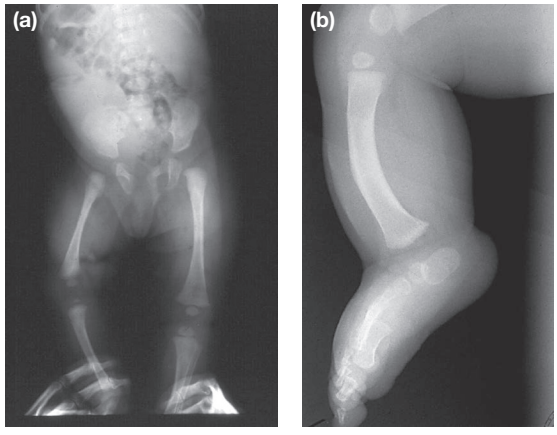

Figure 44.26 Anteroposterior (a) and lateral (b) radiographs of two lower limbs showing some of the features of a fibular hemimelia: absent fifth ray in the foot, absent fibula and deformed tibia.

Management is tailored to the severity of the deficiency. Treatment options range from a shoe raise, through multiple episodes of limb equalisation surgery to amputation for the worst cases. An early prediction of the leg length discrepancy at maturity allows a realistic treatment plan to be devised for the patient, which should include consideration of a contralateral epiphysiodesis.

Blount's disease

The aetiology of the disordered growth in the posteromedial proximal tibial physis is unknown. The infantile form is more common in Afro-Caribbean children but adolescent-onset disease affects all ethnic groups. The child presents with progressive and often severe tibia vara with significant intoeing. The radiographic features are diagnostic (*Figure 44.27*).

Treatment is surgical: following correction of limb alignment via an osteotomy, an epiphysiodesis of the remaining physis prevents recurrence. In unilateral cases, the limb – once straightened – is short and concomitant tibial lengthening with an external fixator is often an attractive option.

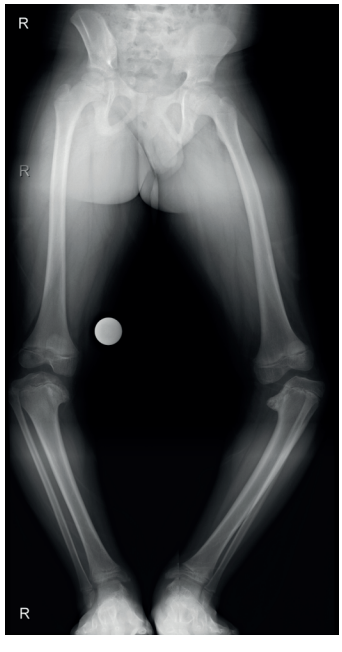

Figure 44.27 Standing leg length and alignment radiograph of a child with bilateral asymmetrical bow legs. Both proximal medial tibial physes/epiphyses are abnormal: this is bilateral Blount's disease.

Congenital pseudarthrosis of the tibia

This rare condition presents with an anterolateral bow of the tibia with or without a fracture. Classic radiographic changes are noted and 50% are associated with neurofibromatosis. Once fractured the tibia is reluctant to heal. Long-term orthotic treatment may be necessary, with subsequent surgical procedures designed to obtain bony union and restore leg length (*Figure 44.28*).

Summary box 44.11

Abnormalities of the knee and lower leg

- OCD – better prognosis in children than in adults
- Discoid meniscus – usually lateral, may require surgery
- Anterior knee pain – treatment usually conservative
- Fibular hemimelia – associated with abnormalities from the foot proximally (foot worse than hip); the tibial bow has an anteromedial apex
- Blount's disease – clinically, a sharp proximal tibial angulation
- Congenital pseudarthrosis of the tibia – the tibial bow has an anterolateral apex
- Apex posteromedial tibial bow – the bow improves with time but the limb may be short

Figure 44.28 Anteroposterior radiograph of a child showing a congenital tibial pseudarthrosis and abnormal fibula. She was born with a bowed lower leg that subsequently fractured. She has a family history of neurofibromatosis.

Walter Putnam Blount, 1900–1992, Professor of Orthopaedic Surgery, Marquette University, Milwaukee, WI, USA, described this condition in 1937.

ABNORMALITIES OF THE FOOT AND ANKLE

Parents are often concerned that minor abnormalities will limit function but this is rarely the case.

Congenital talipes equinovarus (the 'club foot')

In true congenital talipes equinovarus (CTEV) the three-dimensional deformity is fixed (*Figure 44.29*). Intrauterine moulding can cause an identical pattern that is postural and therefore correctable.

Incidence and aetiology

The incidence varies from 1 to 6 per 1000 live births, depending on ethnic differences. It is more common in boys and is bilateral in 50% of cases. A family history is common but inheritance is multifactorial. The diagnosis may be made during an antenatal ultrasound: the sensitivity is higher in bilateral cases, which are more likely to have a syndromic association. In some countries, the detection of CTEV may be grounds for a termination of the pregnancy but the parents should be reassured that, with treatment, their child will function as well as his/her peers.

Most cases are idiopathic but because the outcome varies with the aetiology it is important to consider the cause when planning treatment (*Table 44.10*). Many idiopathic cases will have some weakness of the evertor muscles.

Pathology

The talonavicular joint is subluxed, with the navicular displaced medially with respect to the talar head. Ligaments, particularly the calcaneofibular ligament, and tendon sheaths, such as the posterior tibial tendon sheath, are shortened and thickened and contain contractile myofibroblasts. The gastrocsoleus and posterior tibial muscles are smaller than normal, with reduced myofibrils and increased connective tissue, possibly because of a local neuromuscular abnormality. The vascular supply via the dorsalis pedis may be diminished. It remains unclear which abnormalities are primary and which occur as the deformity develops.

Clinical assessment

The postural club foot may benefit from physiotherapy stretches but, by definition, it must be normal by 3 months of age.

TABLE 44.10 Several different types of club foot are recognised.

Type	Example
Postural	
Idiopathic	
Neuromuscular	Spina bifida; arthrogryposis
Syndromic	Trisomy 15 or Disastrophic Dysplasia or Amniotic Band Syndrome

Figure 44.29 (a) Anteroposterior photograph of a foot showing the classic deformities associated with a club foot. The hindfoot (not seen) is in equinus and varus, there is midfoot cavus and the forefoot lies adducted and apparently supinated, although it is actually pronated relative to the hindfoot. **(b)** Untreated congenital talipes equinovarus in a child aged 7 years. Shoe wear is difficult although some independent mobility is possible.

In contrast, the structural idiopathic club foot has fixed deformity with elements of hindfoot equinus and varus, midfoot adductus and pronation of the first ray, giving the appearance of forefoot cavus. The heel feels 'empty' as the calcaneus is pulled up by the shortened tendo-Achilles. There is a deep medial and a single posterior crease.

All children with structural club-foot deformity will have a small calf and foot. Tibial shortening may become apparent with growth. Children should be examined carefully for signs of intraspinal pathology.

Both the Pirani and Diméglio classification systems are based on the appearance of the foot in its position of maximal correction. They predict treatment response and hence outcome.

Shafique Pirani, contemporary, Clinical Professor, Department of Orthopaedic Surgery, University of British Columbia, Vancouver, Canada.
Alain Diméglio, contemporary, orthopaedic surgeon, Montpellier, France.

Summary box 44.12

Club foot

- Multiplanar deformity: hindfoot equinus and varus, midfoot adductus and forefoot cavus
- Incidence is 1–6 per 1000 live births, more common in boys and with a familial tendency
- Most cases are idiopathic but neuromuscular causes include spina bifida and arthrogryposis
- Scoring systems (Pirani/Diméglio), are used to assess severity

Treatment

Ponseti method

The Ponseti method corrects foot deformity in 95% of idiopathic cases without the need for a formal surgical release and is the treatment of choice for all feet. Treatment commences within a few weeks of birth. A specific set of manoeuvres, followed by a series of well-moulded above-knee plaster casts, results in gradual correction of the deformity (***Figure 44.30***). The head of the talus is the fulcrum around which the rest of the foot rotates. After the forefoot has been corrected, most feet lack 15° of dorsiflexion and require a percutaneous Achilles tenotomy (performed under local anaesthetic in the clinic setting).

Once corrected the foot position is maintained by a foot abduction orthosis (FAO) that holds the foot in external rotation and slight dorsiflexion. The FAO is worn full time for 3 months and at 'night and nap time' for up to 4 years. Poor compliance with the FAO is associated with a higher relapse rate. Recurrent deformity can be treated with further plasters, but a tibialis anterior tendon transfer (TATT) may be required around the age of 2.5–4 years for persisting dynamic supination.

Feet treated with the Ponseti method are less stiff, less likely to be painful and less subject to overcorrection than those treated surgically. The Ponseti method also works reasonably well in non-idiopathic feet but both the failure and relapse rates are higher.

Surgical treatment

If conservative treatment fails, surgical intervention is required, ideally before walking age; this is more likely in non-idiopathic deformities.

Surgical release is generally performed 'à la carte', with sequential release of the pathologically tight structures via either Turco or Cincinnati incisions to reduce the subluxated joints. Stabilisation may include temporary Kirschner wire fixation. Following correction, wound closure can be difficult but the Cincinnati incision heals well by secondary intention during the postoperative casting period.

Figure 44.30 A series of casts documenting the stepwise correction of the foot deformity with the Ponseti method of serial manipulation and casting.

Good or excellent results can be achieved but stiffness and over- or undercorrection are common complications.

Surgery for recurrent deformity requires a careful assessment of the forefoot, hindfoot and tibial torsion. The foot becomes progressively stiffer with each surgical intervention.

Summary box 44.13

Treatment of club foot

- The Ponseti method of serial casting is successful in 95% of feet when defined as avoiding formal surgical release

  The standard sequence of manipulations is:

  C – correction of the apparent forefoot **cavus** by elevation of the first ray

  A – gradual forefoot abduction to 60°, and simultaneous

  V – correction of the hindfoot **varus**

  E – correction of hindfoot **equinus** usually follows a percutaneous Achilles tenotomy, which is an integral part of treatment
- TATT is used to correct dynamic supination in older children

If the Ponseti method fails:

- Surgical release addresses posterior, medial, plantar and lateral structures, and results in a stiffer foot than one treated conservatively

Other foot and ankle conditions

Most postural deformities such as metatarsus adductus and calcaneovalgus feet improve spontaneously.

Congenital vertical talus (CVT) is rare and frequently associated with neuromuscular conditions such as

Ignacio Ponseti, 1914–2009, faculty member of the University of Iowa, USA. Born in Menorca, fled Spain during the Civil War because of the political situation, worked as a general practitioner in Mexico and then went to Iowa to train in orthopaedics. The technique that bears his name only became popular years after he retired – but it brought him back to work for another 20 years.

Vincent J Turco, 1916–1999, Chief of Orthopedic Surgery, St. Francis Hospital, Hartford, CT, and Assistant Clinical Professor, Yale University Medical School, New Haven, and the University of Connecticut Medical School, Farmington, CT, USA.

Martin Kirschner, 1879–1942, Professor of Surgery, Heidelberg, Germany, introduced the use of skeletal traction wires in 1909.

arthrogryposis and spinal dysraphism. Clinically, there is a stiff 'rocker-bottom' foot with dorsal dislocation of the navicular on the talus (*Figure 44.31*). A 'reverse' Ponseti method with a limited surgical approach to reduce and Kirschner (K)-wire the talonavicular joint and a percutaneous Achilles tenotomy may be preferable to more extensive surgical releases.

In **tarsal coalition** there is failure of segmentation of adjacent tarsal bones. School-aged children present with hindfoot pain and recurrent ankle sprains. The most common coalitions are talocalcaneal and calcaneonavicular (*Figure 44.4*). Radiographs, computed tomography (CT) or MRI are used to confirm the diagnosis. Treatment is initially conservative, but if the coalition requires surgical excision this should be performed before degenerative changes develop.

Other causes of foot pain in children include the osteochondroses, in which the radiographic changes are similar to AVN. These 'heal' but the change in shape of the affected bone may lead to secondary joint stiffness and loss of function. (Similar 'diseases' affect the lunate [Kienböck's] and the capitellum of the humerus [Panner's].)

- **Freiberg's osteochondrosis** presents with forefoot pain and avascular change in the second metatarsal head. Symptomatic bony spurs and osteochondral fragments may need excision but often it is asymptomatic and seen as an incidental finding on a radiograph.
- **Köhler's disease** presents with dorsal forefoot pain and swelling in young children. The navicular becomes avascular with alteration in the ossification process.
- **Sever's disease** (enthesopathy of the calcaneal apophysis) presents with heel pain related to activity. Tightness in the calf muscle complex may be a contributing factor. The 'features' on a radiograph are, in fact, part of normal growth and development.

Flexed, medially curved 'curly toes' are common and rarely need treatment. Strapping is ineffective. Flexor tenotomy is used when there are symptoms or cosmetic concerns.

Summary box 44.14

Other foot and ankle conditions

- CVT – presents as 'rocker-bottom' foot
- Tarsal coalition – presents as a stiff, painful flat foot
- Osteochondroses – almost always self-limiting
- Curly toes are common – most do not need treatment

ABNORMALITIES OF THE UPPER LIMB

Minor finger abnormalities are common (*Table 44.11*) but not all require surgical intervention. Comfort and function are more important than appearance.

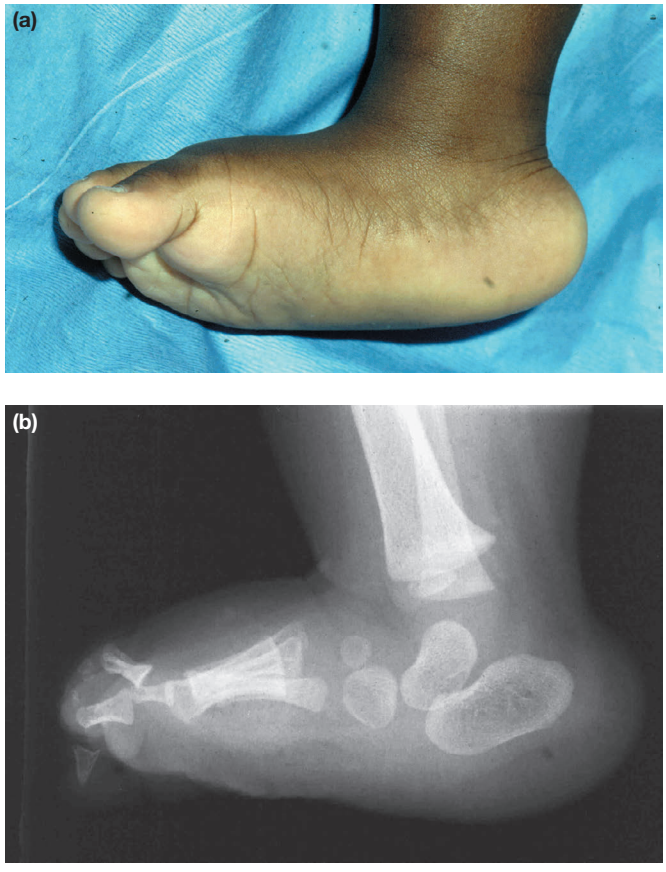

Figure 44.31 Congenital vertical talus: (a) lateral photograph demonstrating a 'rocker-bottom foot'; (b) lateral radiograph showing hindfoot equinus and suggesting dorsal subluxation of the non-ossified navicular and forefoot with respect to the head of the talus.

Function is also the most important consideration when managing more extensive upper limb abnormalities. Treatment is often delayed until hand dominance is established and it is clear what problems a specific deformity is causing any given child. Children are very adaptable and cope with disabilities much more readily than their parents/doctors expect.

Radial club hand

This longitudinal failure of formation is commonly associated with other malformations, for example as part of the VACTERL (abnormal vertebrae, anus, cardiovascular system, trachea, oesophagus, renal system and limb buds) syndrome. The clinical problem depends on whether the thumb is present and functional (*Figure 44.32*). Treatment is a balance of conservative measures, including physiotherapy and splinting, and judicious surgery to centralise and stabilise the hand and wrist on the single bone forearm. Thumb reconstruction may be technically challenging. In later childhood, forearm lengthening may be considered.

Robert Kienböck, 1871–1953, Professor of Radiology, Vienna, Austria, described this condition in 1910.
Hans Jessen Panner, 1871–1930, radiologist, Copenhagen, Denmark, described this condition in 1927.
Albert Henry Freiberg, 1869–1940, Professor of Orthopaedic Surgery, The University of Cincinnati, Cincinnati, OH, USA, described this disease in 1926.
Alban Köhler, 1874–1947, radiologist, of Wiesbaden, Germany, described this disease in 1908.
James Warren Sever, 1878–1964, orthopaedic surgeon, The Children's Hospital, Boston, MA, USA, described apophysitis of the os calcis in 1912.

TABLE 44.11 Common minor congenital anomalies affecting the hand.

Anomaly	Definition	Treatment
Extra/accessory digits		Excise/amputate when necessary
Syndactyly	Failure of separation of digits	Separation with/without skin grafting for functional or cosmetic reasons
Trigger thumb (digit)		Release of the A1 pulley of the flexor tendon sheath
Clinodactyly (usually the fifth digit)	Abnormal angulation of the digit in the radioulnar plane	Surgical treatment of the delta phalanx if deformity is progressive or interfering with hand function
Camptodactyly (usually the fifth digit)	Fixed flexion deformity of the proximal interphalangeal joint	Splinting/physiotherapy; surgery rarely indicated

Figure 44.32 Anteroposterior radiograph of a radial club hand demonstrating a short radius, a deformed ulna and an absent thumb.

Radioulnar synostosis

Failure of proximal separation of the embryonic radius and ulna means that the forearm has no ability to pronate/supinate. The hand, on the end of the forearm, is therefore in a fixed position along the arc from full pronation–neutral–full supination. The child presents if this fixed position results in functional difficulties. Osteotomy of the forearm bones changes the fixed position (for example, from pronation to neutral) but does not restore movement. The choice of the postoperative position depends on hand dominance, cultural considerations and functional demands. Undoing the synostosis is not successful.

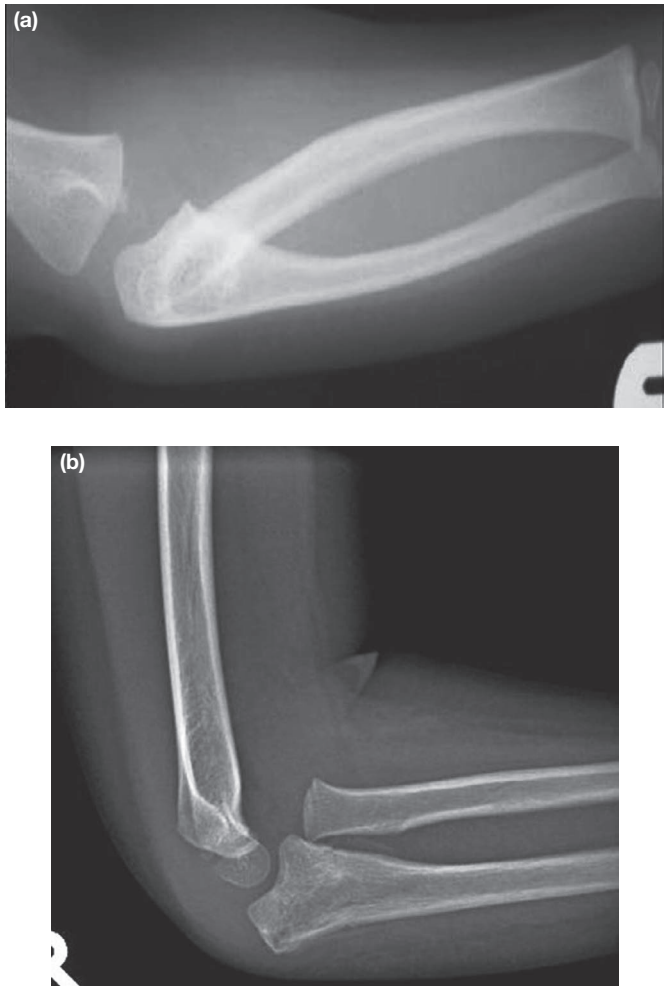

Figure 44.33 Radial head dislocation: **(a)** lateral radiograph of a forearm showing a proximal radioulnar synostosis with a congenital posterolateral dislocation of the radial head. Note the underdeveloped radial head and neck and compare with **(b)**, a lateral radiograph of a traumatic anterior dislocation of the radial head with a normal appearance to the head and neck and a deformity in the proximal ulna.

Congenital radial head dislocation

The dislocation is usually posterolateral, compared with the classic traumatic anterior dislocation (***Figure 44.33***). Some restriction of elbow joint movement and forearm rotation is noted along with discomfort on activity. Surgical treatment should be avoided in children.

Summary box 44.15

Upper limb abnormalities

- Radial club hand is frequently associated with other congenital anomalies, for example the VACTERL or Holt–Oram syndromes
- Radioulnar synostosis presents with a fixed forearm position
- Congenital radial head dislocation is usually posterolateral

Mary Clayton Holt, 1924–1993, cardiologist, The London Hospital for Women and Children, London, UK.
Samuel Oram, 1913–1991, cardiologist, King's College Hospital, London, UK. Holt and Oram described this syndrome in a joint paper in 1960.

SPINAL DEFORMITIES AND BACK PAIN

Congenital deformities

Congenital vertebral deformities are failures either of formation (a hemivertebra) or of segmentation (unilateral or bilateral fusions or bars). The clinical result is usually a scoliosis (***Figure 44.34***). Treatment should be based on the potential for curve progression. When a kyphosis develops, progressive neurological deficit is common. Bracing is ineffective for congenital vertebral deformities.

Scoliosis

The term 'scoliosis' describes spinal deformity in three planes: lateral curvature is the most obvious deformity while the rotational component is most apparent in forward flexion when the rib asymmetry creates a 'rib hump' (***Figure 44.35***). The cause may be idiopathic, neuromuscular, related to a syndrome or congenital. Both the aetiology and the age of onset affect the natural history (***Table 44.12***). In general, the earlier the onset, the more likely the deformity is to be progressive. As most lung development occurs in early childhood, the management of early-onset scoliosis must preserve growth: casting techniques or the use of 'growing rods' may be appropriate.

The adolescent idiopathic curve is the most common, affecting girls more than boys. Idiopathic scoliosis is generally not painful and, therefore, in the presence of significant pain tumour and infection must be excluded. The Cobb angle is a radiological measurement that defines severity and guides treatment (***Figure 44.36***). Curves <20° do not need treatment, progressive curves of 25–40° may be braced and those >40° are considered for surgery, which involves instrumenting and fusing the spine (see also ***Chapter 37***).

TABLE 44.12 Classification of idiopathic scoliosis.

Type	Age at onset
Early onset	<10 years
Adolescent	11–18 years
Adult	Onset at maturity

Kyphosis

When a kyphosis exceeds the normal 20–50° the cause may be postural or structural. Scheuermann's disease presents as a progressive structural adolescent kyphosis characterised radiologically by >5° vertebral wedging at three adjacent levels with end-plate changes. The aetiology is unknown. Treatment ranges from physiotherapy and bracing to surgery.

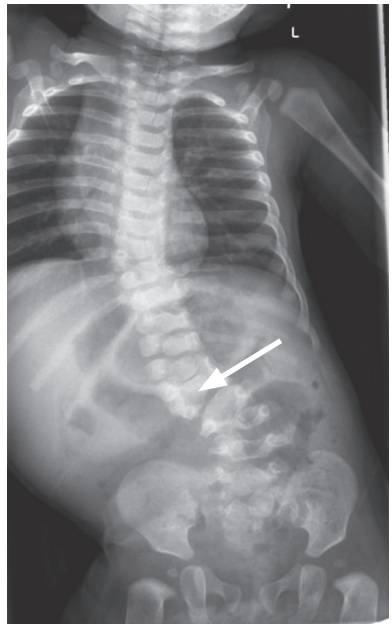

Figure 44.34 Anteroposterior radiograph of the spine demonstrating multiple congenital vertebral anomalies including hemivertebrae. The arrow points to one of the congenital vertebral anomalies.

Figure 44.35 Clinical photograph of the Adams forward bend test that demonstrates the presence of a rib hump on the right and a prominence of the lumbar paravertebral muscles on the left.

Summary box 44.16

Scoliosis

- Multiplanar deformity includes a rotational component
- Aetiology may be congenital (underlying bony malformation), neuromuscular, syndromic or idiopathic
- A leg length discrepancy causes a postural scoliosis
- Adolescent idiopathic scoliosis is the most common structural scoliosis
- Back pain associated with scoliosis may be due to infection or tumour
- Treatment depends on the severity and likelihood of curve progression – it varies from observation, through bracing to surgery

William Adams, 1820–1900, described the forward bending test for scoliosis in 1865.
John R Cobb, American surgeon, wrote a paper in 1948 on how to measure the angle on a radiograph in scoliosis.
Holger Werfel Scheuermann, 1877–1960, radiologist, The Municipal Hospital, Sundby, Copenhagen, Denmark, described juvenile kyphosis in 1920.

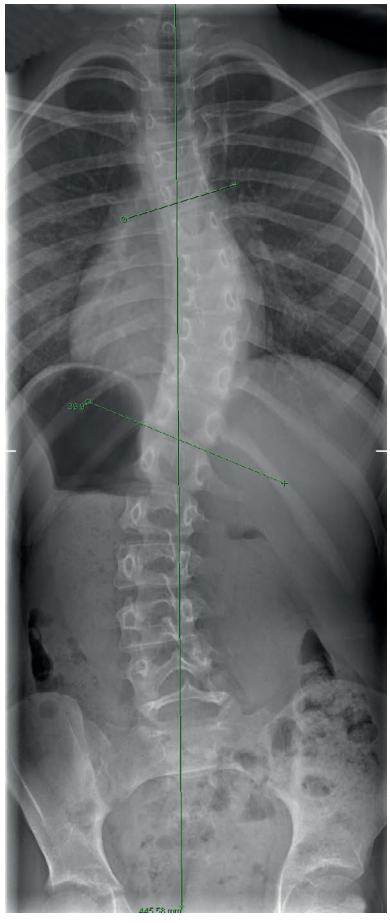

Figure 44.36 Posteroanterior radiograph of a spine with a scoliosis (right thoracic), with a Cobb angle of 40°.

Spondylolisthesis

Spondylolysis defines a defect in the pars interarticularis of the vertebra. There are six types including congenital and traumatic. Spondylolisthesis occurs when the upper vertebra slips forward on the lower; it is graded according to the percentage slip, measured by relating the slipped vertebra to the one below (*Table 44.13*).

Mild slips are often asymptomatic and require no treatment. Treatment (physiotherapy, bracing and surgery) depends on the degree of slip and symptoms; mechanical back pain may respond to conservative methods, but neurological involvement usually requires surgical intervention.

TABLE 44.13 Classification of spondylolisthesis according to severity of the slip.

Grade	Percentage slip
0	No slip
1	<25
2	26–50
3	51–75
4	>75
Spondyloptosis	>100 – complete translation

Torticollis

In torticollis the head is tilted towards and rotated away from the tight sternocleidomastoid muscle.

Congenital torticollis is usually secondary to intrauterine moulding but may present with a fixed sternocleidomastoid contracture or a palpable 'tumour' within the muscle. Most cases resolve with stretching but persistent cases develop facial asymmetry requiring release of the origin and/or insertion of the sternocleidomastoid muscle.

Acquired torticollis is rare and may be caused by inflammation/infection, ocular problems, atlantoaxial rotatory subluxation or a posterior fossa tumour.

Back pain

Children report back pain less frequently than adults, although >50% will have had one episode by late adolescence. Back pain in a child is a 'red flag' for serious spinal pathology; however, if it is mild, intermittent or occurring only on strenuous activity, it is usually self-limiting. Many adolescents do suffer posture-related discomfort. Physiotherapy to improve core strength and stability reduces symptoms if exercises are performed regularly.

Summary box 44.17

'Red flag' symptoms and signs for spinal pathology

- Systemic illness, fever or weight loss
- Progressive neurological deficit
- Unrelenting or night pain
- Spinal deformity

All 'red flag' signs require urgent investigation with a full blood count (FBC), erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), plain radiograph and MRI or other imaging. Other causes of back pain include intra-abdominal, renal and systemic pathology.

Summary box 44.18

Other spinal conditions

- Excessive kyphosis may be due to Scheuermann's disease
- Spondylolisthesis is a forward slip of one vertebra on another; it may cause mechanical and, rarely, neurological symptoms
- Torticollis may be congenital and usually responds to stretching of the sternocleidomastoid muscle
- Acquired torticollis may be due to one of several significant pathologies
- Back pain with red flag symptoms and signs requires urgent investigation

NEUROMUSCULAR CONDITIONS

Joint stability and limb function rely on the complex integration of the musculoskeletal and neurological systems. Damage to either leads to one of several conditions linked only by the

fact that they are incurable and often progressive, particularly during the period of skeletal growth. Management is directed at helping the child cope with their disability, minimising further deterioration and maximising function. It is important to have an understanding of what the damage is and what the future holds (*Table 44.14*).

Spina bifida and polio are classic lower motor neurone lesions, whereas cerebral palsy and head injuries affect upper motor neurones and the higher centres. There are often other disabilities such as blindness, epilepsy and intellectual difficulties to consider.

TABLE 44.14 Factors to be considered in the assessment of a neuromuscular disability.

- Is the insult to the neurological system progressive or non-progressive?
- Is it located centrally or peripherally?
- Is it general or focal?
- Is it associated with other abnormalities or not?
- If the insult is not neurological, is it myopathic?

In children, even if the initial insult to the neuromuscular system is non-progressive, the effects of the insult change with growth. Damage at any level of the neuromuscular system leads to an alteration in tone and muscle imbalance associated with decreased control of movement. Abnormal muscle pull, particularly in combination with the effects of gravity, alters bone growth, leading to deformity and joint contracture. Muscles are relatively weak and, with body growth and a weight increase, they are no longer strong enough to control a heavier limb, particularly when deformity means they are working at a mechanical disadvantage.

A multidisciplinary approach to management is essential. Physiotherapy and orthotic management may reduce the need for surgical intervention and postoperatively they ensure that the surgical benefits are maximised. In conditions such as Duchenne muscular dystrophy there is substantial evidence for the benefits of certain surgical procedures; however, in other conditions (cerebral palsy) there are fewer such long-term validated studies.

In general, it is important to maintain good joint movement, muscle length and tendon excursion. This is easier to achieve in patients with a flaccid paralysis or low tone. The maintenance of muscle strength is also important. The use of splints, positioning techniques and seating and sleeping systems is common with the aim of preventing fixed contractures.

Surgery has a valuable role in the management of selected patients (*Table 44.15*).

The surgeon must understand that altering ankle posture may affect knee and hip posture/function and vice versa. The patient must have the intellectual ability and motivation to recover from the surgical procedure. Some of the factors mentioned previously (*Table 44.14*) must be considered in any holistic approach to the patient.

Summary box 44.19

Principles of treatment of neuromuscular conditions

- A neurological defect, whether progressive or not, may cause progressive deformity with skeletal growth
- A multidisciplinary approach is essential
- Primary therapy aims to maintain range of movement and prevent fixed contractures with an emphasis on managing tone and position
- Surgery has a limited role in the management of neuromuscular conditions

Cerebral palsy

Cerebral palsy (CP) is caused by a non-progressive insult to the developing brain in the perinatal period; in most cases only risk factors, such as prematurity, rather than specific causes, such as hypoxia (hypoxic ischaemic encephalopathy [HIE]), can be identified. The effects of CP may only become apparent as the child grows and fails to reach developmental milestones. Investigations may identify the aetiology and predict the pattern of the CP: premature babies may show evidence of periventricular leukomalacia (PVL) on MRI, associated with a spastic diplegia and relative preservation of intellectual function.

TABLE 44.15 General types of surgical procedure that may be considered in the management of a patient with a neuromuscular condition.

Surgical procedure	Aim of treatment
Lengthening of the muscle–tendon unit	Restores joint range (but results in relative muscle weakness)
Tendon transfer	Improves functional movement; rebalances muscle forces, after correction of fixed deformity
Release of joint contracture; correction of bony deformity	Restores mechanical alignment and allows muscles to work in a more efficient manner
Fuse/stabilise/relocate joints	Improves posture/function; reduces pain
Neurological procedures: • selective dorsal rhizotomy (SDR) • intrathecal baclofen pumps (ITB)	Reduce spasticity – ***not*** useful in dystonia
Leg equalisation procedures	Improve lower limb mechanics

Guillaume Benjamin Amand Duchenne (Duchenne de Boulogne), 1806–1875, neurologist, worked successively in Boulogne and Paris, France, but never held a hospital appointment.

TABLE 44.16 Classification of cerebral palsy with respect to muscle tone and site of involvement.

	Characteristics
Tone	
Spastic ('high')	• Commonest type of abnormality; due to pyramidal system damage • Velocity-dependent increased muscle tone and brisk reflexes
Dyskinetic • Dystonic • Choreoathetoid	 • Increased tone but reduced activity – stiff movements • Low tone but increased activity – uncoordinated jerky movements ◦ Due to damage in the extrapyramidal system
Ataxia	• Generalised low tone, loss of muscle coordination ◦ Due to cerebellar damage
Mixed	• No one tone/movement disorder predominatesw ◦ Combination of spasticity and dystonia is common
Hypotonia	Usually a phase (which may last years) before the features of spasticity develop
Site	
Unilateral • Hemiplegia	 Arm more affected than leg
Bilateral • Diplegia • Total body involvement	 Legs more affected than arms Often significant intellectual impairment and associated difficulties

In general, the pattern of involvement can be classified according to the anatomical site involved and the effect on muscle tone (*Table 44.16*). The prognosis for walking can be predicted by identifying evidence of neurological development, i.e. gaining motor skills and losing primitive reflexes. The age-related Gross Motor Function Classification System (GMFCS) has five categories that relate to mobility and prognosis (GMFCS I – near-normal versus GMFCS V – wheelchair based). Many children with GMFCS V CP have multiple associated problems and a short life expectancy.

An important aspect of management is the control of high tone. Tone can be reduced with drugs (e.g. diazepam and baclofen). Alternatively, neuromuscular blockers such as botulinum toxin allow a focal reduction in tone by preventing acetylcholine release at the neuromuscular junction. The effect is temporary, giving a 'window' during which the physiotherapists can stretch agonists and strengthen antagonists. It is important to differentiate between dynamic and fixed contractures; the latter will not respond to tone management or splinting.

The classic CP gait patterns demonstrate flexor spasticity. The child with spastic diplegia has problems at all levels of the lower limb. Single-event multilevel surgery (SEMLS) is popular, and gait analysis (both observational and computerised) contributes to the selection of an appropriate management plan for an individual patient. Computerised analysis provides objective evidence of joint movement and mechanics in multiple planes (*Figure 44.37*). Appropriate bone and soft-tissue procedures can then be planned. Botulinum toxin helps with postoperative pain and spasm.

In the child with total body involvement (TBI) and high muscle tone, hip subluxation leading to dislocation is common (*Figure 44.38*). Current thinking is that symmetry and pelvic position are important so the hips should be kept in joint with early surgical intervention if necessary. Aggressive management of a spinal deformity initially concentrates on seating position and subsequently emphasises spinal bracing or surgery.

Overall, it is important to remember that, in adulthood, independent mobility, even if in a wheelchair, and effective communication are the most important requirements.

Summary box 44.20

Cerebral palsy

- Brain injury is non-progressive
- Classified as unilateral or bilateral involvement: hemiplegia, diplegia or TBI
- Tone may be high, low or variable but there is always a generalised, relative muscle weakness
- In ambulant children, gait analysis may be used to plan management
- In TBI, primary concerns are hip subluxation and spinal deformity

Polio

Despite an effective polio vaccine, this disease still occurs. About 1–2% of patients develop neurological problems when the virus affects the anterior horn cells. Muscle weakness is proportionate to the number of motor units destroyed. Patients develop trick movements to adjust to their muscle weakness and minor joint contractures may improve function (for example, ankle equinus in the presence of weak quadriceps muscles). Careful preoperative assessment is required and both the surgeon and the patient must understand the goals of treatment.

Spina bifida

The extent of the disability varies with the level of the lesion: upper motor neurone involvement will produce spasticity while the more classic lower motor neurone lesion produces a flaccid paralysis. Muscle imbalance leads to secondary joint

deformity but the accompanying sensory disturbance may affect the choice of surgical and non-surgical options. Many children require a ventriculoperitoneal (VP) shunt to drain the hydrocephalus that develops following closure of the myelocele. With growth, a tethered cord or a blocked VP shunt may develop with a deterioration in the neurological picture.

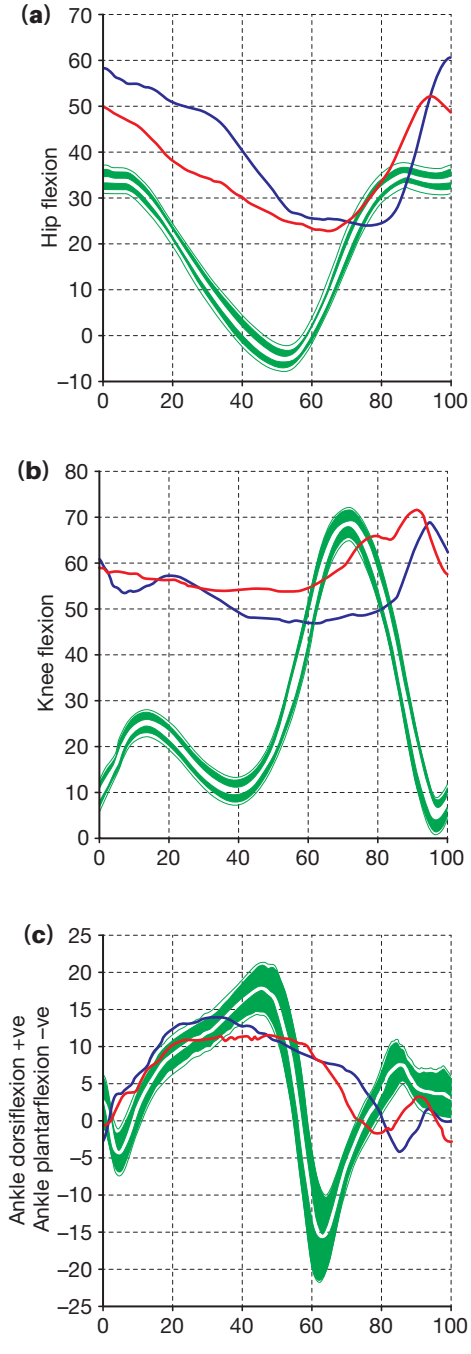

Figure 44.37 Gait analysis graphs such as these demonstrate the normal range of joint movements (green band) at the hip **(a)**, knee **(b)** and ankle **(c)** during the stance and swing phases of the gait. The abnormal joint ranges are shown in red (right leg) and blue (left leg) and demonstrate the excessive hip flexion, lack of knee extension and abnormal ankle mechanics associated with the 'crouch' gait of a child with cerebral palsy.

Muscular dystrophy

Many types of muscular dystrophy exist that vary in severity and distribution of involvement. Surgical intervention aims to improve quality of life. This is best achieved by operating early to release joint contractures and maintain the ability to walk with a good spinal posture.

Brachial plexopathy

Neonatal brachial plexus injury is still common, with a devastating effect on upper limb function, particularly if antigravity motor activity has not recovered by 6 months. Physiotherapy is the mainstay of early treatment to maintain muscle length and joint range of movement and thus reduce the risk of glenohumeral dislocation. Neural repair may be necessary in the infant. Later surgical interventions aim to release joint/muscle contractures and improve function, perhaps with tendon transfers.

INFECTION

Worldwide, osteoarticular infection remains a frequent cause of significant morbidity.

Septic arthritis

Joint infection is usually secondary to haematogenous spread but direct inoculation can occur, for example during a neonatal venepuncture. Diagnosis can be difficult in the very young and in those presenting with overwhelming sepsis. Neonates, children with immunocompromise and those with sickle cell

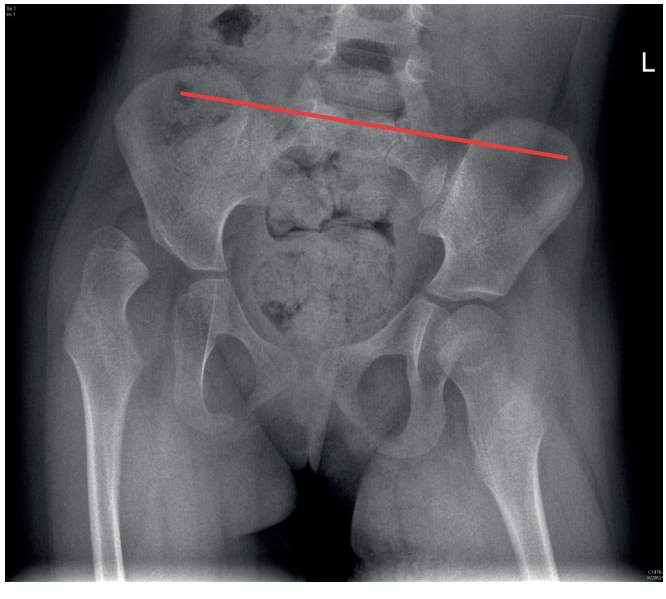

Figure 44.38 Anteroposterior pelvic radiograph of a child with spastic cerebral palsy. The right hip is dislocated: none of the head lies medial to the vertical Perkins line. The acetabulum is dysplastic. The left hip is in abduction. There is often a 'windswept' appearance with one leg stiff in abduction and the other stiff in adduction. The red line demonstrates the pelvic obliquity; many children also have a scoliosis. Note the significant constipation; this can cause significant pain, which will increase spasm and increase the pain still further.

disease are at increased risk. At the other end of the spectrum the differentiation between joint sepsis and transient synovitis of the hip can also be difficult.

Classically, the child presents with pain, fever and a reluctance to move the joint; in the lower limb, this implies a reluctance to weight bear. On examination, local tenderness and painful restriction of movement are apparent and in superficial joints inflammation may be obvious, with a hot, swollen joint.

Investigations include FBC, ESR, CRP and blood cultures. Plain radiographs help exclude other diagnoses and may identify osteomyelitis. Ultrasound scans of deep joints, such as the hip, will identify joint effusions (***Figure 44.39***). MRI is considered the investigation of choice but this resource is not available to all (in a timely manner) and, in young children, it requires a general anaesthetic. Good clinical skills, regular patient review and a high index of suspicion are still the most valuable tools. Four clinical predictors can differentiate between septic arthritis and transient synovitis (***Table 44.17***).

Pus in a joint is destructive: the proteases produced by leukocytes destroy both the bacteria and the collagen matrix of the articular cartilage. AVN may occur secondary to pressure effects or ischaemic infarction. The treatment of a presumed septic arthritis therefore requires the prompt removal of pus from the joint and appropriate adequate antibiotic therapy. Pain relief and rest are also important, as are the general health and nutrition of the patient. The joint is aspirated and, if pus is confirmed, a formal washout is mandatory; standard teaching states that the joint must be opened, irrigated and free drainage encouraged via the capsulotomy. Recent literature supports repeated aspiration/irrigation via a large-bore cannula or a small arthroscope for all joints except the hip. Antibiotic usage is guided by local hospital policy, the source of the infection, the Gram stain and, in due course, the culture and sensitivity of the organism identified. Joint instability, particularly in the hip joint (***Figure 44.40***), may require the reduced joint to be splinted while the inflammatory process settles.

TABLE 44.17 Septic arthritis.

(a) The clinical predictors of Kocher *et al*. (2004) for the diagnosis of septic arthritis:

- History of fever >38.5°C
- Non-weight-bearing
- Erythrocyte sedimentation rate >40 mm/h
- White cell count >12 × 10^9/L

(b) The value of the clinical predictors of Kocher *et al*. in determining the likelihood of a joint being septic:

Number of positive predictors	Predicted probability of joint sepsis
0	2.0%
1	9.5%
2	35.0%
3	72.8%
4	93.0%

The most frequently identified organism is *Staphylococcus aureus*. Streptococcal infection is also common and other organisms are more prevalent in certain age groups, e.g. the neonate, in certain conditions, e.g. sickle cell disease, or in certain countries. The *Haemophilus influenzae* type B (Hib) vaccine has essentially eliminated *H. influenzae* as a cause of infection, but in some countries *Kingella kingae* has taken its place.

Improvement is judged clinically and by monitoring the inflammatory markers. Reaccumulation of pus does occur and must be suspected and treated promptly if the child fails to improve.

Summary box 44.21

Septic arthritis

- Diagnosis is difficult in neonates and the immunocompromised
- Typical presentation is pain, fever and a reluctance to move the joint or weight bear
- Investigations should include FBC, ESR, CRP, blood cultures and appropriate imaging studies, combined with astute clinical skills
- Pus in a joint destroys articular cartilage and causes avascular necrosis of intra-articular epiphyses
- Treatment is prompt removal of pus, appropriate antibiotic therapy, pain relief and splintage

Osteomyelitis

As with septic arthritis, bone infection is usually caused by haematogenous spread. Infection starts in the metaphyses of long bones, where the slow flow through the looped vessels combined with microtrauma encourages seeding of infection during a bacteraemia (***Figure 44.41a***). Inflammation follows

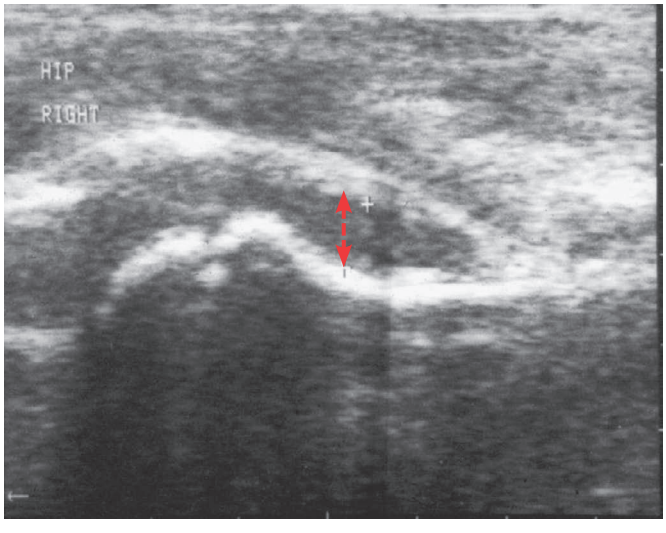

Figure 44.39 Ultrasound scan of a hip joint. A large effusion is distending the joint capsule. The dotted line represents the distance between the femoral neck and the joint capsule.

Hans Christian Joachim Gram, 1853–1938, Professor of Pharmacology (1891–1900) and of Medicine (1900–1923), Copenhagen, Denmark, described this method of staining bacteria in 1884.

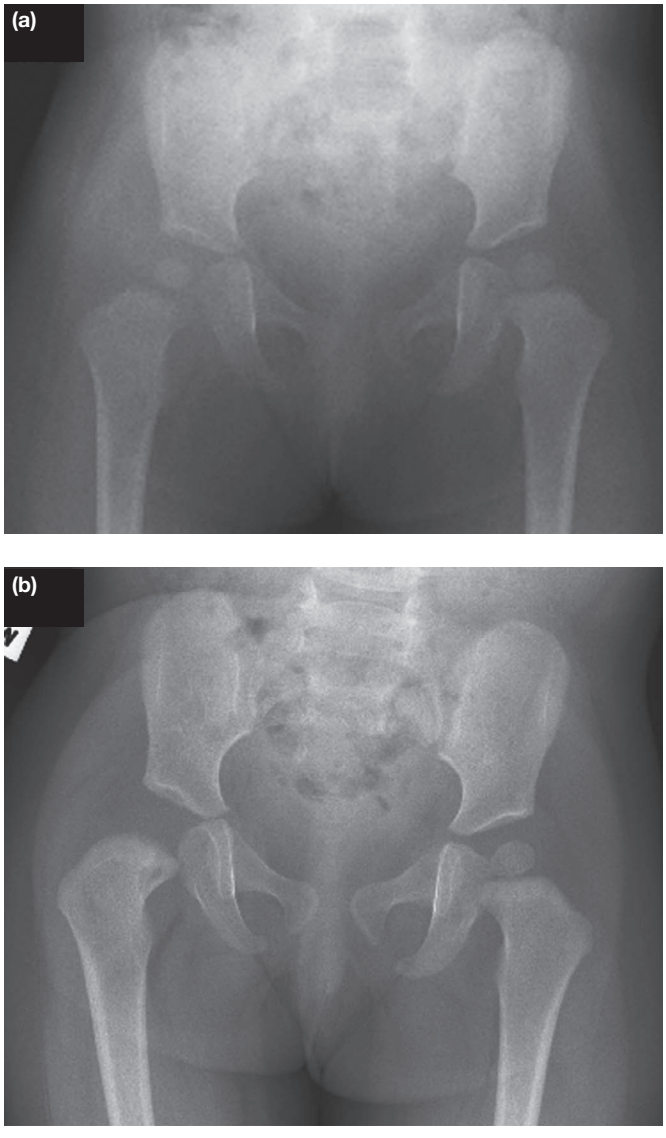

Figure 44.40 Septic arthritis of the right hip: **(a)** anteroposterior (AP) pelvic radiograph with subtle signs of right hip subluxation; **(b)** AP pelvic radiograph 6 months later showing destruction of the femoral head secondary to late treatment of a septic joint.

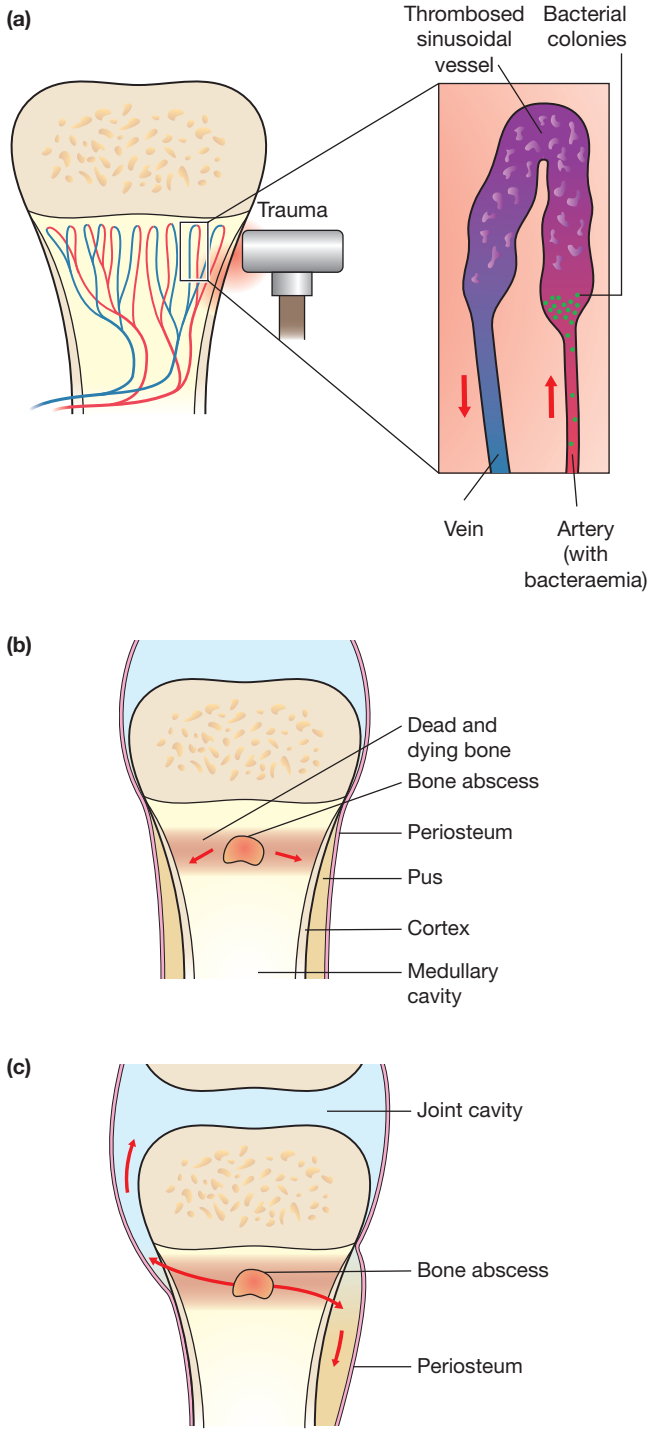

Figure 44.41 (a–c) Diagrams illustrating the pathology underlying the development of osteomyelitis. The longer the infection goes untreated the greater the destruction, with the possibility of sequestrum formation and secondary joint infection.

and, if purulent material forms, the pressure effects secondary to the abscess formation lead to bony destruction. Pus passes through cortical bone and when it does so it elevates the strong periosteum, which may render the cortical bone avascular. As in cases of trauma or tumour, the periosteal elevation is a potent stimulus for new bone formation. In cases of untreated or chronic infection this new bone or involucrum may surround the dead bone, the sequestrum, leading to a 'bone-within-a-bone' appearance (*Figure 44.41b*).

The presentation and investigation of osteomyelitis can be similar to those for joint sepsis. The differentiation between the two may be difficult and a sympathetic joint effusion may occur with metaphyseal osteomyelitis. Thus, if there are no organisms seen on microscopy of a joint aspirate, the possibility of a coexisting osteomyelitis must be considered. The metaphysis of a long bone may be intracapsular and infection may spread easily into the joint once the periosteum is breached. In the neonate, proximal femoral osteomyelitis and septic arthritis are essentially the same condition (*Figure 44.41c*).

General principles for the management of infection should be followed. Pus needs to be drained but otherwise the treatment is medical. Debate continues over the duration of

treatment and indeed whether antibiotics should be parenteral or oral: management varies from region to region and relates to the local bacteriological prevalences. Methicillin-resistant *S. aureus* (MRSA) is common in some areas and the presence of the Panton–Valentine leukocidin gene increases morbidity.

The shortened intravenous and oral treatment regimes are for **uncomplicated** cases of osteomyelitis and septic arthritis only, and only for patients who are improving clinically and haematologically.

Summary box 44.22

Bone and joint infection

- Occurs by haematogenous spread, enhanced by microtrauma
- In untreated and/or chronic osteomyelitis, new involucrum envelops dead sequestrum
- In addition to antibiotics, treatment consists of:
  - Rest/splintage of affected limb
  - Analgesia
- A joint effusion may be sympathetic, a primary septic arthritis or caused by direct spread from the adjacent metaphyseal infection
- Treatment involves:
  - Drainage of pus when present
  - Appropriate and often prolonged antibiotic therapy: parenteral and then oral
  - Treatment of the underlying condition, e.g. nutritional deficiency, sickle cell disease

Complications of bone and joint sepsis

Treated appropriately, most cases of sepsis resolve with no sequelae. However, significant complications can occur, particularly in terms of chronic infection and where there has been damage to the joint and/or the physis and the epiphyseal growth centres. In the neonate, vascular channels pass through the physis, connecting the metaphysis with the epiphysis, and a poorer outcome may ensue (***Figure 44.40b***). Orthopaedic follow-up should be continued until normal growth patterns are documented.

Meningococcal sepsis

The often debilitating, late orthopaedic sequelae of meningococcal septicaemia are secondary to endotoxin-induced microvascular injury and ischaemic physeal damage (***Figure 44.42***).

Tuberculosis

Globally, tuberculosis is common. The clinical presentation is often insidious, with malaise and weight loss combined with a boggy joint swelling, muscle wasting and joint contractures. Spinal deformity and neurological symptoms are particular problems.

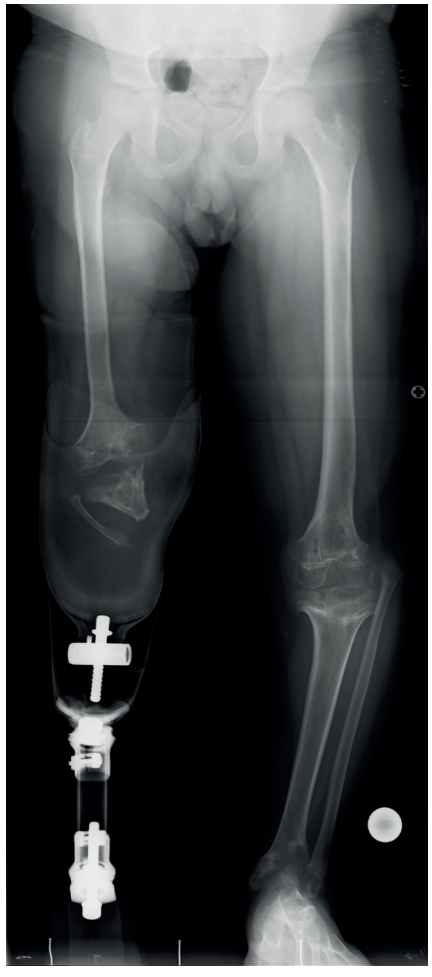

Figure 44.42 Anteroposterior leg length and alignment radiograph of an adolescent who had meningococcal septicaemia as a child. He has a right below-knee amputation. Many of his lower limb physes are not growing well so he has deformity of his remaining right proximal tibia, a short left tibia and an overgrown fibula. His right femur is also short.

Chronic relapsing/recurrent multifocal osteomyelitis

The radiographic features suggest subacute or chronic osteomyelitis (or tumour) but laboratory and histopathological findings are non-specific and cultures negative. This is an inflammatory (**not** infective) condition.

Discitis

Children who refuse to weight bear and complain of back pain may have discitis. The aetiology of this condition may be infective or inflammatory but if vertebral bodies are involved, infection is assumed.

Sir Philip Noel Panton, 1877–1950, Consultant Adviser in Pathology, Ministry of Health, UK.
Francis Valentine, 1897–1957, described Panton–Valentine leukocidin as a dermo-necrotic and leukocidal toxin while working with Philip Panton at the Hale Clinical Laboratory, London, UK, in 1932.

Figure 44.43 Anteroposterior radiograph of a knee showing metaphyseal corner fractures that are considered to be pathognomonic of non-accidental injury.

Brodie's abscess

Chronic infections may present with radiographic features of a sclerotic walled cyst.

CLINICAL DILEMMAS

The limping child

Children may limp because of pain, weakness, deformity or to gain attention; the causes vary from sepsis to a spinal tumour and from a leg length discrepancy to a simple blister. Serious causes must be excluded and the 'surgical sieve' helps identify the most likely diagnoses (***Table 44.18***).

TABLE 44.18 A guide to the clinical assessment of the limping child.

- Symptom onset: sudden or gradual?
- Symptom duration
- Concurrent events: recent viral infection, trauma, new sport?
- General health: is the child well?

The examination must include all joints and soft tissues and, in addition, a brief neurological examination, measurement of leg length and an assessment of pain at rest or on weight-bearing.

Many conditions, such as sepsis and juvenile arthritis, can present at any age but certain hip conditions are more likely in particular age groups (***Table 44.19***).

Plain radiographs should include both anteroposterior and 'frog' lateral views of the pelvis. Always bear in mind the possibility of a tumour; further imaging such as MRI may be required.

TABLE 44.19 Age at presentation of certain hip conditions.

Age (years)	Diagnosis
1–3	• Sepsis • Late presenting developmental dysplasia of the hip
3–10	• Transient synovitis • Perthes' disease
11–15	• Slipped upper femoral epiphysis

Non-accidental injury

No child is exempt but some children are at particular risk, including those under 3 years of age, those with disabilities and those in families suffering socioeconomic deprivation. A careful clinical assessment is required (***Figure 44.43*** and ***Table 44.20***). Characteristic patterns should alert the clinician to the possibility of non-accidental injury (NAI) (***Table 44.21***).

NAI occurs in different forms: emotional, physical, sexual and neglect. When suspected it should be discussed with child safeguarding teams. All injuries should be documented carefully. It may be prudent to admit the child until further checks have been made.

TABLE 44.20 Factors that raise concern in the clinical assessment of suspected non-accidental injury.

History
- Delay in seeking medical advice
- Variable story
- Mechanism inconsistent with injury pattern

Examination
- Unexpected bruising to the buttocks/back of legs
- 'Finger-mark' bruises
- Bruises of various ages
- Burns, deep scratches, etc.

TABLE 44.21 Fracture patterns with a high specificity for non-accidental injury.

- Multiple fractures at different stages of healing/old fractures
- Posterior rib fractures
- Corner or bucket-handle metaphyseal fractures
- Scapular fractures
- Any fracture in a child below walking age

Sir Benjamin Collins Brodie, 1783–1862, surgeon, St George's Hospital, London, UK, described 'Brodie's abscess' in 1828.

PART 6 | Skin, plastic and reconstructive

CHAPTER 45

Skin and subcutaneous tissue

Learning objectives

To understand:

- The structure and functional properties of skin
- The classification of vascular skin lesions
- The cutaneous manifestations of generalised disease as related to surgery
- The classification of benign skin tumours
- The management of malignant skin tumours

FUNCTIONAL ANATOMY AND PHYSIOLOGY OF SKIN

Skin can be divided into two layers: the outer epidermis and the inner dermis. Deep to the dermis lies subcutaneous fat and any remnants of the panniculus carnosus.

Epidermis

The epidermis constitutes 5% of the skin and is composed of five layers of keratinised, stratified squamous epithelium – the strata: basalis (deep), spinosum, granulosum, lucidum and corneum (superficial).

Most epidermal cells are keratinocytes arranged in layers. The basal epidermis (stratum basalis) also contains melanocytes. Keratinocytes are classified according to their depth in the epidermis and their degree of differentiation. Keratinocytes grow and are replaced via mitosis in the cells of the stratum granulosum as they progress from deep to superficial, losing their nuclei and organelles as they ascend, before forming the stratum corneum. The other keratinocyte layers in the skin (strata lucidum, granulosum and spinosum) are variably thick according to body site; for instance, all three are thick in the glabrous skin of the palms and soles of the feet and almost absent in eyelid skin.

Melanocytes are dendritic cells of neural crest origin, usually located in the basal epidermis. Each melanocyte synthesises melanin, a brown-black pigment, which is transferred via membrane processes to the keratinocytes in the strata granulosum and spinosum. Melanin provides protection against ultraviolet radiation (UVR). Ethnic differences in skin colour are determined by variations in the amount, combination and distribution of melanin within the keratinocytes, not by differences in the number of melanocytes.

The surface of the epidermis is coated with a mixture of secreted molecules and microorganisms and generally has an acid pH, which is protective against harmful flora.

Dermis

The dermis constitutes 95% of the skin and is structurally divided into a superficial papillary layer, which is composed of delicate collagen and elastin fibres in ground substance, into which a capillary and lymphatic network ramifies, and a deeper reticular layer, which is composed of coarse branching collagen, layered parallel to the skin surface (***Figure 45.1***).

The epidermis and dermis meet at the dermoepidermal junction in a three-dimensional wave-like arrangement in which epidermal rete ridges project down, interdigitating with upward-pointing, dermal papillae containing vascular and lymphatic plexi.

The skin also contains specialised cells such as Langerhans cells, whose role is to engulf antigens and present them to T cells. Merkel cells, and Meissner's and Pacinian corpuscles have roles in mechanosensation.

Skin adnexa

Adnexal structures such as hair follicles, sebaceous glands and sweat glands span both the epidermal and dermal layers and contain some keratinocytes in their ducts. In injuries where epidermis is lost, re-epithelialisation occurs from these structures as well as from the wound margins.

Paul Langerhans, 1847–1888, Professor of Pathological Anatomy, Freiberg, Germany.
Friedrich Sigmund Merkel, 1845–1919, Professor of Anatomy, successively at Rostock, Königsberg (now Kaliningrad in Russia) and Göttingen, Germany.
George Meissner, 1829–1905, Professor of Physiology, Göttingen, Germany.
Filippo Pacini, 1812–1883, Professor of Anatomy and Physiology, Florence, Italy.

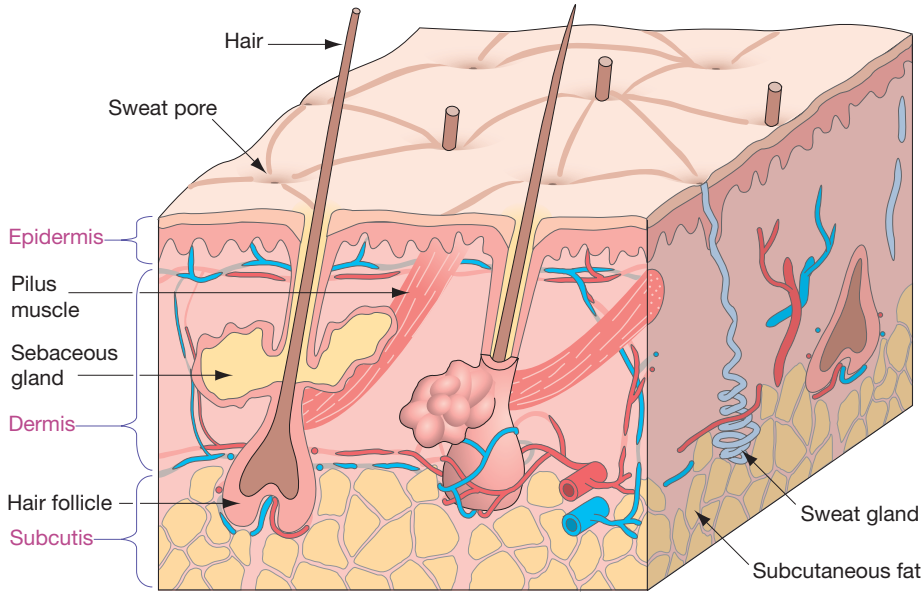

Figure 45.1 Three-dimensional diagram of the structural layers of the skin and its adnexal structures. (Reproduced from Simonsen T, Aarbakke J, Kay I *et al. Illustrated pharmacology for nurses*. London: Hodder Arnold, 2006 with kind permission of the illustrator, Roy Lysaa.)

Hair follicles are tubular invaginations of the epidermis, from which grow hair shafts (dead keratinised tissue). Strips of smooth muscle (arrector pili) are inserted into the wall of the hair follicle and elevate it in response to stress and cold.

Sebaceous glands are hair follicle appendages situated between the follicle and arrector pili muscle such that muscle contraction compresses the gland and sebum is released (holocrine secretion) along the elevated hair.

Simple eccrine and apocrine sweat glands open into pores in hair follicles. Eccrine glands are distributed throughout the entire body surface, except the lips. They secrete sweat in response to emotion or during thermoregulation. Apocrine glands are found in the axillae and groins and become active at puberty. Their secretion, characteristically malodorous after bacterial degradation, is in response to emotion and hormone secretion.

Skin dimensions

The skin is a large organ. In an adult it may have an area of 1–2 m^2 and weigh 15–20 kg. Skin thickness varies with age, location and sun damage, but in any given region it is thinner in children than in adults. The dermis is between 15 and 40 times thicker than the epidermis, but starts to thin during the fourth decade. The epidermis is thickest on the palms, soles, back and buttocks and thinnest on eyelids (0.5–1 mm on the sole of the foot; 0.05–0.09 mm on the eyelid).

Blood supply of the skin

The body can be envisaged as three-dimensional segments of tissue called angiosomes, each with an arterial supply and a venous drainage. Blood equilibrates and flows between neighbouring angiosomes via 'choke' vessels, which tend to be situated within muscles. Cutaneous arteries, direct branches of segmental arteries (concentrated at the dorsoventral axes and intermuscular septae), perforate the underlying muscles or run directly within fascial layers to the skin from the deep tissues (***Figure 45.2***).

The blood supply to the skin anastomoses in subfascial, fascial, subdermal, dermal and subepidermal plexi. The epidermis contains no blood vessels so cells there derive nourishment by diffusion.

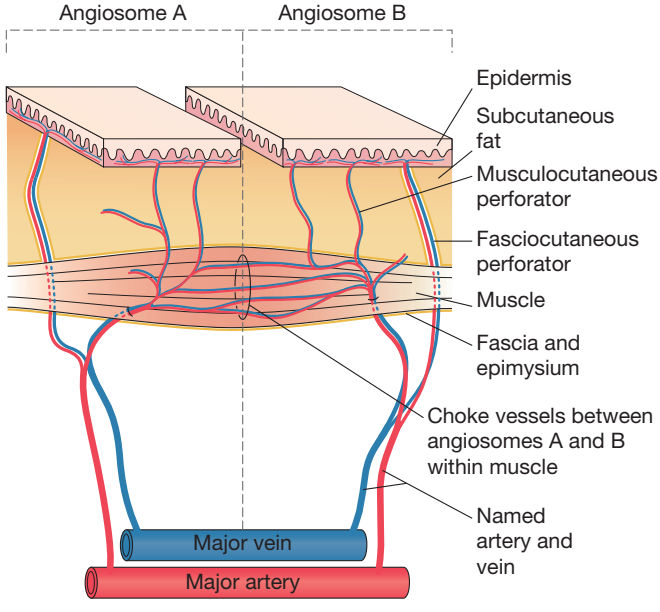

Figure 45.2 Schematic showing two neighbouring angiosomes. Note the choke vessels within the muscle spanning the two cutaneous territories of angiosomes A and B; two common examples of myocutaneous flaps that utilise this physiology include the rectus abdominis and the latissimus dorsi flaps.

The venous drainage of the skin is via both valved and unvalved veins. Unvalved veins allow oscillating flow in the subdermal plexus between cutaneous territories, equilibrating flow and pressure. The valved cutaneous veins drain via plexi to the deep veins.

Anomalies of skin metabolism

Skin has the potential for a blood supply 20–100 times greater than its metabolic and thermoregulatory requirements. This apparent excess enables restitution of mechanical integrity after the myriad of trivial injuries (scratching, stretching, compressing, thermal) to which skin is subjected; however, blood supply is inadequate to support full-thickness wound healing, which requires primary closure or granulation tissue.

Skin functions optimally at temperatures below body core temperature and can tolerate long periods of ischaemia, allowing it to be both grafted and/or expanded for use in reconstruction.

FUNCTION OF THE SKIN

Skin and subcutaneous tissue have several important functions:

- Barrier to the environment enveloping the body and protecting against trauma, radiation and pathogens. Secreted sebum and sweat mix to form a microscopic acidic film across the epidermis – 'the acid mantle' – which is protective against microorganisms and toxic substances.
- Regulates temperature and water homeostasis.
- Organ of excretion for urea, sodium chloride, potassium and water, as well as sulphur-containing metabolites from drugs (e.g. dimethyl sulphoxide) or food (garlic, cumin).
- The skin has significant endocrine and metabolic functions and interactions. Skin cells contain receptors for and respond to peptides, steroid sex hormones, thyroid hormones and neurotransmitters and they both produce (cholecalciferol) and metabolise (androgens) hormones and precursors to activate, potentiate and inactivate their functions.
- Sensory organ with multiple receptors for pain, pressure and movement.

PATHOPHYSIOLOGY OF THE SKIN AND SUBCUTANEOUS TISSUES

Radiation damage

UVR and ionising radiation (IR) damage cellular DNA via the tumour suppressor gene *p53*, inhibiting cellular repair and apoptotic mechanisms. There is also evidence that efferent immune responses are impaired after skin exposure to UVR, facilitating neoplasia.

Figure 45.3 Neurofibromatosis (courtesy of St John's Institute for Dermatology, London, UK).

Ultraviolet radiation

UVR is divisible into A, B and C according to wavelength. UVR, inducing oxidative damage, is the principal cause of skin cancer in all skin types as well as sunburn and skin ageing. UVA and UVB are the principal natural causes of ultraviolet (UV)-induced damage (UVC is absorbed by the atmosphere, but can be emitted by artificial sources). UVA has a longer wavelength than and less energy per photon than UVB, but penetrates more deeply. The effects of UVR are attenuated by melanin and there is an inverse relationship between melanin content and skin susceptibility to UV-induced neoplasia. Some protection is afforded by the stratum corneum, which reflects and refracts UVR, and by clothing, protective creams, cloud cover, particulate air pollution and buildings.

Ionising radiation

The effects of IR are dose, wavelength and time dependent. The skin, with its rapid cellular turnover, shows signs soon after exposure. High-frequency rays cause electron coupling at the molecular level, damaging proteins, polysaccharides and lipids.

Infrared radiation

Infrared radiation generates heat; cumulative exposure can cause thermal burns.

Congenital/genetic disorders

Neurofibromatosis

There are two distinct neurofibromatosis (NF) syndromes, in which Schwann cells form tumours (***Figure 45.3***). Each is caused by different genes on different chromosomes: 70% are autosomal dominant and 30% arise from sporadic mutations. NF-1 (Von Recklinghausen's disease) is the commoner variant,

Friedrich Theodor Schwann, 1810–1882, Professor of Anatomy, successively at Louvain (1839–1848) and Liege, Belgium (1849–1880). Original research before the age of 27 laid the foundation of the physiology of nerve and muscle. The first to deal with problems related to living matter on a purely physical and chemical basis and to recognise the cell as the unit of living matter. Discovered pepsin and the role of living organisms in fermentation.
Friedrich Von Recklinghausen, 1833–1910, German Professor of Pathology, also described haemochromatosis.

affecting approximately 1:4000 births. It arises from a gene mutation on chromosome 17. Skin manifestations appear in early life, with the development of more than five smooth-surfaced café-au-lait spots, subcutaneous neurofibromata, armpit or groin freckling and Lisch nodules. NF-2 produces multiple central nervous system tumours.

Naevoid basal cell carcinoma (Gorlin's) syndrome

This is an autosomal dominant inherited condition caused by an abnormal tumour suppressor gene on chromosome 9q 22–31 coding the 'patched' protein; 90% of patients develop multiple basal cell carcinomas (BCCs). Patients may exhibit specific phenotypical characteristics, including overdeveloped supraorbital ridges; broad nasal roots; hypertelorism; bifid ribs; scoliosis; brachymetacarpalism; palmar pits; and molar odontogenic cysts; patients are also prone to other tumours.

Xeroderma pigmentosum

This syndrome is caused by an abnormality on the 'patched' gene of chromosome 9q, resulting in aberrant nucleotide repair during cellular DNA maintenance. It confers a >2000-fold increase in skin cancer risk and has autosomal recessive inheritance. Sufferers are intolerant of UVR, leading to premature skin ageing and development of multiple neoplasms. Most affected individuals die in early adulthood from metastatic disease (60% mortality by 20 years of age).

Gardner's syndrome

This syndrome is an autosomal dominant disease variant of familial adenomatous polyposis (FAP), which is caused by *APC* gene mutations on chromosome 5q 22. Gardner's syndrome can cause the development of cutaneous pathology, such as multiple epidermoid cysts and lipomata.

Ferguson-Smith syndrome

A rare autosomal dominant inherited abnormality on chromosome 9q in which affected individuals develop multiple self-healing squamous cell carcinomas (SCCs) without relation to sun exposure.

Cutaneous manifestations of generalised disease

Many diseases have cutaneous manifestations that present in surgical practice. These include: necrobiosis lipoidica, granuloma annulare in diabetes mellitus and pyoderma gangrenosum in inflammatory bowel disease. Their management should be sought in appropriate texts.

Hyperhidrosis

This involves excessive eccrine sweating of the palms, soles of the feet, axillae and groins, causing functional and social problems. It can be treated with antiperspirants or periodic local injections with botulinum toxin A. More resistant cases are treated by transthoracic endoscopic sympathectomy.

Figure 45.4 Hidradenitis suppurativa affecting the axilla (courtesy of St John's Institute for Dermatology, London, UK).

Lipodystrophy

Lipodystrophy (lipoatrophy) is a localised or generalised loss of fatty tissue, which can be primary or secondary. It can be a complication of long-term administration of insulin, following treatment of human immunodeficiency virus (HIV) with protease inhibitors or in transplant recipients.

It can be treated in selected cases by autologous fat grafting, injections of poly-l-lactic acid and free tissue transfer.

Inflammatory conditions

Hidradenitis suppurativa

Characterised by follicular occlusion, folliculitis and secondary infection (usually with *Staphylococcus aureus* and *Propionibacterium acnes*), hidradenitis suppurativa culminates in chronic suppurative, painful skin abscesses, sinus tracts and scarring. It affects apocrine gland-bearing skin in the axillae, groins and, less often, scalp, breast, chest and perineum (***Figure 45.4***). Affecting four women for every man, it has a genetic predisposition, but variable penetrance, and is strongly associated with obesity, smoking and sex hormones (it starts at puberty and often resolves at menopause).

Karl Lisch, 1907–1999, ophthalmologist, Wörgl, Austria.
Robert J Gorlin, 1923–2006, American dentist and Professor of Oral Pathology, published over 400 articles on craniofacial syndromes.
Eldon John Gardner, 1909–1989, geneticist, The University of Utah, Salt Lake City, UT, USA, described this syndrome in 1950.
John Ferguson-Smith, 1888–1978, Glaswegian dermatologist.

Management. Patients should stop smoking and lose excess weight. Symptoms can be reduced by the use of antiseptic soaps, tea tree oil and wearing non-compressive and aerated underwear. Medical treatments include topical and oral antibiotics and antiandrogen drugs. In selected cases, patients require radical excision of the affected skin and subcutaneous tissue. Reconstruction after excision avoids contracture and functional impairment.

Pyoderma gangrenosum

Characterised by rapid onset and painful cutaneous ulceration with purple undermined edges, pyoderma gangrenosum is secondary to heightened immunological reactivity, usually from another disease process, such as inflammatory bowel disease, rheumatoid arthritis, non-Hodgkin's lymphoma or granulomatosis with polyangiitis (***Figure 45.5***). Ulcers generally respond to steroids; surgery is rarely indicated and may exacerbate the condition.

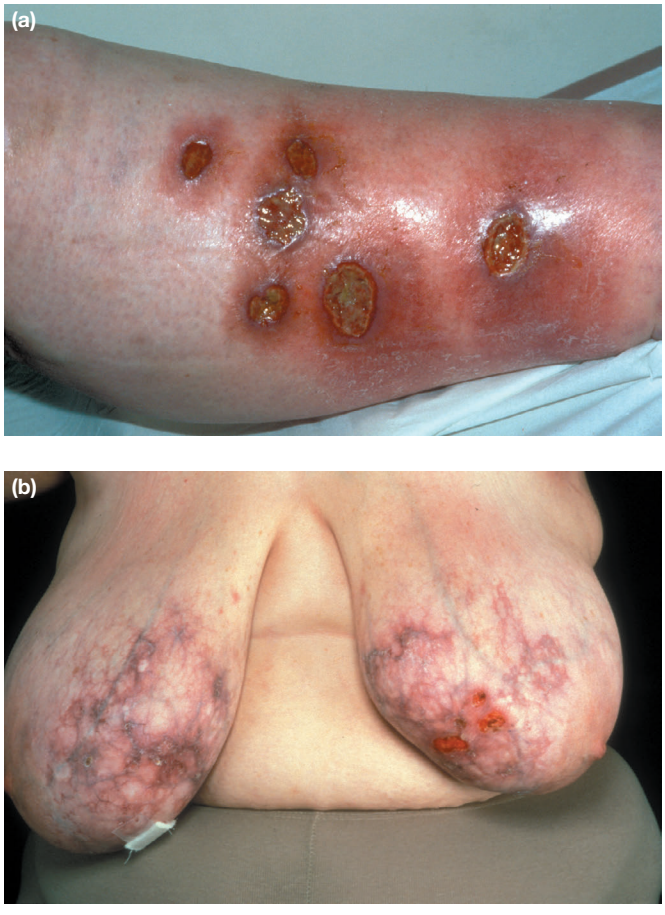

Figure 45.5 Pyoderma gangrenosum affecting the legs **(a)** and the breasts **(b)** (courtesy of St John's Institute for Dermatology, London, UK).

Infections

Skin and soft-tissue infections can be localised or spreading, necrotising or non-necrotising. Localised or spreading non-necrotising infections usually respond to broad-spectrum antibiotics. Localised necrotising infections need surgical debridement as well as antibiotic therapy. Spreading necrotising soft-tissue infection constitutes a life-threatening surgical emergency, requiring immediate resuscitation, intravenous antibiotic therapy and urgent surgical intervention with radical debridement.

Impetigo

Impetigo is a superficial infection of skin with staphylococci, streptococci or both (***Figure 45.6***). It is highly infectious and is characterised by blisters that rupture and coalesce to form a honey-coloured crust; it usually affects children. Treatment is directed at washing the affected areas and applying topical antistaphylococcal treatments; broad-spectrum oral antibiotics are required if streptococcal infection is also implicated.

Figure 45.6 Impetigo. Note the honey-coloured crust (courtesy of St John's Institute for Dermatology, London, UK).

Erysipelas

Erysipelas is a sharply demarcated streptococcal infection of the superficial lymphatics, usually associated with broken skin on the face (***Figure 45.7***). The area affected is erythematous and oedematous. The patient may be febrile and have a leukocytosis. Prompt administration of broad-spectrum antibiotics after swabbing the area for culture and sensitivity is usually all that is necessary.

Cellulitis/lymphangitis

This is a bacterial infection of the skin and subcutaneous tissue that is more generalised than erysipelas. It is usually associated with broken skin or pre-existing ulceration. It is characterised by an expanding area of erythematous, oedematous tissue that is painful, in association with fever, malaise and leukocytosis. Erythema tracking along lymphatics may be visible (lymphangitis) (***Figure 45.8***). The commonest causative organisms are *Streptococcus pyogenes* and *S. aureus*. Blood and skin cultures for sensitivity should be taken before prompt administration of broad-spectrum intravenous antibiotics and elevation of the affected extremity.

Thomas Hodgkin, 1798–1866, curator of the museum and demonstrator of morbid anatomy, Guy's Hospital, London, UK.

Figure 45.7 Erysipelas (courtesy of St John's Institute for Dermatology, London, UK).

Figure 45.8 Cellulitis affecting the left leg (courtesy of St John's Institute for Dermatology, London, UK).

Necrotising fasciitis

Meleney's synergistic gangrene and Fournier's gangrene are variants of a similar disease process.

Necrotising fasciitis results from synergistic polymicrobial infection, most commonly a group A β-haemolytic *Streptococcus* in combination with *Staphylococcus*, *Escherichia coli*, *Pseudomonas*, *Proteus*, *Bacteroides* or *Clostridium*; 80% of patients have a history of previous trauma/infection and over 60% of cases commence in the lower extremities. Predisposing conditions include diabetes mellitus, smoking, penetrating trauma, pressure sores, immunosuppression, intravenous drug abuse, perineal infection (perianal abscess, Bartholin's cysts) and skin damage/infection (abrasions, bites, boils).

Summary box 45.1

Necrotising fasciitis

- Surgical emergency
- Polymicrobial synergistic infection
- 80% have a history of previous trauma or infection
- Rapid progression to septic shock
- Urgent resuscitation, antibiotics and surgical debridement
- Mortality 30–50%

Classical clinical signs include oedema stretching beyond visible skin erythema; a woody-hard texture to the subcutaneous tissues; an inability to distinguish fascial planes and muscle groups on palpation; disproportionate pain in relation to the affected area, with associated skin vesicles and soft-tissue crepitus (***Figure 45.9***). Lymphangitis tends to be absent. Early on, patients may be febrile and tachycardic, with a very rapid progression to septic shock. Radiographs, which should not have delayed urgent treatment, may demonstrate air in the tissues.

Management should commence with urgent fluid resuscitation, monitoring of haemodynamic status and administration of high-dose intravenous broad-spectrum antibiotics. This is a surgical emergency and the diseased area should be debrided as soon as possible until viable, healthy, bleeding tissue is reached. Early surgical review and further debridement is advisable, together with the use of vacuum-assisted dressings. Early skin grafting in selected cases may minimise protein and fluid losses. Where available, hyperbaric oxygen therapy after debridement may be helpful. Mortality of between 30% and 50% can be expected, even with prompt operative intervention.

Purpura fulminans

This is a relatively rare condition in which intravascular thrombosis produces rapid skin necrosis and haemorrhagic infarction, which progresses rapidly to septic shock and disseminated intravascular coagulation. Usually seen in children, it can occur in adults and may be subdivided into three types based on the aetiological mechanism: 'acute infectious', 'neonatal' and 'idiopathic' purpura fulminans.

Acute infectious is the commonest form. It is associated with a mortality rate of 40–50%, usually from multiorgan

Frank Meleney, 1889–1963, American surgeon in the First World War, then became a Professor at Columbia Medical School in New York, NY, USA.
Jean Fournier, 1832–1914, French dermatologist, also described tertiary syphilis.
Caspar Bartholin (Secundus), 1655–1709, Professor of Medicine, Anatomy and Physics, Copenhagen, Denmark, described these glands in 1677.

Figure 45.9 Necrotising fasciitis affecting the left orbit and facial skin (courtesy of St John's Institute for Dermatology, London, UK).

Figure 45.10 Acute infectious purpura fulminans caused by meningococcal septicaemia. Note the sharply demarcated necrotic areas distal to the affected end or perforating arteries with surrounding normal skin (courtesy of St John's Institute for Dermatology, London, UK).

failure, and is secondary to either an acute bacterial (*Neisseria meningitidis*) or viral infection (varicella). It is most common in children under 7 years, following an upper respiratory tract infection or in asplenia. Endotoxins produce an imbalance in procoagulant and anticoagulant endothelial activity, producing protein C deficiency; this gives the clinical picture of an initial petechial rash developing into confluent ecchymoses and haemorrhagic bullae, which necrose to form well-demarcated lesions that form hard eschars. Extensive tissue loss is common, which often culminates in limb amputation (***Figure 45.10***).

Skin and soft-tissue cysts

Milia

Small, hard, keratin retention cysts (***Figure 45.11***) seen both in babies and, after chronic sun exposure, in the elderly as part of Favre–Racouchot syndrome (solar comedones, pseudocysts and leathery, furrowed sun-damaged skin – heightened by smoking).

Epidermal cysts

These cysts are lined with true stratified squamous epithelium, derived from hair follicle infundibuli or traumatic inclusion. Commonly known as sebaceous cysts, they can occur anywhere. They are fixed to the skin and usually have a central punctum (***Figure 45.12***).

Figure 45.11 Milia (courtesy of St John's Institute for Dermatology, London, UK).

Treatment depends on the clinical state of the cyst. When inflamed or infected, they should be incised and drained initially; they should be removed later once the inflammation and induration has subsided. It is important to excise the cyst in its entirety as failure to do so usually results in recurrence.

Meibomian cysts are epidermal cysts found on the free edge of the eyelid. Trichilemmal (pilar/pilosebaceous) cysts are derived from the epidermis of the external root sheath of the hair follicle; 90% are found in the scalp and 70% are multiple. They are usually distinguished from epidermal cysts by pathologists, rather than clinically.

Albert Ludwig Siegmund Neisser, 1855–1916, Director of the Dermatological Institute, Breslau, Germany (now Wrocław, Poland).
Maurice Favre, 1876–1954, French dermatologist.
Jean Racouchot, 1908–1994, French dermatologist.
Heinrich Meibom (Meibomius), 1638–1700, Professor of Medicine, History and Poetry, Helmstadt, Germany, described these glands in 1666.

Figure 45.12 Multiple scrotal epidermal cysts (courtesy of St John's Institute for Dermatology, London, UK).

SKIN TUMOURS

Benign lesions

Basal cell papilloma (seborrhoeic keratosis, senile keratosis, verruca senilis)

Their appearance varies from macular to soft, excrescent, warty lesions – often pigmented and hyperkeratotic – but may be flesh-coloured or pink. They are formed from the basal layer of epidermal cells and contain melanocytes.

Papillary wart (verruca vulgaris)

This is a benign skin tumour arising from infection with the human papillomavirus (HPV), which is also responsible for plantar warts and condylomata acuminata.

Freckle (ephelis)

A freckle is an area of skin that contains a normal number of melanocytes, producing an abnormally large number of melanin granules.

Lentigo

These are small, circumscribed pigmented macules that stem from sun damage and some systemic syndromes. Solar lentigos are commoner in fairer skins.

Moles/naevi

Melanocytes migrate from the neural crest to the basal epidermis during embryogenesis. When melanocytes aggregate in the dermis or at the dermoepidermal junction, they are called naevus cells.

Figure 45.13 Junctional naevus (courtesy of St John's Institute for Dermatology, London, UK).

Junctional naevus

A junctional naevus is a dermoepidermal proliferation of naevus cells, visible as deeply pigmented macules or papules that occur commonly in childhood or adolescence, usually progressing to form compound or intradermal naevi with advancing age. Benign mucosal lesions tend to be junctional naevi (***Figure 45.13***).

Compound naevus

This is a maculopapular, pigmented lesion that becomes most prominent during adolescence (***Figure 45.14***). It represents a junctional proliferation of naevus cells, with nests and columns in the dermis.

Intradermal naevus

Intradermal naevi are faintly pigmented papules in adults that show no junctional proliferation; however, they do show a cluster of dermal melanocytes (***Figure 45.15***).

Spitz naevus

These are reddish brown (occasionally deeply pigmented) nodules, previously termed 'juvenile melanoma' (***Figure 45.16***). They most commonly occur on the face and legs, growing rapidly initially then remaining static or regressing. The differential diagnosis is melanoma and excision biopsy is warranted if there is doubt as to the diagnosis.

Spindle cell naevus

Spindle cell naevi are dense black lesions that contain spindle cells and atypical melanocytes at the dermoepidermal junction. They are commonly seen on the thighs and affect women more frequently. They may have malignant potential.

Halo naevus

The halo of depigmentation around any benign naevus represents an antibody response to melanocytes. Depigmentation may also be a feature of a malignant melanoma. Halo naevi are associated with vitiligo (***Figure 45.17***).

Sophie Spitz, 1910–1956, American dermatopathologist at the Memorial Sloan Kettering Cancer Center, published the first case series of 'juvenile melanoma' in 1948.

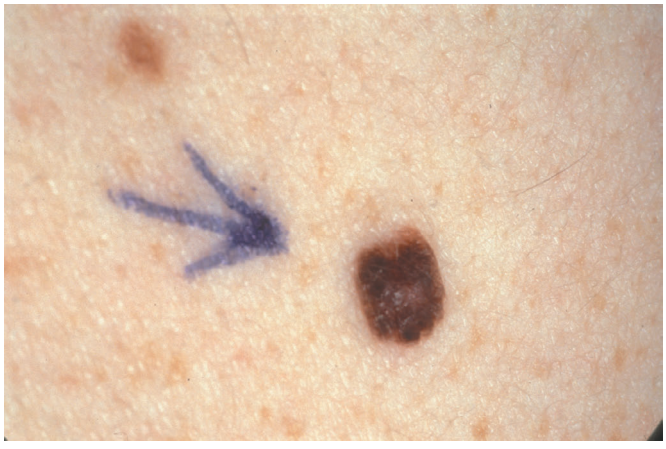

Figure 45.14 Compound naevus (courtesy of St John's Institute for Dermatology, London, UK).

Figure 45.15 Intradermal naevus (courtesy of St John's Institute for Dermatology, London, UK).

Figure 45.16 Spitz naevus (courtesy of St John's Institute for Dermatology, London, UK).

Figure 45.17 Halo naevus (courtesy of St John's Institute for Dermatology, London, UK).

Café-au-lait spots

These are coffee-coloured macules of variable size (from a few millimetres to 10 cm) (***Figure 45.18***). Multiple lesions are associated with NF-1 and McCune–Albright syndromes. They are more common in dark-skinned people.

Naevus spilus (speckled lentiginous naevus)

These are similar in appearance to café-au-lait spots but with hyperpigmented speckles throughout (***Figure 45.19***). They are benign lesions that are associated with various cutaneous diseases, but whose speckled appearance can be confused with malignant change. The mainstay of management is observation and serial photography as malignant transformation is rare.

Mongolian spot

A Mongolian spot is a congenital blue-grey macule found on the sacral skin (***Figure 45.20***). Pigmentation initially deepens and then regresses completely by age 7 years.

Blue naevus

This is a benign skin lesion that is four times more common in children, typically affecting the extremities and face (***Figure 45.21***).

Naevi of Ota and Ito

A naevus of Ota is a dermal melanocytic hamartoma visible as a blue or grey macule in the trigeminal V1 and V2 dermatomes. It is four times more common in women and most frequently seen in Asian and African people (***Figure 45.22***).

A naevus of Ito is characterised by dermal melanocytosis in the shoulder region and can occur simultaneously in patients with naevus of Ota (***Figure 45.23***).

Donovan James McCune, 1902–1976, American pediatrician.
Fuller Albright, 1900–1969, physician, Massachusetts General Hospital, Boston, MA, USA.
Masao Ota, 1885–1945, Japanese dermatologist.
Minoru Ito, 1892–1986, Professor of Dermatology, Tohoku University, Sendai, Honshu, Japan.

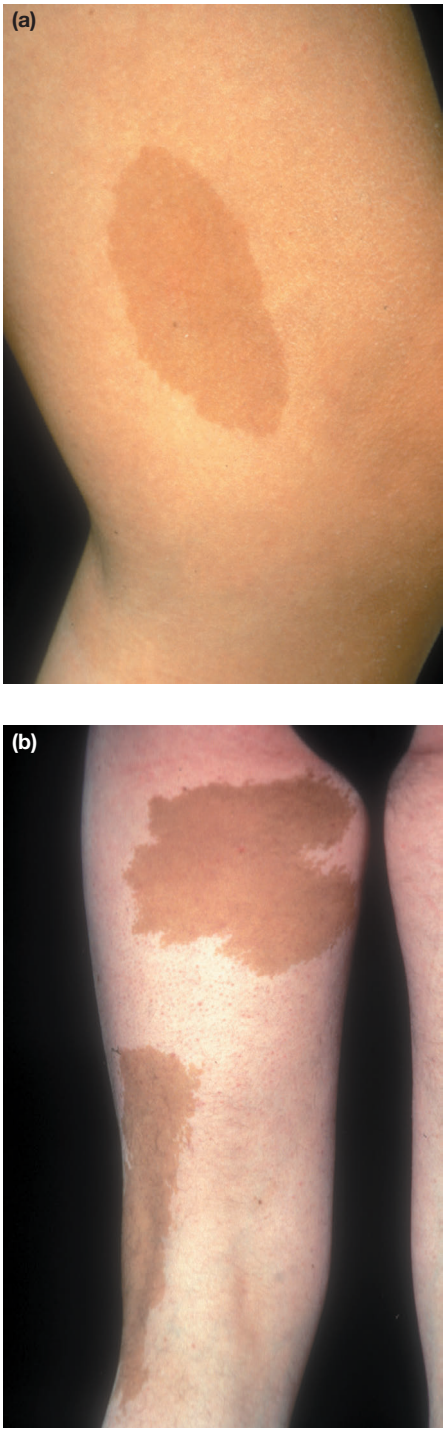

Figure 45.18 Café-au-lait spots. Note the two topographical variants: in (a) the spot has a smooth 'coast of California' border, whereas the upper spot in (b) has an irregular 'coast of Maine' border. Multiple smooth-bordered lesions are commonly associated with syndromes (courtesy of St John's Institute for Dermatology, London, UK).

Figure 45.19 Naevus spilus (courtesy of St John's Institute for Dermatology, London, UK).

Figure 45.20 Mongolian spot (courtesy of St John's Institute for Dermatology, London, UK).

Hair follicles

Trichoepithelioma

These are small skin-coloured nodules found most often in the nasolabial folds. Trichoepithelioma is clinically and histologically similar to a BCC.

Pilomatrixoma (calcifying epithelioma of Malherbe)

These are benign hair matrix cell tumours that often calcify; 40% are found in the under-10 age group.

Albert Hippolyte Malherbe, 1845–1945, Professor of Histology, Anatomy and Surgery, Nantes, France.

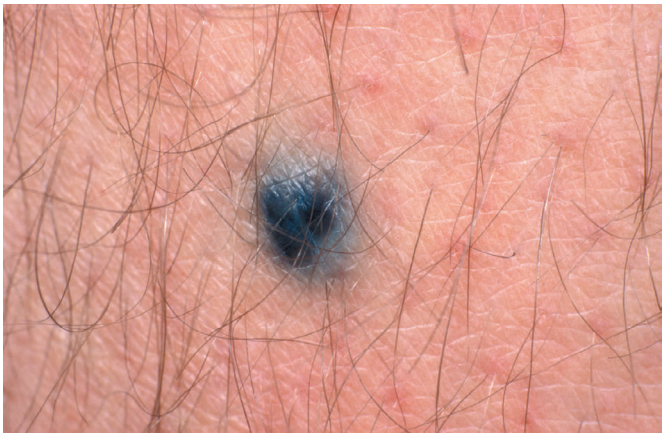

Figure 45.21 Blue naevus (courtesy of St John's Institute for Dermatology, London, UK).

Figure 45.22 Naevus of Ota (courtesy of St John's Institute for Dermatology, London, UK).

Figure 45.23 Naevus of Ito (courtesy of St John's Institute for Dermatology, London, UK).

Figure 45.24 Naevus sebaceous of Jadassohn (courtesy of St John's Institute for Dermatology, London, UK).

Trichilemmoma (naevus sebaceous of Jadassohn)

Trichilemmoma is a congenital hamartoma with the appearance of a linear verrucous naevus; 10% lifetime risk of forming a BCC (***Figure 45.24***).

Adenoma sebaceum (tuberous sclerosis, Bourneville disease)

These are facial papules (angiofibromata) that are red-brown depending on skin colour and usually appear on the nasolabial folds, cheek and chin. They usually appear in children before 10 years of age and increase in size and number until adolescence. Cosmetic removal by argon or pulsed-dye lasers or scalpel is indicated (***Figure 45.25***).

Rhinophyma

Rhinophyma is the end-stage sequela of nasal acne rosacea (***Figure 45.26***). It is nasal sebaceous gland hypertrophy and hyperplasia and tends to affect elderly men (male-to-female ration 12:1). Occult BCCs exist in 3%. Treatment by dermabrasion or laser resurfacing produces good results.

Sweat glands

Cystadenoma (hydrocystadenomas, hidradenomas)

These are 1- to 3-cm translucent blue cystic nodules.

Josef Jadassohn, 1863–1936, dermatologist, Breslau, Germany (now Wrocław, Poland).
Desire M Bourneville, 1840–1909, physician, Le Bicêtre, Paris, France.

Figure 45.25 Adenoma sebaceum (courtesy of St John's Institute for Dermatology, London, UK).

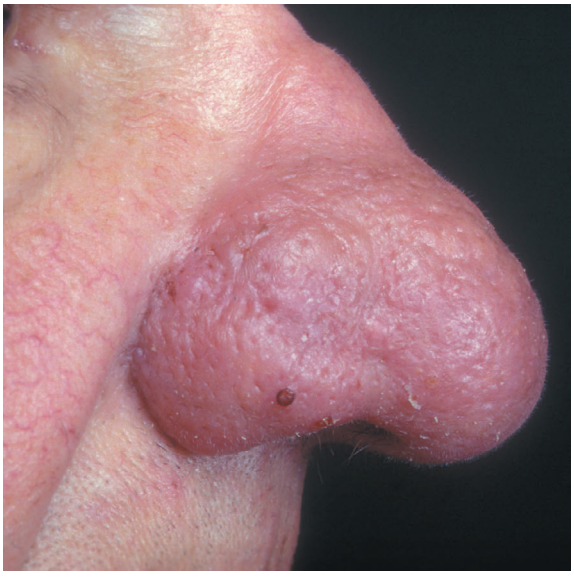

Figure 45.26 Rhinophyma (courtesy of St John's Institute for Dermatology, London, UK).

Eccrine poroma (papillary syringoma)

These are single raised or pedicled lesions found most often on the palm or sole.

Cylindroma (turban tumour)

A variant of eccrine spiradenoma that coalesce when multiple on the scalp, forming a 'turban tumour'.

Premalignant lesions

Extramammary Paget's disease (intraepidermal adenocarcinoma)

This occurs in cutaneous sites that are rich in apocrine glands such as the axillae and the genital and perianal regions. Approximately 25% are associated with an underlying *in situ* or invasive adenocarcinoma. Early skin changes are subtle and may present as an eczematous lesion or intertrigo. Surgical excision forms the basis of treatment, with up to 20% demonstrating invasive disease after pathology assessment (***Figure 45.27***).

Figure 45.27 Extramammary Paget's disease involving the perineum (courtesy of St John's Institute for Dermatology, London, UK).

Giant congenital pigmented naevus or giant hairy naevus

This hamartoma of naevo-melanocytes causes confusion because its definition and management are contentious. It has a similar histology to compound naevi, but with naevus cells distributed variably throughout all skin layers and into the subdermal fat and muscle and with a tendency to dermatomal distribution (***Figure 45.28***). Giant congenital pigmented naevi (GCPNs) are precursors of melanoma but the magnitude of this risk is unclear, largely because of the lack of well-conducted studies and variable classification of the naevus. A 3–5% lifetime risk of melanoma is quoted. One in three childhood malignant melanomas arise in patients with GCPN, but the risk decreases with age: 15% of malignant melanomas present at birth, 62% present by puberty and 99% by 45 years of age.

A multidisciplinary management approach is advocated, with initial investigations examining for neurocutaneous melanosis as there may be leptomeningeal involvement. Removal of GCPN should be considered for both aesthetic and oncological reasons.

Atypical (dysplastic) naevus

To be 'atypical naevi', lesions must have three of the following characteristics: variegated pigmentation; ill-defined borders;

Sir James Paget, 1814–1899, surgeon, St Bartholomew's Hospital, London, UK.

Figure 45.28 Giant congenital pigmented naevus (courtesy of St John's Institute for Dermatology, London, UK).

undulating irregular surfaces; or size >5 mm. Terminology is confused because, although the terms 'dysplastic' and 'atypical' are often used interchangeably, dysplasia is a histological diagnosis with findings of irregular proliferations of melanocytes at the basal layer of the epidermis. In fact, a small proportion of clinically 'atypical naevi' are actually dysplastic when examined microscopically.

Atypical naevi can be sporadic or familial (familial atypical multiple mole–melanoma [FAMMM] syndrome). Possession of more than five lesions confers a relative risk of melanoma six times greater than usual; within FAMMM syndrome, they confer a 100% risk of malignant melanoma and patients with FAMMM syndrome should be screened for melanoma 6-monthly, lifelong (***Figure 45.29***).

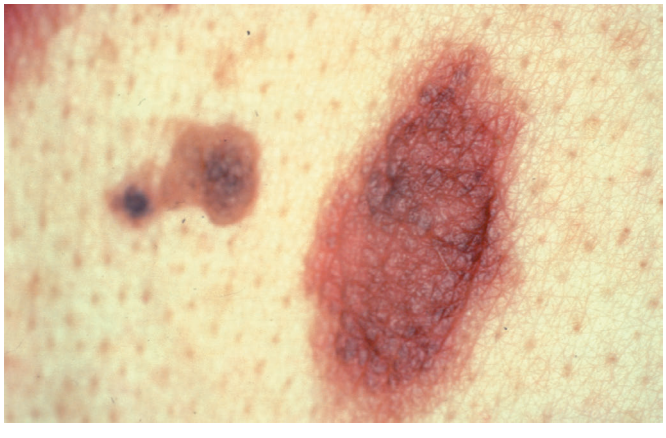

Figure 45.29 Dysplastic naevus (courtesy of St John's Institute for Dermatology, London, UK).

Malignant lesions

Data from the World Health Organization suggest that both non-melanoma and melanoma skin cancers continue to increase in incidence, despite educational programmes and wide-ranging changes in uptake of sun protective measures and improvements in sunscreens. Skin cancer is the commonest malignancy in white-skinned people, constituting 33% of all recorded malignancies annually, with 2–3 million new non-melanoma skin cancers and 132 000 new malignant melanomas (4.5% of all new cancers are melanomas) diagnosed each year.

Basal cell carcinoma

This is usually a slow-growing, locally invasive, malignant tumour of pluripotential epithelial cells arising from basal epidermis and hair follicles; hence, it affects the pilosebaceous skin.

Summary box 45.2

Basal cell carcinoma

- Slow growing
- Risk factor – UVR
- 90% nodular/nodular cystic
- High- and low-risk BCC

Epidemiology

The strongest predisposing factor to BCC is UVR. It occurs in the elderly or the middle-aged after excessive sun exposure, with 95% occurring between the ages of 40 and 80 years. The incidence of BCC rises with proximity to the equator, although 33% arise in parts of the body not usually exposed to the sun. Other predisposing factors include exposure to arsenical compounds, coal tar, aromatic hydrocarbons and IR and genetic skin cancer syndromes. White-skinned people are almost exclusively affected. BCC is more common in men than in women.

Pathogenesis

BCCs have no apparent precursor lesions and their development is proportional to the initial dose of the carcinogen, but not duration of exposure. The most likely model of pathogenesis for BCCs involves mesodermal factors as intrinsic promoters coupled with an initiation step. BCCs metastasise extremely rarely.

Macroscopic

BCCs can be divided into localised (nodular, nodulocystic, cystic, pigmented and naevoid) and generalised (superficial: multifocal and superficial spreading; or infiltrative: morphoeic, ice pick and cicatrising). Nodular and nodulocystic variants account for 90% of BCCs.

Microscopic

Twenty-six histological subtypes have been described. The characteristic finding is of ovoid cells in nests with a single

'palisading' layer. It is only the outer layer of cells that actively divide, explaining why tumour growth rates are slower than their cell cycle speed would suggest and why incompletely excised lesions are more aggressive. Morphoeic BCCs synthesise type 4 collagenase and so spread rapidly (*Figure 45.30*).

Figure 45.30 (a) A nodulocystic basal carcinoma (BCC). Note the characteristic pearly surface with telangiectasia. (b) An ulcerating BCC on the lower eyelid. (c) A recurrent morphoeic BCC. ((a, b) courtesy of Mr AR Greenbaum; (c) courtesy of St John's Institute for Dermatology, London, UK.)

Prognosis

There are 'high-risk' and 'low-risk' BCCs. High-risk BCCs: are large (>2 cm); are located at sites where direct invasion gives access to the cranium (near the eye, nose and ear); are recurrent tumours; are tumours forming in the presence of immunosuppression; or have micronodular or infiltrating histological subtypes.

Management

Treatment can be surgical or non-surgical. Tumour and surrounding surgical margins should always be assessed and marked under loupe magnification, the latter varying between 2 and 15 mm depending on the macroscopic variant. Where margins are ill-defined or tissue is at a premium (nose, eyes), either a two-stage surgical approach with subsequent reconstruction after confirmation of clear margins or Mohs' micrographic surgery is advisable. The histological sample must be orientated and marked for pathological examination.

Mohs' micrographic surgery is a method used by dermatological surgeons (dermatologists who have undergone extra training in techniques of cutaneous surgery and histopathology) to excise skin cancer under microscopic control.

In elderly or infirm patients, radiotherapy produces similar recurrence rates to surgery, but with the risk of generating further malignancy after one to two decades. Biopsy-proven, superficial tumours can be treated with topical treatments (5-fluorouracil, imiquimod).

Unless excision of a BCC is complete, there is a 67% recurrence rate if margins are grossly involved and a 33% recurrence rate within 2 years with microscopic involvement or when reported 'close'.

Patients with uncomplicated, completely excised lesions can be discharged. Follow-up is reserved for patients with tumours in high-risk areas; for those with globally sun-damaged skin; for those with syndromes; and for those who decline further surgery after incomplete excisions.

Cutaneous squamous cell carcinoma

SCC is a malignant tumour of keratinising cells of the epidermis or its appendages. It arises from the stratum basalis of the epidermis and expresses cytokeratins 1 and 10.

Epidemiology

Four BCCs occur for every SCC, which is the second most common form of skin cancer. It is strongly related to cumulative sun exposure and damage, especially in white-skinned individuals living nearer the equator. In the northern hemisphere it affects the elderly, whereas it is not uncommon in sun-damaged, middle-aged white people in the southern hemisphere. Everywhere, it is more common in men than in women. SCC is also associated with chronic inflammation (chronic sinus tracts, pre-existing scars, osteomyelitis, burns, vaccination points) and immunosuppression. When a SCC appears in a scar it is known as a Marjolin's ulcer.

Frederic E Mohs, 1910–2002, American physician and general surgeon, University of Wisconsin, Madison, WI, USA, developed Mohs' micrographic surgical technique in 1938 for cutaneous malignant lesions.

Jean-Nicolas Marjolin, 1780–1850, surgeon, Paris, France, described the development of carcinomatous ulcers in scars in 1828.

Summary box 45.3

Squamous cell carcinoma

- Associated with UVR, chronic inflammation, immunosuppression and chemical carcinogens
- High- and low-risk SCC
- Metastasis in 2% of low-risk and up to 30% of high-risk cases

IR causes SCC, as do chemical carcinogens (arsenicals, tar) and infection with HPV subtypes 5 and 16. There is also evidence that current and previous tobacco use doubles the relative risk of SCC.

In the past, actinic (solar) keratoses (AKs), i.e. cutaneous horns and keratoacanthomas, were considered to be premalignant lesions leading to SCC. Current thinking is to classify these lesions on a continuum of lesions, some of which can improve, as with other squamous cell tumours such as cervical intraepithelial neoplasia.

AKs are areas of permanent sun damage in which there is dyskeratosis, partial-thickness cellular atypia and subepidermal inflammation, but an intact basement membrane (***Figure 45.31***). They 'wax and wane' macroscopically between macular and papular, with and without keratinous surfaces. Most improve after moisturisation and remain as erythematous macules; however, up to 20% form SCC.

When an AK has a keratinous surface with a height greater than its base diameter, it is termed a keratin horn; 10% will have an underlying SCC (***Figure 45.32***).

Keratoacanthomas are rapidly growing, nodular tumours exhibiting symmetry around a central keratin-filled crater.

Figure 45.31 Actinic keratosis (courtesy of St John's Institute for Dermatology, London, UK).

Figure 45.32 Cutaneous horn (courtesy of St John's Institute for Dermatology, London, UK).

Current thinking is that, rather than being separate premalignant entities, they are better considered as self-healing SCCs and, as such, are often reported by pathologists as 'keratoacanthoma-like SCCs' (***Figure 45.33***). Keratoacanthomas are twice as common in men as in women and are usually found on the face or limbs of chronically sun-damaged 50- to 70-year-old white-skinned individuals. They may be caused by HPV in a hair follicle during the growth phase and are also associated with smoking and chemical carcinogen exposure. Excision is recommended, rather than observation, as the differential diagnosis includes anaplastic SCC and the excision scar is often better than that which remains after resolution.

Bowen's disease is SCC *in situ* and often develops as full-thickness dysplasia in hypertrophic AKs (***Figure 45.34***). SCC *in situ* usually presents as a slowly enlarging erythematous scaly plaque and may occur anywhere on the mucocutaneous surface of the body. On the glans penis, it is called erythroplasia of Queyrat (***Figure 45.35***). Topical therapy with 5-fluorouracil or imiquimod is an effective treatment. Alternatives include surgical excision with a 4-mm margin or Mohs' micrographic surgery for larger or recurrent lesions.

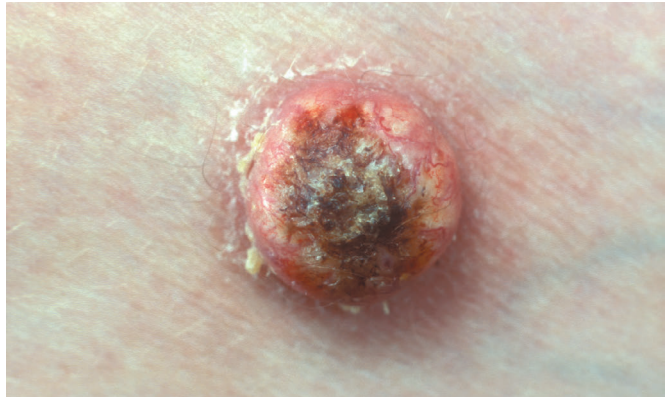

Figure 45.33 Keratoacanthoma (courtesy of St John's Institute for Dermatology, London, UK).

John T Bowen, 1857–1941, Professor of Dermatology, Harvard University Medical School, Boston, MA, USA, described this condition in 1912.
August Queyrat, 1856–1933, dermatologist, Paris, France, described this condition in 1911.

Figure 45.34 Bowen's disease – squamous cell carcinoma *in situ* (courtesy of St John's Institute for Dermatology, London, UK).

Macroscopic

The appearance of SCC may vary from smooth nodular, verrucous, papillomatous to ulcerating lesions. All ulcerate eventually as they grow. The ulcers have a characteristic everted edge and are surrounded by inflamed, indurated skin. Differential diagnoses of SCC include: AK; BCC; pyoderma gangrenosum; warts; and lichen simplex chronicus (***Figure 45.36***).

Figure 45.35 Erythroplasia of Queyrat – squamous cell carcinoma *in situ* on the glans penis; also called Paget's disease of the penis (courtesy of St John's Institute for Dermatology, London, UK).

Microscopic

Characteristic irregular masses of squamous epithelium are noted to proliferate and invade the dermis from the basal layer. The tumour stains positive for cytokeratins 1 and 10. SCC can be graded histologically according to Broders' grading, which describes the proportion of dedifferentiated cells in the tumour. ***Table 45.1*** presents tumour classification and staging.

Prognosis

There are several independent prognostic variables for SCC:

- Depth: the deeper the lesion, the worse the prognosis. For SCC <2 mm, metastasis is highly unlikely; if SCC >6 mm, 15% will have metastasised.

TABLE 45.1 Tumour–node–metastasis (TNM) classification and staging of squamous cell carcinoma.

Size	Nodes	Metastases	Stages
TX Primary tumour cannot be assessed	NX Nodal involvement cannot be assessed	M0 No metastatic disease	Stage 0 Tis, N0, M0
T0 No evidence of primary tumour	N0 No regional nodes	M1 Metastatic disease present	Stage I T1, N0, M0
Tis *In situ* (confined to full-thickness epidermal) disease	N1 Spread to 1 ipsilateral nearby node that is <3 cm in diameter		Stage II T2, N0, M0
T1 Primary <2 cm	N2a Spread to 1 ipsilateral nearby node that is 3–6 cm in diameter		Stage III T3, N0, M0 or T1–T3, N1, M0
T2 Primary >2 cm	N2b Spread to >1 ipsilateral nearby nodes but none >6 cm in diameter		Stage IV T1–T3, N2, M0 or any disease that is N3, or T4 or M1
T3 Primary invasion of a facial bone	N2c Spread to contralateral node(s) but none are >6 cm in diameter		
T4 Invasion of muscle, base of skull or other bones	N3 Spread to any node >6 cm in diameter		

Albert Compton Broders, 1885–1964, American pathologist, MN, USA, and Chairman of the Department of Surgical Pathology, Mayo Clinic, Rochester, MN, USA; for 1 year in 1935 Professor of Surgical Pathology and Director of Cancer Research, University of Virginia, Charlottesville, VA, USA. Broders also graded rectal cancer in the USA in a similar manner to the one that Cuthbert Dukes used to classify it in the UK. A combination of Broders' grading and Dukes' classification gave a more accurate prognosis for rectal carcinoma than either method alone.

Figure 45.36 (a) A squamous cell carcinoma (SCC) on the face. **(b)** A recurrent SCC arising in a previously skin-grafted area of the scalp. **(c)** SCC arising on the dorsum of the hand in a renal transplant recipient on immunosuppressive therapy. **(d)** SCC arising on the lip of a smoker who worked outside on a farm. (**(a–c)** courtesy of Mr AR Greenbaum; **(d)** courtesy of St John's Institute for Dermatology, London, UK.)

- Surface size: lesions >2 cm have a worse prognosis than smaller ones.
- Histological grade: the higher the Broders' grade, the worse the prognosis.
- Microscopic invasion of lymphovascular spaces or nerve tissue carries a high risk of metastatic disease.

Therefore, as well as information on pathological pattern, cellular morphology and Broders' grade, any histopathology report for SCC should include the depth of invasion, the presence of perineural or lymphovascular invasion and the deep and peripheral margin clearance.

- Site: SCCs on the lips and ears have higher local recurrence rates than lesions elsewhere, and tumours at the extremities fare worse than those on the trunk.
- Aetiology: SCCs that arise in burn scars, osteomyelitis skin sinuses, chronic ulcers and areas of skin that have been irradiated have a higher metastatic potential.
- Immunosuppression: SCCs will invade further in those with impaired immune response.

The overall rate of metastasis varies between 2% and 30% for SCC (usually to regional nodes) with a local recurrence rate of 20%.

Management

SCC is a heterogeneous tumour with a malignant potential that varies between subtypes. Management must address the tumour's tendency for lymphatic metastasis and the possibility of in-transit metastasis.

Surgical excision is the only means of providing accurate information on histology and clearance. The margins for primary excision should be tailored to surface size in the first instance. This should ideally be assessed using surgical loupe magnification. A 4-mm clearance margin should be achieved if the SCC measures <2 cm across, and a 1-cm clearance margin if the SCC measures >2 cm; 95% of local recurrence and regional metastases occur within 5 years, thus follow-up beyond this period is not indicated.

Cutaneous malignant melanoma

Melanoma is a cancer of melanocytes and can, therefore, arise in skin, mucosa, retina and the leptomeninges.

Epidemiology

Observational data suggest that cutaneous melanoma is caused by exposure to UVR, but this general observation, which is a generally reliable fact, may hide some of the nuanced variables that contribute to melanoma formation.

Generally speaking, its rise in incidence reflects increased recreational activity in the sun and emigration among white-skinned people not suited to sun exposure. Although it accounts for less than 5% of skin malignancy (and 1.6% of all malignancy worldwide), it is responsible for over 75% of skin malignancy-related deaths.

It is the commonest cancer in young adults (20–39 years) and the most likely cause of cancer-related death.

Distribution between the sexes varies around the world and reflects occupational and recreational exposure to sunlight. Likewise, geographical distribution reflects exposure of white-skinned individuals to sunlight: Australia and New Zealand, countries with a predominantly white-skinned, immigrant population, have an incidence of 33.6 per 100 000. Five per cent of all patients with malignant melanoma will develop a second primary melanoma; 7% of malignant melanomas present as occult metastasis from an unknown primary.

What is less clear within data on cutaneous melanoma is the contribution by variables such as serum vitamin D levels and vitamin receptor genotypes, because thinner melanomas and lower recurrence rates have been linked to higher serum vitamin D levels, and why some forms of melanoma seem more attributable to cumulative sun exposure (superficial spreading) than others (nodular). Studies exploring whether there may be benefit from a degree of sun exposure that avoids 'sunbathing' and burning and whether sun-related vitamin D production in skin, rather than supplemental vitamin D, is beneficial are ongoing, but our best information still bases sun avoidance at the centre of melanoma prevention.

Pathophysiology

Cumulative UV exposure favours the development of lentigo maligna melanoma (LMM) and later onset of disease, whereas 'flash fry' exposure, typical of rapidly acquired holiday tans, favours the other morphological variants and early onset of disease.

A small proportion of malignant melanoma is genetically mediated and develops at an earlier age. People at most risk of developing malignant melanoma include: those with genetic syndromes; those with a past history of malignant melanoma or with a first-degree relative who has malignant melanoma; those who have more than 30 sun-acquired naevi or a history of five significant sunburns before the age of 16; fair-skinned/red-haired people living close to the equator; anyone with excessive UVR exposure (environmental or salon-delivered); or anyone with immunosuppression (which increases malignant melanoma incidence 20- to 30-fold). Male gender and solitary living are both associated with thicker melanomas at diagnosis. In women, higher socioeconomic status is positively correlated with developing melanoma.

Summary box 45.4

Malignant melanoma

- Rising incidence
- Genetic and acquired risk factors
- Superficial spreading form the most common
- Breslow thickness is the most important prognostic indicator
- Sentinel node biopsy (SNB) is useful for staging

Macroscopic

Only 10–20% of malignant melanomas form in pre-existing naevi, with the remainder arising *de novo* in previously normally pigmented skin. The most likely naevi to form malignant melanoma are atypical naevi, atypical junctional lentiginous naevi (usually facial) and giant pigmented congenital naevi.

Macroscopic features in a pre-existing naevus that suggest malignant change are listed in ***Summary box 45.5***.

There are four common macroscopic variants of malignant melanoma and several other notable, but rarer, forms, as follows.

Superficial spreading melanoma (SSM). This is the most common presentation (70%); usually arises in a pre-existing naevus after several years of slow change, followed by rapid growth in the months before presentation (***Figure 45.37***). Nodularity within SSM heralds the onset of the vertical growth phase.

Nodular melanoma (NM). NM accounts for 15% of all malignant melanoma and tends to be more aggressive than SSM, with a shorter clinical onset. These lesions often arise *de novo* in skin and are more common in men than in women, often presenting in middle age and usually on the trunk, head or neck (***Figure 45.38***). They typically appear as blue/black papules, 1–2 cm in diameter, and because they lack the horizontal growth phase they tend to be sharply demarcated. Up to 5% are amelanotic.

Figure 45.37 Superficial spreading melanoma (courtesy of St John's Institute for Dermatology, London, UK).

Alexander Breslow, 1928–1980, pathologist, George Washington University, Washington, DC, USA, first reported in 1970 that the prognosis depends upon the thickness of the tumour.

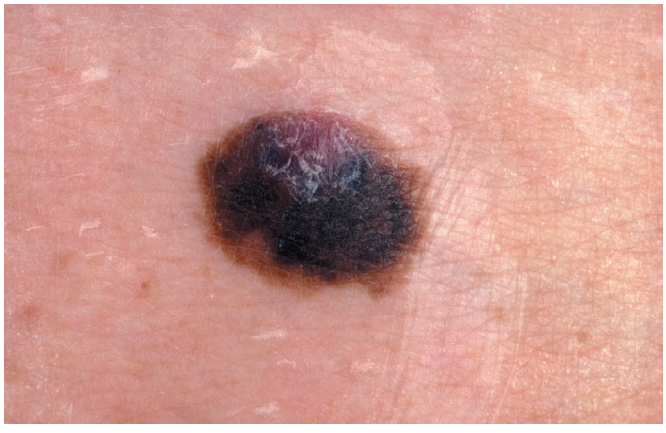

Figure 45.38 Nodular melanoma (courtesy of St John's Institute for Dermatology, London, UK).

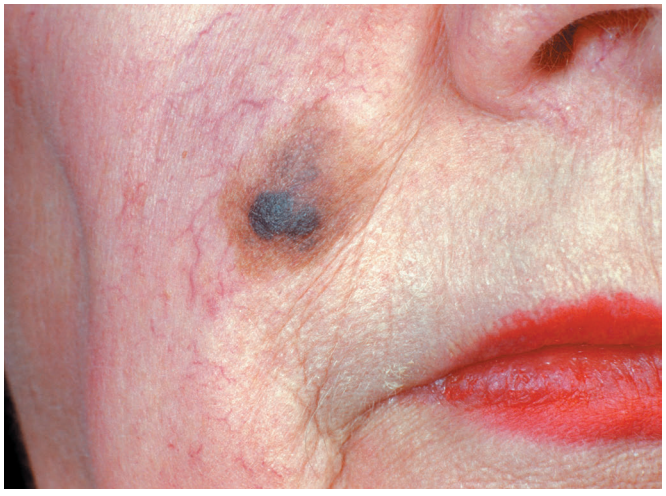

Figure 45.39 Lentigo maligna melanoma (courtesy of St John's Institute for Dermatology, London, UK).

Lentigo maligna melanoma. LMM was previously also known as Hutchinson's melanotic freckle. This variant presents as a slow-growing, variegated brown macule on the face, neck or hands of the elderly (***Figure 45.39***). They are positively correlated with prolonged, intense sun exposure and affect women more than men. They account for between 5% and 10% of malignant melanomas.

LMMs are thought to have less metastatic potential than other variants as they take longer to enter a vertical growth phase. Nonetheless, when they have entered the vertical growth phase their metastatic potential is the same as any other melanoma.

Acral lentiginous melanoma (ALM). ALM affects the soles and palms. It is rare in white-skinned individuals (2–8% of malignant melanoma) but more common in Afro-Caribbean, Hispanic and Asian populations (35–60%). It usually presents as a flat, irregular macule in later life; 25% are amelanotic and may mimic a fungal infection or pyogenic granuloma.

Malignant melanomas under the fingernail are usually SSM rather than ALM. For finger- or toenail lesions it is vital to biopsy the nail matrix rather than just the pigment on the nail plate. A classical feature of a subungual melanoma is Hutchinson's sign: nail fold pigmentation that widens progressively to produce a triangular pigmented macule with associated nail dystrophy. The differential diagnosis is 'benign racial melanonychia', which produces a linear dark streak under a nail in a dark-skinned individual. Malignancy is unlikely if the nail fold is uninvolved (***Figure 45.40***).

Miscellaneous

- Amelanotic melanoma may present as a flesh-coloured skin lesion; as a metastasis from an unknown skin primary; or in the gastrointestinal tract, with obstruction or intussusception.

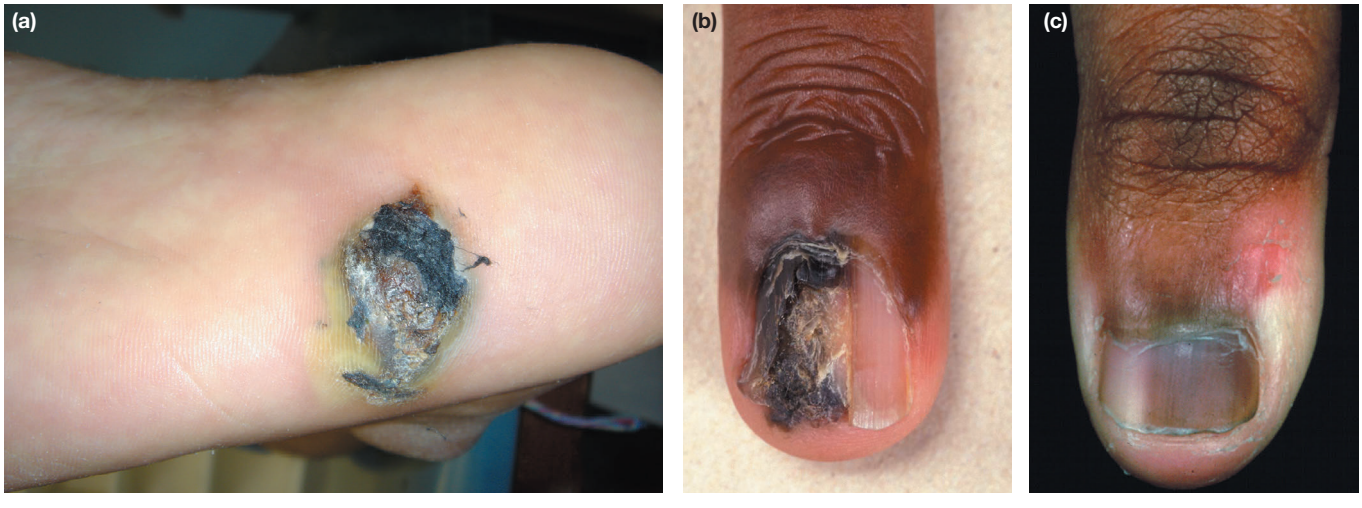

Figure 45.40 (a) Acral lentiginous melanoma on the sole of the foot. **(b)** Subungual melanoma – probably a superficial spreading melanoma. Note the swelling proximal to the nailfold. **(c)** Benign racial melanonychia. (**(a)** courtesy of Mr AR Greenbaum; **(b, c)** courtesy of St John's Institute for Dermatology, London, UK.)

Sir Jonathan Hutchinson, 1828–1913, surgeon, St Bartholomew's Hospital, London, UK.

- Desmoplastic melanoma is mostly found on the head and neck region. It has a propensity for perineural infiltration and often recurs locally if not widely excised. It may be amelanotic clinically.

Summary box 45.5

Macroscopic features in naevi suggestive of malignant melanoma

- Change in size
- Shape
- Colour
- Thickness (elevation/nodularity or ulceration)
- Satellite lesions (pigment spreading into surrounding area)
- Tingling/itching/serosanguineous discharge (usually late signs)

Microscopic

Malignant change occurs in the melanocytes in the basal epidermis, while *in situ* atypical melanocytes are limited to the dermoepidermal junction and show no evidence of dermal involvement. During the horizontal growth phase, cells spread along the dermoepidermal junction; although they may breach the dermis, their migration is predominantly radial. During the vertical growth phase, the dermis may be invaded. The greater the depth of invasion, the greater the metastatic potential of the tumour.

Management

History and clinical examination should be directed at discovering the primary lesion and identification of local, regional or distant spread.

An excision biopsy with a 2- to 3-mm margin of skin and a cuff of subdermal fat is acceptable. Incision biopsy is occasionally indicated: for instance, in large lesions on the face where an excision biopsy of the whole lesion would be disfiguring.

In experienced hands, observation and review every 2 months may avoid biopsies in equivocal cases, but serial clinical and dermoscopic photography by a clinician with expertise in dermoscopy is mandatory when observation is chosen, rather than excision biopsy for definitive histopathological diagnosis. Dermoscopy coupled to computers with learning capability may soon outperform clinicians in melanoma diagnosis to the point where screening becomes much easier.

Biopsy and pathological examination provide the first step towards staging melanoma. The Breslow thickness of a melanoma (measured to the nearest 0.1 mm from the granular layer to the base of the tumour) is the most important prognostic indicator in the absence of lymph node metastases. The American Joint Committee on Cancer (AJCC) staging system takes lymph node involvement, distant metastases and evidence-based prognostic factors into account; these can then be used to guide optimum care and inclusion in research studies for adjuvant or other treatments where applicable.

The detail of the AJCC melanoma staging system has become too specialised for the ambit of this text; most specialists look up its detail as they assign a stage to a patient (***Table 45.2***).

Investigations

Guidelines for staging are controversial. The author suggests that investigations should be directed towards detecting occult disease, so as to upstage patients and treat them accurately and appropriately, the only cure for malignant melanoma currently being appropriate surgery. Thus, offering SNB to patients with T2a disease and greater is critical and investigations for T3a disease and greater should be directed to individual clinical presentation.

Local treatment

The treatment for melanoma is surgery. Lentigo maligna (melanoma *in situ*) should be excised completely in most clinical situations because of the risk of it entering the vertical growth phase to become LMM. A complete excision requires no further treatment.

For melanoma *in situ* a wide excision of 5 mm is sufficient; for melanoma <1 mm deep, a 1-cm margin is sufficient; and for deeper lesions, a 2-cm only margin is recommended, as there is no evidence that wider margins make a difference.

Regional lymph nodes

The likelihood of metastatic spread to regional lymph nodes is proportional to the Breslow thickness of the melanoma. Management of regional lymph nodes has been a contentious topic for well over a century. Some advocated simultaneous elective lymph node clearance at the time of wide excision of the primary melanoma. Others favoured a therapeutic lymphadenectomy if regional metastases became clinically evident. Ideally, one would like to be able to select for treatment those patients with the highest risk of metastatic spread. SNB, an investigation based on the fact that lymphatic metastases proceed in an orderly fashion and can be predicted by mapping the lymphatic drainage from a primary tumour to the first or 'sentinel' node in the regional lymphatic basin, offered that potential, but prospective controlled studies have shown no survival benefit from lymphadenectomy after positive SNB involving micrometastasis <0.2 mm in a single node. This may be because most patients have been treated by removing the sentinel node, which was the only node involved at that stage.

However, completion lymphadenectomy after positive SNB remains, on current evidence, the optimum method for regional control, if patients accept the morbidity associated with regional lymphadenectomy.

Adjuvant therapy

When mutation locks BRAF protein signalling to 'on', it affects the mitogen-activated protein kinase (MAPK) cellular pathway, promoting initiation, malignant transformation, tumour progression and metastasis in the 50% of malignant melanomas with BRAF V600 mutations. Targeted therapy in stage IV melanoma using dabrafenib or vemurafenib, which block BRAF action, has shown promising results with metastatic melanoma. Trametinib has a different action on the MAPK pathway: stopping cell growth and promoting apoptosis. Combined use with dabrafenib to counter acquired tumour resistance via MAPK pathway reactivation shows promising results in stage IV disease. Also, the selective immune

TABLE 45.2 Summary of the American Joint Committee on Cancer melanoma staging, 8th edition.

Primary tumour		Regional nodes		Distant metastases
		N0 No node involvement		
T1 <1.0 mm	a: <0.8 mm, no ulceration b: 0.8–1.0 mm, no ulceration; or <1.0 mm with ulceration	N1 1 node	a: Micrometastasis (no MSI) b: Macrometastasis (no MSI) c: MSI present	M1a Skin, subcutaneous or distant lymph node metastases (normal serum LDH levels)
T2 1.01–2.0 mm	a: No ulceration b: With ulceration	N2 2 or 3 nodes	a: Micrometastasis (no MSI) b: Macrometastasis (no MSI) c: MSI present	M1b Lung metastases (normal serum LDH levels)
T3 2.01–4.0 mm	a: No ulceration b: With ulceration	N3	a: Micrometastasis, >3 nodes (no MSI) b: Micrometastasis, >3 nodes or matted or 1 clinical node (no MSI) c: >1 clinical or occult node with MSI present	M1c All other visceral metastases or any distant metastases with elevated serum LDH levels
T4 >4 mm	a: No ulceration b: With ulceration			M1d Brain metastases
Clinical staging of melanoma				
Stage 0: Tis, N0, M0 Stage Ia: T1a, N0, M0 Stage Ib: T1b or T2a, N0, M0		Stage IIa: T2b or T3a, N0, M0 Stage IIb: T3b or T4a, N0, M0 Stage IIc: T4b, N0, M0		Stage III: any T, >N1, M0 Stage IV: any T, any N1, M1

LDH, lactate dehydrogenase; MSI denotes the presence of satellite lesions, in-transit lesions or local recurrence.

checkpoint inhibitors ipilimumab and nivolumab demonstrate benefit in metastatic or unresectable melanoma.

Over the last 5 years, five randomised prospective trials of adjuvant therapy have reported findings in the treatment of patients with stage II to IV disease. While all five trials showed a significant improvement in relapse-free survival, only two of the trials were mature enough to report on overall survival.

Prognosis

The Breslow thickness of the primary tumour offers the best correlation with survival in stage I disease. The higher the mitotic index, the poorer the prognosis of the primary tumour. This has greater significance than the presence or absence of ulceration.

The presence of lymph node metastases is the single most important prognostic index in melanoma, outweighing both tumour and host factors. The number of affected nodes and the presence of extranodal extension are also significant outcome predictors. Once regional nodes are clinically involved, 70–85% of patients will have occult distant metastases.

Merkel cell (dermal mechanoreceptor) tumour

This is an aggressive malignant tumour of Merkel cells and usually affects the elderly. It is four times more common in women than in men (***Figure 45.41***). Treatment is with wide local excision, aiming for a 25- to 30-mm margin, followed by radiotherapy.

VASCULAR LESIONS

Congenital: haemangiomata and vascular malformations

These can be subclassified biologically into vascular tumours or vascular malformations based on their endothelial characteristics, or radiologically into haemangiomata, vascular and lymphatic malformations based on their vascular dynamics.

Haemangiomata

These are benign endothelial tumours that affect three girls for every boy. Thirty per cent have a herald patch at birth, which then grows rapidly in the first year of life and slowly involutes over several years, with 70% having resolved by 7 years of age. Large haemangiomata can trap platelets, leading to thrombocytopenia (Kasabach–Merritt syndrome).

Vascular malformations

Vascular malformations affect boys and girls equally and are associated with numerous syndromes. They are invariably

Haig H Kasabach, 1898–1943, radiologist, Presbyterian Hospital, New York, NY, USA.
Katharine K Merritt, 1886–1986, pediatrician, Babies Hospital, Columbia University College of Physicians and Surgeons, New York, NY, USA. Kasabach and Merritt described the condition as a joint paper in 1940.

Figure 45.41 Merkel cell tumour (courtesy of St John's Institute for Dermatology, London, UK).

present at birth but may be missed if deep to the skin. Vascular malformations subsequently grow in proportion to the child's growth (rather than in response to sepsis or hormonal stimulation). Stasis can lead to a localised, consumptive coagulopathy in large venous malformations. Low-flow malformations may cause skeletal hypoplasia, while high-flow malformations can cause hypertrophy.

Common vascular birthmarks

Salmon patch

A salmon patch is a vascular malformation that presents as a pinkish macule, usually at the nape of neck (***Figure 45.42***). It is caused by an area of persistent fetal dermal circulation that usually disappears at 1 year.

Capillary haemangioma (strawberry naevus)

This is the commonest 'birthmark', occurring most frequently on the head and neck (***Figure 45.43***). Ninety per cent are present at birth; as a consequence of intravascular thrombosis, fibrosis and mast cell infiltration, 10% resolve each subsequent year, with 70% resolved by 7 years old.

White skin is affected most commonly and girls are affected three times more than boys.

Capillary vascular malformations ('port-wine' stains)

Capillary vascular malformations ('port-wine stains' [PWSs]) are 20 times less common than capillary haemangiomata and result from defective maturation of the cutaneous sympathetic innervation during embryogenesis, leading to localised intradermal capillary vasodilatation (***Figure 45.44***). They appear at birth as flat, smooth, intensely purple-stained areas, most frequently on the head and neck, often within the maxillary and mandibular dermatomes of the trigeminal nerve.

Treatment with intense pulsed light and pulsed-dye laser is successful. PWSs may be associated with various syndromes.

Figure 45.43 Capillary haemangioma (courtesy of St John's Institute for Dermatology, London, UK).

Acquired

Campbell de Morgan spots

These are arteriovenous fistulae at the dermal capillary level in sun-exposed skin of older patients (***Figure 45.45***).

Campbell Greig de Morgan, 1811–1876, surgeon, Middlesex Hospital, London, UK. First to propose that cancer started locally and then spread first to lymph nodes and beyond.

Figure 45.44 'Port-wine' stain (courtesy of St John's Institute for Dermatology, London, UK).

Figure 45.45 Campbell de Morgan spot (courtesy of Mr AR Greenbaum).

Spider naevi

These are angiomata that appear (and may disappear) spontaneously at puberty or in two-thirds of pregnant women, usually disappearing in the puerperium (***Figure 45.46***). Spider naevi are also associated with chronic liver disease. They can be treated with intense pulsed light or pulsed-dye laser.

Pyogenic granuloma

These share many histological characteristics of haemangiomata and are probably a subtype thereof (***Figure 45.47***). Most are small (0.5–1.5 cm), raised, pedunculated, soft, red nodular lesions showing superficial ulceration and a tendency to bleed after trivial trauma. They should be excised with a minimal margin.

Glomus tumour

This arises from a subcutaneous arteriovenous shunt (Sucquet–Hoyer canals), especially in the corium of the nail bed. Typically,

Figure 45.46 Spider naevus (courtesy of St John's Institute for Dermatology, London, UK).

Figure 45.47 Pyogenic granuloma (courtesy of St John's Institute for Dermatology, London, UK).

it is a small, purple nodule measuring a few millimetres in size, which is disproportionately painful in response to insignificant stimuli, including cold exposure (***Figure 45.48***). Subungual varieties may be invisible causes of paroxysmal digital pain.

Angiosarcoma ('malignant angioendothelioma')

A rare, highly malignant tumour arising from the endothelial cells (***Figure 45.49***). The lymphangiosarcoma variant arises from lymphatic endothelium and can develop in lymphoedematous tissue, particularly an extremity. Proliferation is rapid with early systemic spread.

JP Sucquet, 1840–1870, anatomist, Paris, France.
Heinrich Hoyer, 1834–1907, Professor of Histology, Embryology and Anatomy, Central Medical School, The Polish University, Warsaw, Poland.

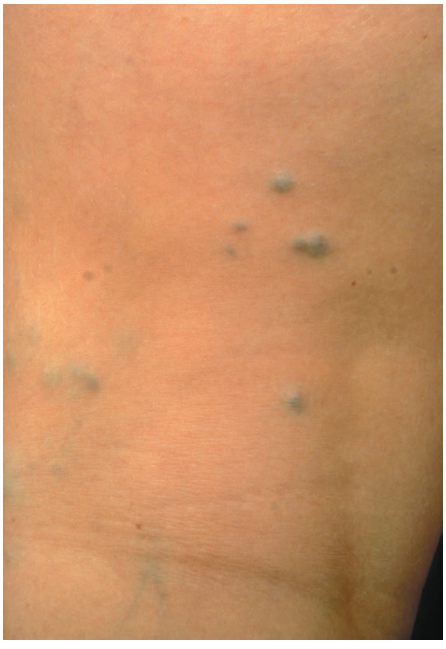

Figure 45.48 Glomus tumour (courtesy of St John's Institute for Dermatology, London, UK).

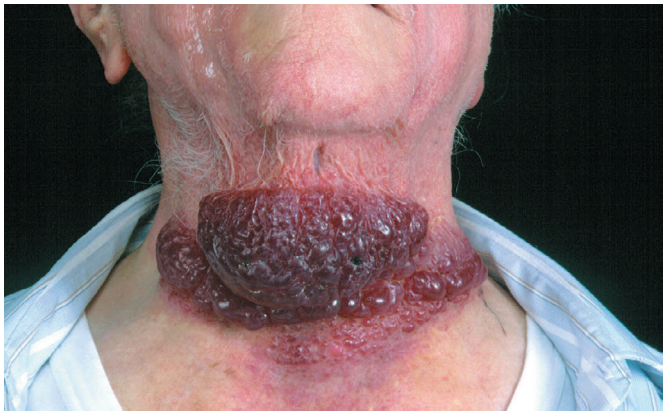

Figure 45.49 Angiosarcoma (courtesy of St John's Institute for Dermatology, London, UK).

Figure 45.50 Kaposi's sarcoma (courtesy of St John's Institute for Dermatology, London, UK).

Kaposi's sarcoma

Kaposi's sarcoma is a malignant, proliferative tumour of vascular endothelial cells, which was first described in elderly Jewish men but is now most commonly associated with immune compromise after transplantation or HIV infection (***Figure 45.50***). There appears to be a causal link with infection by human herpesvirus 8. Kaposi's sarcoma usually starts as a red-brown, indurated, plaque-like skin lesion that becomes nodular and then ulcerates. Treatment is with radiotherapy.

WOUNDS

Congenital

Cutis aplasia congenita

This is a rare condition characterised by the congenital absence of epidermis, dermis and, in some cases, subcutaneous tissues, with underlying bony defects in 20%. Treatment depends on the severity of the presentation, but usually involves plastic surgery.

Parry–Romberg disease (linear morphoea)

A rare variant of scleroderma affecting up to 3:100 000 children. It is linked to certain HLA subtypes and to a family history of autoimmune disease. It is three times more common in females and often develops after an external physical trigger, such as friction or trauma.

Parry–Romberg disease is a progressive, hemifacial atrophy of skin, soft tissue and bone. The disease commonly starts in the late twenties but can present in childhood, when the resulting deformity is worse because it is magnified by differential growth elsewhere. The condition is self-limiting, usually by 5–10 years after onset. Once stable, plastic surgery techniques can be employed alone or in combination to reconstruct an aesthetic contour. Coup de sabre is a variant that affects the cranium and scalp and resembles a 'blow from a sabre'.

Spina bifida

Failure of closure of the caudal neuropore during the fourth week *in utero* results in incomplete development of some or all of the structural elements posterior to the spinal cord. This can occur anywhere, but is commonest in lumbar vertebrae and presents as gross variants: spina bifida occulta, in which there is a bony defect without neural protrusion, and spina bifida cystica, in which there is herniation of the meninges (meningocele), spinal cord (myelocele) or, most commonly,

Moritz Kaposi, 1837–1902, Austrian dermatologist, described xeroderma pigmentosum in 1874. He also described a rare cutaneous sarcoma in Ashkenazi Jews, now more often an AIDS-defining condition.
Caleb Hillier Parry, 1755–1822, physician, The General Hospital, Bath, UK.
Moritz Heinrich Romberg, 1795–1873, neurologist, Director of the University Hospital, Berlin, Germany.

both (meningomyelocele). Management ideally involves a multidisciplinary approach and is directed towards protecting the spinal cord and preventing cerebrospinal fluid contamination, secondary hydrocephalus and meningitis.

Acquired

Pressure sores

These begin with tissue necrosis at a pressure point and develop into a cone-shaped volume of necrotic loss. As many as 10% of acute hospital inpatients will have some degree of pressure sore. The majority affect the elderly and patients with spinal injury or decreased sensibility; 80% of paraplegics will get a pressure sore and 8% die as a result.

The pathogenesis of pressure sores revolves around unrelieved pressure: an increase in local tissue pressure above that of perfusion pressure produces ischaemic necrosis that is directly proportional to the duration and degree of pressure and inversely proportional to the area over which it is applied. Muscle and fat are more susceptible to pressure than skin.

In a patient who has no predisposing factors management is aimed at debridement and repair of the defect, on the assumption that recurrence will not occur once normal function and sensibility returns. In the paraplegic patient, recurrence is likely, so management should involve a multidisciplinary approach. Primary treatment involves relieving pressure (special mattress, nursing care, relief of muscle spasm and contractures), optimising nutrition, correcting anaemia and preventing infection. Surgery involves thorough debridement to promote healing and plastic surgery to reconstruct the defect.

Ulcers

An ulcer is a discontinuity of an epithelial surface. It is characterised by destruction of the surface epithelium and a granulating base. Ulcers can be classified as non-specific, specific and malignant (***Figure 45.51***).

Sinus

A sinus is a blind-ending tract connecting a cavity lined with granulation tissue (often an abscess cavity) to an epithelial surface (***Figure 45.52a***). Sinuses may be congenital or acquired. Congenital sinuses arise from the remnants of persistent embryonic ducts. Acquired sinuses can result from: a retained foreign body (ingrown hair or suture material); chronic infection (tuberculosis, osteomyelitis or actinomycosis); chronic inflammation (Crohn's disease); malignancy; or inadequate surgical drainage of a cavity.

Treatment of a sinus is directed at removing the underlying cause. Biopsies should always be taken from the wall of a sinus to exclude malignancy or specific infection. For specific management of the disease conditions, please refer to the appropriate chapter.

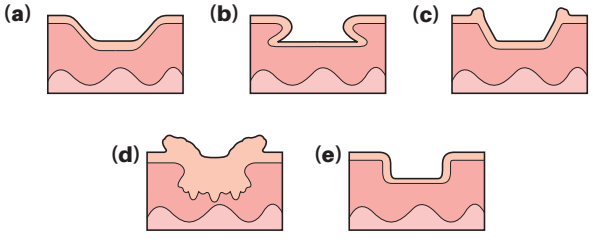

Figure 45.51 Some characteristic shapes of the edges of ulcers. **(a)** Non-specific ulcer: note the shelving edge. **(b)** Tuberculous ulcer: note the undermined edge. **(c)** Basal cell carcinoma (rodent ulcer): note the rolled edge, which may exhibit small blood vessels. **(d)** Epithelioma: note the heaped-up, everted edge and irregular thickened base. **(e)** Syphilis: note the punched-out edge and thin base, which may be covered with a 'wash-leather' slough.

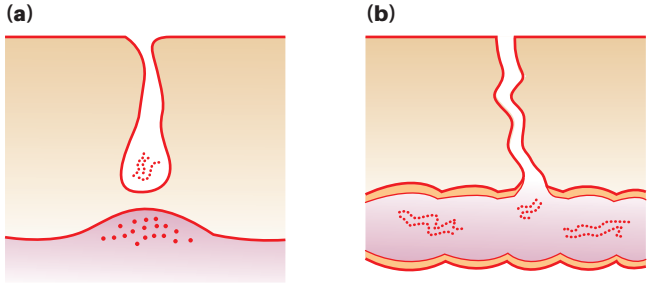

Figure 45.52 A sinus **(a)** and a fistula **(b)**; both usually arise from a preceding abscess. **(a)** This is a blind track, in this case a pilonidal abscess. **(b)** This is a track connecting two epithelium-lined surfaces, in this case a colocutaneous fistula from colon to skin.

Fistula

A fistula is an abnormal communication between two epithelium-lined surfaces (***Figure 45.52b***). This communication or tract is usually lined by granulation tissue, but may become epithelialised in chronic cases. Fistulae may be congenital (e.g. tracheo-oesophageal and branchial fistulae) or acquired (e.g. enterocutaneous complicating Crohn's disease or surgery, or arteriovenous). Management of a fistula is directed at the underlying aetiology (see the appropriate chapters).

PART 6 | Skin, plastic and reconstructive

CHAPTER 46

Burns

Learning objectives

To assess:
- The area and depth of burns in adults and children
- The requirement for transfer to a specialist burn unit

To understand:
- The pathophysiology of burn injury and the systemic effects
- Methods for calculating the rate and quantity of fluids required
- Principal techniques for treating burns and the patient
- The pathophysiology of electrical and chemical burns

INTRODUCTION

The last 50 years have seen great strides made to reduce both morbidity and mortality from burn injuries. The coming years will see a better understanding of the control of physiology along with improvements in reconstruction and rehabilitation and utilising new technology.

A large burn injury will have a significant effect on the patient's family and friends and the patient's future. The importance of multidisciplinary care needs to be stressed for the adequate and effective care of the burn patient.

Incidence and mechanism of burn injury

The incidence of burn injury varies greatly among countries and cultures. In the UK (with its population of 67 million), each year around 175 000 people visit accident and emergency departments with burns; of these, about 13 000 need to be admitted. About 1000 have severe burns requiring fluid resuscitation, and half of the victims are under 16 years of age.

The mechanism of burn injury varies according to age, with the extremes of age being particularly vulnerable. The majority of burns in children are scalds caused by accidents with kettles, pans, hot drinks and bath water. It is important in this age group to screen for non-accidental injury as this may become a safeguarding issue. Delay in presentation, inconsistent history from care givers or an unexpected burn pattern/depth should trigger a concern and further investigation; alerting senior staff is essential. Among adolescent patients, burns are usually caused by experimentation with matches and flammable liquids. In adults flame burns are more frequent, and scald burns and contact burns (such as a fall against a radiator and an inability to extract) become more common with age. Often a burn injury in the elderly is the trigger point at which increasing frailty and inability to self-care are recognised. Again, non-accidental injuries should be screened for in this vulnerable age group. The majority of electrical and chemical injuries occur in adults and are frequently associated with occupation. Cold and radiation are rarer thermal injuries. Associated conditions in adults, such as mental disease (attempted suicide or assault), epilepsy and alcohol or drug abuse, are underlying factors in as many as 80% of patients with burns admitted to hospital in some populations.

Summary box 46.1

Screening for non-accidental burn injury
- Delay in presentation, perceived lack of concern by the care giver
- Inconsistency with the history of the burn and the burn pattern/depth
- Other unexplained injuries such as bruises/fractures
- Frequent hospital attendances

Burn prevention

Legislation, health promotion and appliance design have reduced the incidence of burns: regulations regarding flame-retardant clothes and furniture; the promotion of smoke alarms; the design of cookers and gas fires; the almost universal use of cordless kettles; and the education of parents to set their hot water thermostat to 60°C all play their part. Recent campaigns have included highlighting the dangers of leaving hot hair straighteners near children and the slogan 'hot water burns like fire' in relation to the danger of scald injuries.

Summary box 46.2

Prevention of burns

A significant proportion of burns can be prevented by:
- Implementing good health and safety regulations
- Educating the public
- Introducing effective legislation

THE PATHOPHYSIOLOGY OF BURN INJURY TO THE SKIN

Burns cause a multisystem injury, but by far the most common organ affected is the skin. An understanding of the function and the structure of the skin is essential when assessing and treating a burn injury (see ***Chapter 45***).

Summary box 46.3

Functions of the skin

- Waterproofing and protection from ultraviolet light
- Immune response
- Thermoregulation
- Vitamin D production
- Facilitates movement, sensation and cosmesis

INJURY TO THE AIRWAY AND LUNGS

Burns can also damage the airway and lungs, with life-threatening consequences. Inhalation injury of hot, smoked-filled air has three components, each of which can present alone or in any combination. They are: upper airway injury, lower airway injury (true smoke inhalation) and metabolic poisoning. Airway injuries occur when the face and neck are burned; the significance of being trapped in an enclosed space (burning room or car) cannot be underestimated.

Summary box 46.4

Warning signs of burns to the respiratory system

- Burns around the face and neck, blistering inside the mouth
- A history of being trapped in an enclosed space
- Change to/hoarseness of voice
- Stridor
- Singeing of facial and nasal hair

Metabolic poisoning

Incomplete combustion of carbonaceous materials may produce carbon monoxide, and burning of nitrogen-containing polymers releases hydrogen cyanide. Carbon monoxide poisoning is the most common immediate cause of death from fire. It is an odourless, colourless gas that binds with erythrocyte haemoglobin approximately 250 times more avidly than oxygen. Carboxyhaemoglobin is inactive in oxygen transport and impairs oxygen delivery at the tissue level. Additionally, it competes with, and inhibits, oxygen binding to cytochrome oxidase. This disrupts aerobic metabolism and decreases the capacity for cellular respiration. The treatment for carbon monoxide poisoning is early recognition and therapy with high-flow, high-concentration oxygen. Cyanide combines with trivalent iron in the mitochondrial cytochrome A3 complex, inhibiting electron transport and cellular respiration.

Mechanical block on rib movement

Full-thickness burned skin loses its elasticity, becoming stiff and leathery in appearance. This, combined with subcutaneous oedema, can physically stop rib expansion when the burn extends across the chest, compromising respiratory function.

Summary box 46.5

Dangers of smoke, hot gas or steam inhalation

- Inhaled hot gases can cause supraglottic airway burns and laryngeal oedema
- Inhaled steam can cause subglottic burns and loss of respiratory epithelium
- Inhaled smoke particles can cause chemical pneumonitis and respiratory failure
- Inhaled poisons, such as carbon monoxide, can cause metabolic poisoning
- Full-thickness burns to the chest can cause mechanical blockage to rib movement

INFLAMMATION AND CIRCULATORY CHANGES

The circulatory changes initiated by a burn injury are complex and multifactorial, originating from both the actual injury of burned skin (eschar) and the inflammatory cascade. It is governed by a complex series of events. The release of neuropeptides and the activation of complement are initiated by the stimulation of pain fibres and the alteration of proteins by heat. The activation of Hageman factor initiates a number of protease-driven cascades, altering the arachidonic acid, thrombin and kallikrein pathways. Fluid is lost from capillaries and oedema formation occurs.

Summary box 46.6

The shock reaction after burns

- Burns produce an inflammatory reaction
- This leads to vastly increased vascular permeability
- Water, solutes and proteins move from the intra- to the extravascular space
- The volume of fluid lost is directly proportional to the area of the burn
- Above 15% of surface area, the loss of fluid produces shock requiring resuscitation

OTHER LIFE-THREATENING EVENTS WITH MAJOR BURNS

The immune system and infection

The inflammatory changes caused by the burn have an effect on the patient's immune system. Cell-mediated immunity is significantly reduced in large burns, leaving them more

John Hageman was a 37-year-old railroad brakeman, in whom this factor deficiency was discovered by Dr Oscar Ratnoff in 1955.

susceptible to bacterial and fungal infections. There are many potential sources of infection, primarily from the burn wound and from the lung if this is injured, but also from any central venous lines, tracheostomies or urinary catheters present.

Changes to the intestine

The inflammatory stimulus and shock can cause microvascular damage and ischaemia to the gut mucosa. This reduces gut motility and can prevent the absorption of food. Failure of enteral feeding in a patient with a large burn is a life-threatening complication. This process also increases the translocation of gut bacteria, which can become an important source of infection in large burns. Gut mucosal swelling, gastric stasis and peritoneal oedema can also cause abdominal compartment syndrome, which splints the diaphragm and increases the airway pressures needed for respiration.

Danger to peripheral circulation

In full-thickness burns, the collagen fibres are coagulated. The normal elasticity of the skin is lost. A circumferential full-thickness burn to a limb acts as a tourniquet as the limb swells. If untreated, this will progress to limb-threatening ischaemia.

Summary box 46.7

Other complications of burns

- Infection from the burn site, lungs, gut, lines and catheters
- Malabsorption from the gut
- Circumferential burns may compromise circulation to a limb

IMMEDIATE CARE OF THE BURN PATIENT

Prehospital care

Good prehospital care is essential in ensuring rapid assessment and transfer. The key principles are:

- **Ensure rescuer safety**. This is particularly important in the case of electrical and chemical injuries and building fires.
- **Stop the burning process**. Stop, drop and roll is a good method of extinguishing fire burning on a person.
- **Check for other injuries**. A standard ABC (airway–breathing–circulation) check followed by a rapid secondary survey will ensure that no other significant injuries are missed. Patients burned in explosions or even escaping from fires can have coexisting fractures or blast pattern injuries.
- **Cool the burn wound**. This provides analgesia and slows the delayed microvascular damage that can occur after a burn injury. Cooling should occur for a minimum of 20 minutes and is effective up to 1 hour after the burn injury. It is a particularly important first aid step in partial-thickness burns, especially scalds. In temperate climates, cooling should be at about 15°C – tepid water – and hypothermia must be avoided, particularly in the extremes of age.
- **Give oxygen**. Anyone involved in a fire in an enclosed space should receive oxygen, especially if there is an altered consciousness level.
- **Elevate**. Sitting a patient up with a burned airway may prove life-saving in the event of a delay in transfer to hospital care. Elevation of burned limbs will reduce swelling and discomfort.
- **Analgesia**. Administration of analgesia prior to or during transfer will alleviate pain.

Hospital care

The principles of managing an acute burn injury follow the advanced trauma life support (ATLS) principles as per any major trauma:

- A, airway control;
- B, breathing and ventilation;
- C, circulation;
- D, disability – neurological status;
- E, exposure with environmental control;
- F, fluid resuscitation.

The possibility of injury additional to the burn must be sought both clinically and from the history, and treated appropriately. The major determinants of severity of any burn injury are the percentage of total body surface area (TBSA) that is burned, the presence of an inhalation injury, the depth of the burn and the age/comorbidities of the patient.

Not all burned patients will need to be admitted to a burns unit, but the main criteria are given in *Table 46.1*.

Summary box 46.8

Major determinants of the outcome of a burn

- Percentage surface area involved
- Depth of burns
- Presence of an inhalational injury
- Age and comorbidities of the patient

TABLE 46.1 The criteria for acute admission to a burns unit.

- Suspected airway or inhalational injury
- Any burn likely to require fluid resuscitation
- Any burn likely to require surgery
- Patients with burns of any significance to the hands, face, feet or perineum
- Patients whose psychiatric or social background makes it inadvisable to send them home
- Any suspicion of non-accidental injury
- Any burn in a patient at the extremes of age
- Any burn with associated potentially serious sequelae, including high-tension electrical burns and concentrated hydrofluoric acid burns

Airway

Summary box 46.9

Recognition of the potentially burned airway

- A history of being trapped in the presence of smoke or hot gases
- Burns on the palate or nasal mucosa, or loss of all the hairs in the nose
- Deep burns around the mouth and neck
- Hoarseness/change in voice

The burned airway creates problems for the patient by swelling and, if not managed proactively, can completely occlude the upper airway. The treatment is to secure the airway with an endotracheal tube until the swelling has subsided, which is usually after about 48 hours (***Figure 46.1***). The indications of laryngeal oedema, such as a change in voice, stridor, anxiety and respiratory difficulty, are very late symptoms. Intubation at this point is often difficult or impossible owing to swelling, so acute cricothyroidotomy equipment must be at hand when intubating patients with a delayed diagnosis of airway burn. Because of this, early intubation of suspected airway burn is the treatment of choice in such patients. The time frame from burn to airway occlusion is usually between 4 and 24 hours, so there is time to make a sensible decision with senior staff and allow an experienced anaesthetist to intubate the patient. Although antidotes exist to some specific components of smoke (carbon monoxide and cyanide), the treatment of smoke inhalation usually involves endotracheal intubation and ventilatory support (sometimes for several weeks).

Summary box 46.10

Initial management of the burned airway

- Early elective intubation is safest
- Delay can make intubation very difficult owing to swelling
- Be ready to perform an emergency cricothyroidotomy if intubation is delayed

Breathing

Inhalational injury

Time is a major factor; anyone trapped in a fire for more than a couple of minutes must be observed for signs of smoke inhalation. Other signs that raise suspicion are the presence of soot in the nose and the oropharynx and a chest radiograph showing patchy consolidation.

The clinical features are a progressive increase in respiratory effort and rate, rising pulse, anxiety and confusion and decreasing oxygen saturation. These symptoms may not be apparent immediately and can take 24 hours to 5 days to develop.

Treatment starts as soon as this injury is suspected and the airway is secure. Physiotherapy, nebulisers and warm humidified oxygen are all useful. The patient's progress should be monitored using the respiratory rate, together with blood gas measurements. If the situation deteriorates, continuous

Figure 46.1 Burns to the face and neck with inhalation injury requiring intubation.

or intermittent positive pressure may be used with a mask or T-piece. In the severest cases, intubation and management in an intensive care unit will be needed. Nebulised heparin can be useful in preventing the formation of the fibrin casts, although heparin requires antithrombin for its efficacy (which is deficient after burn injury) and some providers suggest additional antithrombin administration. The efficacy of inhaled heparin therapy may be enhanced by the simultaneous administration of the mucolytic agent *N*-acetylcysteine. Bronchodilators, such as albuterol, may also be of value, additionally stimulating mucosal repair, demonstrating anti-inflammatory properties and decreasing inflammatory mediators such as histamine, leukotrienes and tumour necrosis factor.

The key, therefore, in the management of inhalational injury is to suspect it from the history, institute early management and observe carefully for deterioration.

Thermal burn injury to the lower airway

These rare injuries can occur with steam injuries. The management is supportive and the same as that for an inhalational injury.

Metabolic poisoning

Any history of a fire within an enclosed space and any history of altered consciousness are important clues to metabolic poisoning. Blood gases must be measured immediately if poisoning is a possibility. Carboxyhaemoglobin levels raised above 10% must be treated with high inspired oxygen for 24 hours to speed its displacement from haemoglobin. Metabolic acidosis is a feature of many forms of poisoning. Modern treatment of cyanide poisoning involves the intravenous administration of vitamin B12 (hydroxycobalamin), which interacts with cyanide to form cyanocobalamin, which is water soluble and excreted in the urine. Once again the key to diagnosis is the history and blood gas measurement will confirm the diagnosis.

Mechanical block to breathing

Any mechanical block to breathing from the eschar of a significant full-thickness burn on the chest wall is obvious from

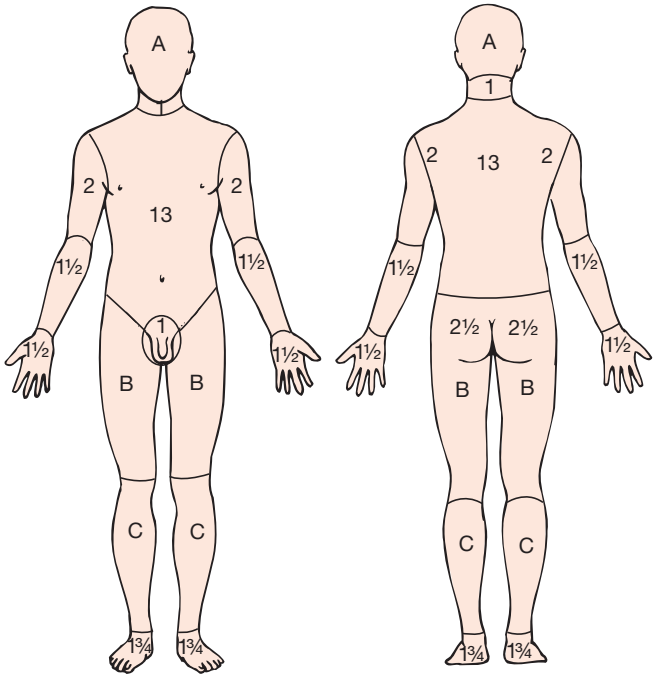
the examination. There will also be carbon dioxide retention and high inspiratory pressures if the patient is ventilated. The treatment is to make some scoring cuts through the burned skin to allow the chest to expand (escharotomy).

ASSESSMENT OF THE BURN WOUND

Assessing size

The defining feature of any burn referral and usually the first question to seek clarification is 'What is the size of the burn?'

From this simple question the burn team can establish the correct method of transfer and the resources needed to appropriately manage the patient with burn on arrival.



The standard method of estimating burn size is to use percentage body surface area. As per the Emergency Management of Severe Burns (EMSB) the distal wrist crease to fingertips of an adult patient's hand is approximately 1% TBSA (1.25%), due to the inherent error in measurement this is useful for small burns of up to 10% TBSA. An estimation of burn size (greater than 15% in an adult; 10% in extremes of age) will also determine whether fluid resuscitation is required.

A useful aide-memoire in the prehospital and emergency setting is the Wallace rule of nines. In this schematic each body part is assigned a burn percentage: each upper limb is 9%, head is 9%, lower limbs are 18% each, posterior torso and buttocks is 18% and the anterior torso 18% (chest 9% and abdomen 9%). The remaining 1% is assigned to the genitalia. The rule of nines has been in established clinical practice for 70 years but it is not without drawbacks. In terms of accuracy there is a tendency to overestimate burn size, and in the obese patient the proportion of surface area of the arms and head decreases as the surface area of the torso and legs increase. A modification of 5% for the arms, 20% for the legs and 50% for the torso has been suggested but is not widely used. However, the rule of nines is an excellent means to quickly and reliably assess the size of a burn in an emergency setting, providing the clinician is aware of the limitations; it is not suitable for children under 10 years of age.

On arrival at a burns unit, the standard formatting for assessment and documentation is the Lund and Browder chart (***Figure 46.2***). Developed in 1942 following a mass casualty burn event at a nightclub in Boston, MA, USA, the chart is a schematic representation of the anterior and posterior body. It further subdivides body areas and allows for differentiation of burn depth by shading.

The Lund and Browder chart can be completed at multiple points during a burn admission to document changes in burn size/depth and can also be used as an adjunct to surgical notes, when skin graft donor sites and grafted areas can be shaded.

In an increasingly digital era, it is worth noting the easy availability of burn management apps that are readily compatible with smart phones. These invariably involve shading a pictorial representation of the body, which then calculates a burn size. Additional features include adding age and weight to allow automatic estimation of fluid resuscitation requirements.

Relative percentage of area affected by growth

Age in years	0	1	5	10	15	Adult
A Head	9	8	6	5	4	3
B Thigh	2	3	4	4	4	4
C Leg	2	2	3	3	3	3

Figure 46.2 Modified Lund and Browder table and diagram.

Burn size calculation: children

The body proportions of children necessitate adjustment of the above-mentioned scales. An infant's head is proportionally larger than an adult's and this adjustment is represented on the modified Lund and Browder chart for children, where at birth the head represents 18% and the lower limbs 13.5% each. For each year 1% is subtracted from the head, with 0.5% being added to each lower limb until the age of 10, when the body proportions are roughly equivalent to those of an adult.

Summary box 46.11

Assessing the area of a burn

- The patient's hand is 1% TBSA, and is a useful guide in small burns
- The Lund and Browder chart is useful in larger burns
- The 'rule of nines' is adequate for a first approximation only

Alexander Burns Wallace, 1906–1974, Scottish plastic surgeon and founding member of the British Association of Plastic Surgeons.
Charles C Lund, 1895–1972, American surgeon, Boston City Hospital, Boston, MA, USA.
Newton C Browder, 1893–1969, American surgeon, Boston City Hospital, Boston, MA, USA. Lund and Browder developed the chart based on their experiences in treating over 300 burn patients injured in a fire in Boston in 1942.

Assessing depth from the history

The first indication of burn depth comes from the history (*Table 46.2*). The burning of human skin is temperature and time dependent. It takes 6 hours for skin maintained at 44°C to suffer irreversible changes, but a surface temperature of 70°C for 1 second is all that is needed to produce epidermal destruction. Taking an example of hot water at 65°C: exposure for 45 seconds will produce a full-thickness burn; for 15 seconds a deep partial-thickness burn; and for 7 seconds a superficial partial-thickness burn (*Figure 46.3*).

TABLE 46.2 Causes of burns and their likely depth.

Cause of burn	Probable depth of burn
Scald	Superficial, but with deep dermal patches in the absence of good first aid. Will be deep in a young infant or the elderly
Fat burns	Deep dermal to full thickness
Flame burns	Mixed deep dermal and full thickness
Alkali burns, including cement	Often deep dermal or full thickness
Acid burns	Weak concentrations superficial; strong concentrations deep dermal
Electrical contact burn	Full thickness

Summary box 46.12

Assessing the depth of a burn

- The history is important: temperature, time and burning material
- Superficial burns have capillary filling
- Deep partial-thickness burns do not blanch, but have some sensation
- Full-thickness burns feel leathery and have no sensation

Superficial partial-thickness burns

The damage in these burns goes no deeper than the papillary dermis. The clinical features are blistering and/or loss of the epidermis. The underlying dermis is pink and moist and will exudate fluid for up to 36 hours post burn injury. The capillary return is clearly visible when blanched. There is little or no fixed capillary staining. Pinprick sensation is normal. Superficial partial-thickness burns heal without residual scarring in 2 weeks (*Figure 46.4*). The treatment is supportive.

Deep partial-thickness burn

These burns involve damage to the deeper parts of the reticular dermis. Clinically, the epidermis is usually lost. The exposed dermis is not as moist as that in a superficial burn. There is often abundant fixed capillary staining, especially if examined after 48 hours. The colour does not blanch with pressure under the examiner's finger. Sensation is reduced, and the patient is unable to distinguish sharp from blunt pressure when examined with a needle. Deep dermal burns take 3 weeks or more to heal without surgery and usually lead to hypertrophic scarring.

Figure 46.3 Photograph showing the difference between superficial dermal (S/D) and deep dermal (D). The burn wound is less than 24 hours old and has been meticulously cleaned in theatre.

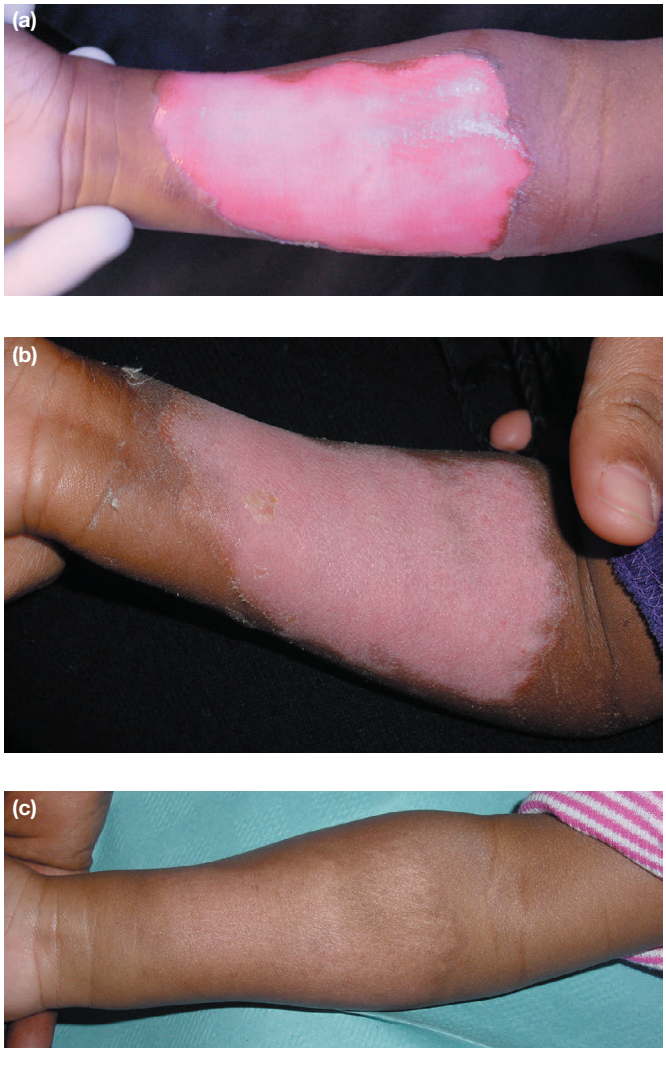


Figure 46.4 **(a)** A superficial partial-thickness scald 24 hours after injury. The dermis is pink and blanches to pressure. **(b)** At 2 weeks, the wound is healed but lacks pigment. **(c)** At 3 months, the pigment is returning.

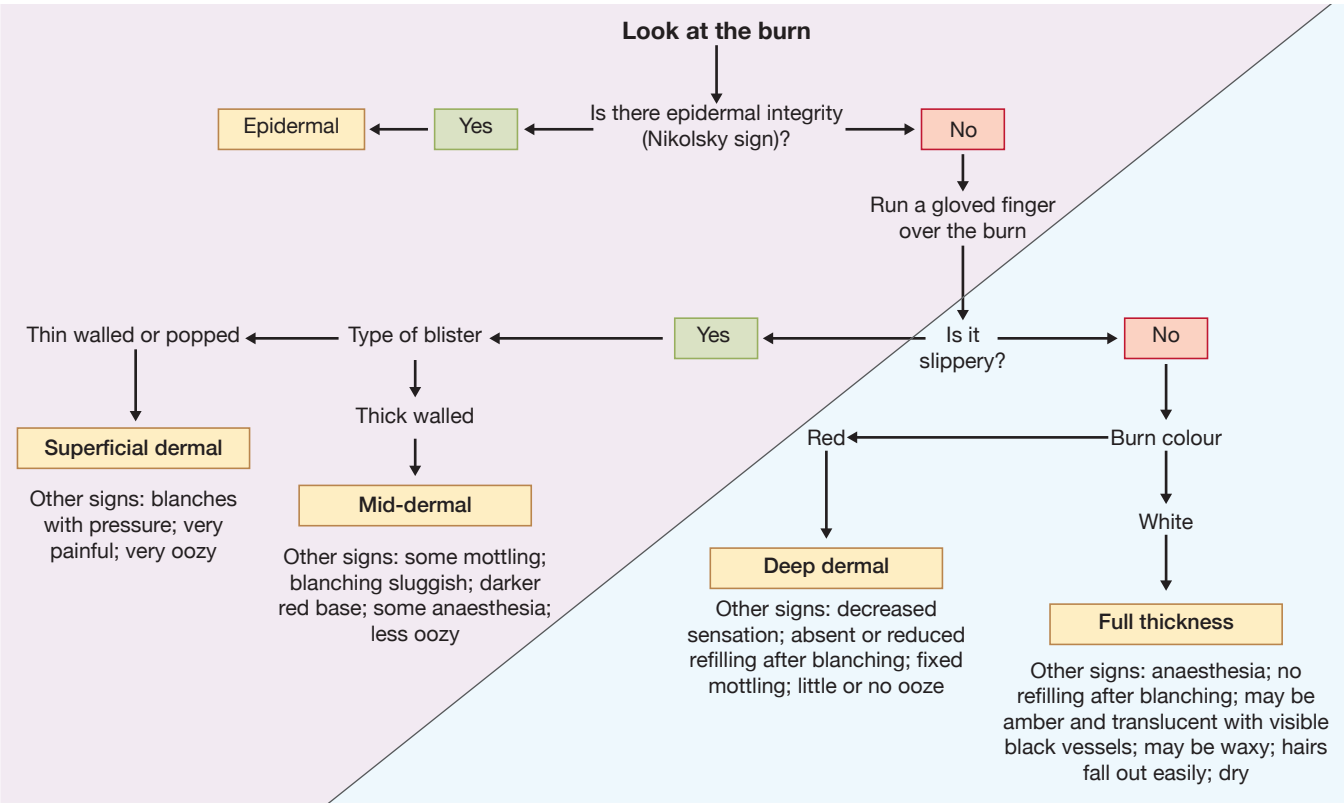

Figure 46.5 Protocol for assessing depth of burn. The Nikolsky sign refers to detachment of the epidermis from the dermis when lateral pressure is applied to the skin.

Full-thickness burns

The whole of the dermis is destroyed in these burns. Clinically, they have a hard, leathery feel. The appearance can vary from that similar to the patient's normal skin to charred black, depending upon the intensity of the heat. There is no capillary return. Often, thrombosed vessels can be seen under the skin. These burns are completely anaesthetic – a needle can be stuck deep into the dermis without any pain or bleeding.

Concept of two burn depths

In treatment terms, there are two burn depths. There are those burns which, with optimal support and good wound management, are superficial enough to heal spontaneously and quickly (within 14 days), leaving an excellent functional and cosmetic result, defined in this chapter as group A. Group B includes those burns that are sufficiently deep to undergo prolonged healing by secondary intention. This process takes weeks or months and involves the degradation and separation of the eschar (burned tissue), the formation of granulation tissue and the process of wound contraction. The course of healing by secondary intention *must* be aborted and replaced as closely as possible by a process of primary intention healing with direct closure, skin graft and skin substitutes.

Figure 46.5 is a pictorial representation of this with burns in the pink section to the left of the line belonging to group A and burns in the blue section to the right to group B.

FLUID RESUSCITATION

As the understanding of 'fluid shifts' developed, the introduction of fluid resuscitation guidelines greatly improved the survival rates for patients with large burns. Standard guidelines and formulae are taught to emergency department and first-responder personnel. Resuscitation fluid should commence from time of burn injury and any delay in commencement must be caught up.

Intravenous resuscitation is appropriate for any adult with a burn greater than 15% TBSA and any child with a burn greater than 10% TBSA. Extremes of age require extra care: for children, additional maintenance fluid is required; in the elderly, judicious monitoring is necessary owing to concurrent comorbidities and the inherent physiology of ageing.

Depending on resources available, the commencement of intravenous fluid resuscitation approaches 30% TBSA in some countries. If oral resuscitation is necessary then additional salt solutions (such as Dioralyte) are required as hyponatraemia and water intoxication can be fatal.

There are three variables in the calculation of fluid requirements: the percentage of TBSA burned, the weight of the patient and the rate/type of fluid. Fluid loss is maximum in the first 8 hours and slows by 24–36 hours, by which stage normal fluid replacement is required.

There are three main fluids used in the resuscitation stage: crystalloid (by far the most common), colloid and, in

Pyotr Nikolsky, 1858–1940, Russian dermatologist.

some centres, hypertonic saline. Each resuscitation fluid has advantages and disadvantages.

Crystalloid resuscitation

Hartmann's solution or Ringer's lactate is the most commonly used crystalloid as it most closely replicates the osmolality of plasma. It is considerably less expensive than colloid and can maintain intravascular volume.

The modified Parkland formula is the most commonly used:

$$\text{TBSA\% burn} \times \text{weight (kg)} \times 4 = \text{volume in mL}$$

The first half is given in 8 hours and the second over 16 hours to complete the 24-hour resuscitation time frame.

In children maintenance fluid must also be given. This is normally dextrose–saline given as follows:

- 100 mL/kg for 24 hours for the first 10 kg;
- 50 mL/kg for the next 10 kg;
- 20 mL/kg for 24 hours for each kilogram over 20 kg body weight.

Crystalloid resuscitation requires eight-fold greater volumes than colloid which can result in increased tissue oedema.

Hypertonic saline

Hypertonic saline is used in some centres; it produces hyperosmolality and hypernatraemia, resulting in a reduction in the shift of intracellular water to the extracellular space. Proponents of this resuscitation fluid cite advantages that include less tissue oedema and a resultant decrease in escharotomies and intubations. However, prolonged hypernatraemia without careful monitoring can be problematic and lead to renal dysfunction.

Colloid resuscitation

The most commonly used colloid is human albumin solution. Plasma proteins are responsible for inward oncotic pressure that counteracts the outward capillary hydrostatic pressure. Albumin should be preferably administered after the first 12 hours post burn as the massive fluid shifts drive proteins out of the cells.

The most common colloid-based formula is the Muir and Barclay formula, which estimates the amount of fluid that needs to be infused during the first 36 hours post burn:

- the basic formula is: TBSA% × weight (kg) × 0.5 = one portion;
- six portions are given in total over 36 hours:
  - give one infusion 4 hourly for 12 hours (three portions in total);
  - then one infusion 6 hourly for 12 hours (two portions in total);
  - the final infusion to be given over 12 hours.

The original Muir and Barclay formula utilised fresh-frozen plasma as the colloid of choice. Both albumin and fresh-frozen plasma are maintained in the blood bank and are more expensive; excessive use can cause additional pressure on the renal system.

Monitoring of resuscitation

Although fluid resuscitation has defined guidelines it is critical to understand that the process is dynamic and rigid adherence to protocols should be avoided. The key to monitoring of resuscitation is urine output. Urine output should be between 0.5 and 1.0 mL/kg body weight per hour. If the urine output drops and the patient is showing signs of hypoperfusion (tachycardia, cool peripheries and a high lactate/metabolic acidosis), then a bolus of 10 mL/kg body weight should be given. It is important that patients are not over-resuscitated; urine output in excess of 2 mL/kg body weight per hour should warrant a decrease in infusion.

Other measures of tissue perfusion such as lactate levels can be useful, particularly in larger burns. A persistent raised lactate/metabolic acidosis can indicate a missed systemic toxicity from cyanide or carbon monoxide. Patients with underlying comorbidities, particularly cardiac or renal, will require further intensive monitoring such as central venous pressure measurement in an intensive care setting.

Summary box 46.13

Fluids for resuscitation

- In children with burns over 10% TBSA and adults with burns over 15% TBSA, consider the need for intravenous fluid resuscitation
- If oral fluids are to be used, salt must be added
- Fluids needed can be calculated from a standard formula and start from time of burn
- The key is to monitor urine output

Temperature management

When undergoing burn assessment and fluid resuscitation it is vital that the patient maintains an adequate core temperature. A key function of skin is thermoregulation and in large burns this is severely impacted. Hypothermia is a component of the 'lethal triad of trauma', which includes acidosis and coagulopathy; the combination of all three significantly increases mortality. Measures to counteract hypothermia include infusing warmed fluids, external warmers such as the 'Bair Hugger' and increasing the ambient room temperature in the emergency department/assessment room.

Alexis Frank Hartmann, 1898–1964, pediatrician, St Louis, MO, USA, described the solution; should not be confused with the name of Henri Albert Charles Antoine Hartmann, French surgeon, who described the operation that goes by his name.
Sidney Ringer, 1835–1910, Professor of Clinical Medicine, University College Hospital, London, UK.
Parkland Memorial Hospital, Dallas, TX, USA.
Ian Fraser Kerr Muir, 1921–2008, plastic surgeon, Aberdeen Royal Infirmary, Aberdeen, UK, referred to as 'a gentle giant of plastic surgery'.

TREATING THE BURN WOUND

Group A burns: superficial dermal partial-thickness burns

There are two key concepts for managing partial-thickness burns:

- prevent any factor that may result in the burn 'changing group', predominantly infection;
- control pain, particularly during dressing changes and therapy.

An array of treatment options are used worldwide for the treatment of these wounds, ranging from honey and simple dressings to synthetic biological dressings with porcine collagen or live cultured keratinocytes.

The ideal dressing should be easy to apply, non-painful, pain-reducing, simple to manage and locally available. The crucial factor is to prevent the borderline mid-dermal burns from progressing to deep dermal. Here, the choice of dressing can make the difference between scar and no scar and/or operation and no operation.

If the wound is heavily contaminated as a result of the accident, then it is prudent to clean the wound formally under a general anaesthetic. With more chronic contamination, silver sulphadiazine cream dressing for 2 or 3 days is very effective and can be changed to a dressing that is more efficient at promoting healing after this period.

The simplest method of treating a superficial burn wound is by exposure, but this is usually only suitable for small burns on the face as this method is painful and requires an intensive amount of nursing support. A variation on this theme is to cover the wound with a permeable wound dressing, such as Mefix® or Fixomull®. This allows the wounds to dry but, because it is a covering, it avoids the problems of the wound adhering to sheets and clothes. A similar method of managing these types of burn is to place a Vaseline-impregnated gauze (with or without an antiseptic, such as chlorhexidine) over the wound. An alternative is a fenestrated silicone sheet (e.g. Mepitel®). To provide antibacterial cover Acticoat dressings with silver nanocrystals are also used. They can be left in place for up to 7 days.

More interactive dressings include hydrocolloids and biological dressings. Hydrocolloid dressings need to be changed every 3–5 days. They are particularly useful in mixed-depth burns as the high protease levels under the occlusive dressing aids debridement of the deeper areas of burn. They also provide a moist environment, which is good for epithelialisation. Duoderm® is a hydrocolloid dressing. There is good evidence for its role in burns.

Biosynthetic (e.g. Biobrane®) and natural (e.g. amniotic membranes) dressings also provide good healing environments and do not need to be changed. They are ideal for one-stop management of superficial burns, being easy to apply and comfortable (***Figure 46.6***). However, they will become detached if applied to deep dermal wounds as the eschar needs to separate. They are therefore not as useful in mixed-depth wounds.

Figure 46.6 Treatment of partial-thickness burns with Biobrane. **(a)** Prior to surgical scrubbing and shaving. **(b)** Following surgical debridement and application of Biobrane; note that the Biobrane is adherent to the wound. **(c)** As the burn wound re-epithelialises the Biobrane lifts and can be trimmed at each dressing change. Normally the Biobrane is fully removed by 3 weeks.

Summary box 46.14

Treatment goals for group A burns

- Prevent burn becoming infected
- Use of appropriate dressings
- Manage pain
- Prevent progression to deeper burn (group B burns)

Group B burns: full-thickness and deep dermal burns

The management of the burn wound remains the same, irrespective of the size of the injury. The burn needs to be cleaned, and the size and depth need to be assessed. For full-thickness burns and deep partial-thickness burns an escharotomy may be required. All but the very smallest of full-thickness burns are likely to involve excision. Smaller deep dermal burns of intermittent depth may require 48 hours to declare but will require appropriate dressing management.

Escharotomy

Circumferential full-thickness burns to the limbs and torso require emergency surgery. The burn has a tourniquet-like effect compromising respiration (torso) and peripheral circulation (limbs). The tourniquet effect of this injury is treated by incising the whole length of full-thickness burns (***Table 46.3***).

For the chest this comprises two longitudinal and two horizontal incisions. Performance of chest escharotomy should show evidence of immediate improvement of respiration and, if intubated, the ventilation pressures. For the limbs the escharotomy incision is performed in the midaxial line, avoiding major nerves (***Figure 46.7***). An escharotomy can cause significant blood loss; therefore consider use of cutting diathermy and have appropriate dressings and blood available.

TABLE 46.3 Key features of escharotomy placement.

Upper limb	Midaxial. Anterior to the elbow medially to avoid the ulnar nerve
Hand	Midline in the digits Release muscle compartments if tight Best done in theatre
Lower limb	Midaxial. Posterior to the ankle medially to avoid the long saphenous vein and anterior to the head of the fibula to avoid the common peroneal nerve
Chest	Down the chest lateral to the nipples, across the chest below the clavicle and across the chest at the level of the xiphisternum
General rules	Extend the wound beyond the deep burn Diathermy any significant bleeding vessels Apply haemostatic dressing and elevate the limb postoperatively

Surgical treatment

Early versus staged full-thickness burn excision

Opinion varies on the timing of burn eschar excision. Early total burn excision refers to excision of the entire burn on arrival at the burns unit or as soon as logistically possible. Once the patient is cleared of trauma in the emergency department, the airway is secure and intravenous access and monitoring achieved, then the decision is whether to take the patient straight to theatre for burn wound debridement/escharectomy or to transfer the patient to the intensive care unit.

The advantage of early burn excision is to exploit the time period or 'window' before the overwhelming systemic response to the burn reaches a crescendo.

The 'anaesthetic' window refers to the effect of the burn on the airway – an upper airway burn can be bypassed by endotracheal intubation but a lower airway burn inhalational injury can cause chemical pneumonitis that may progress to acute respiratory distress syndrome. This usually becomes problematic after 48 hours; therefore, it is prudent to exploit this window and perform the burn excision during the time prior to lung injury decompensation.

The 'haemodynamic' window refers to the progressive inflammatory vasodilation and potential coagulopathy. This leads to an increasing resistance to vasoconstrictor agents in tumescence fluids with the potential for blood loss and need for blood transfusion which can drive further immunocompromise. Excising a full-thickness burn early, prior to these changes, can result in less blood loss. Additionally removing the eschar, which plays a role in driving the fluid shifts, will result in less oedema and lower fluid requirements.

Finally the 'bacterial' window is also important. Excising a full-thickness burn, which is essentially necrotic material, can help to reduce the bacterial load, thereby reducing the risk of infection.

Summary box 46.15

Early burn excision

- Removal of eschar reduces bacterial load
- Majority of surgery is performed prior to substantial lung injury
- Allows effective use of vasoconstrictive fluids
- Requires adequate theatre, staff and facilities

Early burn excision is dependent on the appropriate staff, resources, equipment and time. When these are not readily available a staged approach is also utilised. This involves serial debridement of the burn over several operating sessions in the first week of the burn. Proponents of this approach advocate shorter operating times and reducing the requirements for blood transfusions.

This technique also relies on managing the remaining burn eschar until excision to prevent bacterial colonisation and to prepare for surgery. This is achieved by using silver-based dressing/creams containing antibacterial properties including *Pseudomonas aeruginosa* and methicillin-resistant *Staphylococcus aureus*.

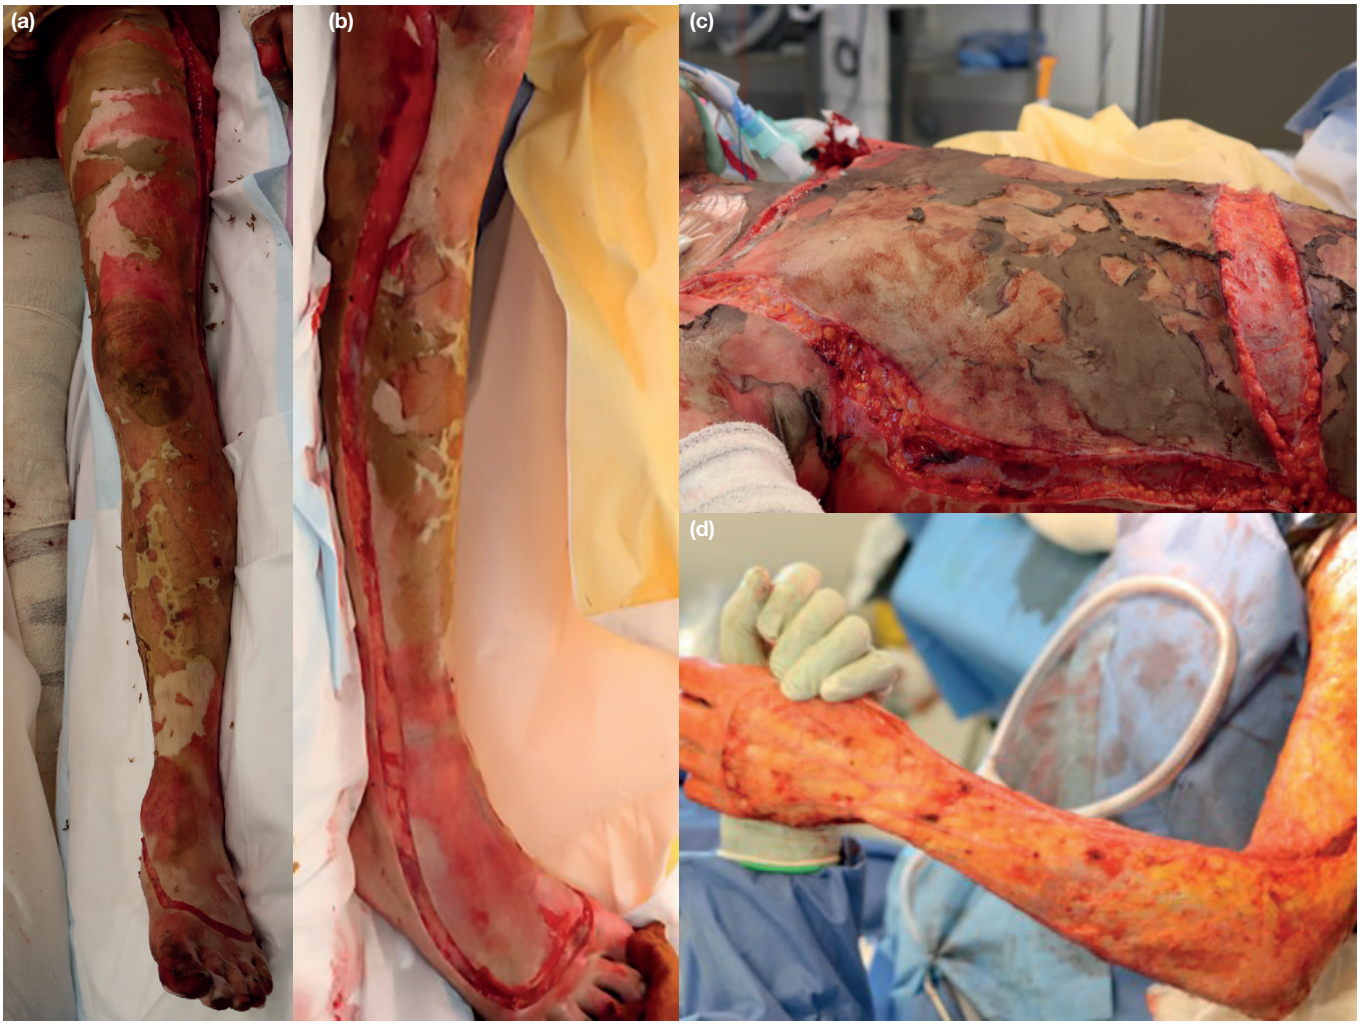

Figure 46.7 (a-d) Extensive full-thickness burns at first operation. Note the placement of the escharotomies on the chest and the lower limb. The leg had an escharectomy followed by escharotomy.

Dressings with silver that are commonly used include:

- **Silver sulphadiazine cream (1%)**. This gives broad-spectrum prophylaxis against bacterial colonisation.
- **Mafenide acetate cream**. This is popular, especially in the USA, but is painful to apply and has been associated with metabolic acidosis. It is usually used as a 5% topical solution.
- **Silver sulphadiazine and cerium nitrate**. This induces a sterile eschar on the burned skin and has been shown in certain instances, especially in elderly patients, to reduce some of the cell-mediated immunosuppression that occurs in burns. It is especially useful in treating burns when a conservative treatment option has been chosen. Cerium nitrate has also been shown to boost cell-mediated immunity in these patients.
- **Acticoat**. This is a nanocrystalline silver barrier dressing and is an effective antimicrobial against a broad spectrum of bacteria.

The keystone of burns surgery is control, regardless of whether early or staged excision is the plan. A wide-bore cannula should be used and the patient's blood pressure must be monitored adequately. If a large excision is considered, then an arterial line (to monitor blood pressure) and central venous access are needed. The anaesthetist also needs measurements and control of the acid–base balance, clotting time and haemoglobin levels. The core temperature of the patient must not drop below 36°C, otherwise clotting irregularities will be compounded.

For most burn excisions, subcutaneous injection of a dilute solution of adrenaline (epinephrine) 1:1 000 000 or 1:500 000 and tourniquet control are important for controlling blood loss. The tumescence fluid is injected into both the burn eschar and the donor sites.

Summary box 46.16

Staged burn excision

- Shorter but more frequent surgical theatre trips
- Will require managing/binding of remaining eschar

Figure 46.8 Full-thickness leg burns. **(a)** Marked for excision; **(b)** excised to healthy tissue fat/fascia; **(c)** skin graft at first dressing change.

In deep dermal burns, tangential excision is performed until punctate bleeding is observed and the dermis can be seen to be free of any small, thrombosed vessels. A topical solution of 1:500 000 adrenaline also helps to reduce bleeding, as does the application of the skin graft/substitute.

Full-thickness burns require full-thickness excision of the skin. In certain circumstances, it is appropriate to go down to the fascia but, in most cases, the burn excision is down to viable fat. Wherever possible, a skin graft/substitute should be applied immediately (***Figure 46.8***).

Graft application results in primary intention healing in the plane deep to the graft and at the horizontal margins where it meets unburned skin. Split-skin grafts can be left as intact sheets where function (over major joints, hands and fingers, anterior neck), cosmesis (face, dorsum of hands) and future growth (developing breasts) are particularly important; however, skin grafts can never result in 'normal' skin. Because we rely on spontaneous healing of the site from which they are harvested (the donor site), they are thin, consisting of the epidermis and a variable proportion of the superficial dermis.

They are often harvested as between 0.30 and 0.38 mm and thus their application into the burn wound creates a donor defect. Because the dermal component of the graft is thin, graft contraction post application occurs. The thinner the harvested graft, the greater the degree of contraction and the greater the degree of functional disability and dysaesthesia. The donor site is painful; as a result techniques must be employed to reduce the size of the donor site in an effort to minimise the pain. These include meshing the graft by putting it through a series of blades mounted on rollers that create offset incisions in the skin graft in horizontal lines. Post meshing, these cuts can be pulled open, extending the graft and resulting in diamond-shaped defects. This has the advantage of reducing the likelihood of graft haematoma/seroma. Meshing can be performed at different ratios. As the ratio increases, the size of the diamond defect increases.

Since the burn bed after excision of deep burn does not contain tissue capable of healing without modification of the bed structure, a small bleb of granulation tissue forms in these diamonds between the graft struts. This results in a characteristic mesh pattern scarring. The wider the mesh, the worse the appearance.

Although the epidermis can regenerate, the dermis removed from the donor site during skin graft harvesting can only repair and a layer of scar forms under the new epidermis at the donor site, which is 'thinner' than it was pre-harvest. The donor site is thus not an infinite resource. With serial graft harvesting, the donor site can become so deep a wound that adnexal structures are no longer present and the donor site has to heal by secondary intention, or receive a skin graft itself. In very extensive burns, where the burn size exceeds donor site availability, the surgeon tends to rely on higher ratios (1:3, up to 1:9) and harvests the skin grafts more thinly. This allows the donor site to heal more rapidly, facilitating earlier reharvest when serial grafting is required.

Postoperative management of these patients requires careful evaluation of fluid balance and levels of haemoglobin. The outer dressings will require attention and regular changing because of expected fluid leaks.

Physiotherapy and splints are important in maintaining range of movement and reducing joint contracture. Elevation of the appropriate limbs is important. The hand must be splinted in a position of function after grafting, although the graft needs to be applied in the position of maximal stretch. Knees are best splinted in extension; axillae in abduction. Supervised movement by the physiotherapists, usually under direct vision of any affected joints, should begin after about 5 days.

Summary box 46.17

Burn excision surgery

- Deep dermal burns need tangential shaving and split-skin grafting or dermal substitutes
- All but the smallest full-thickness burns need surgery
- The anaesthetist needs to be ready for significant blood loss
- Tumescence fluid and topical adrenaline reduces bleeding
- All burnt tissue needs to be excised
- Stable cover, permanent or temporary, should be applied

The use of skin grafts and skin substitutes

Until very recently, the early definitive closure of wounds proved problematic when full-thickness burns exceeded 50% of the TBSA. The mainstay of burn wound repair has been the split-skin autograft and, at >50% TBSA, the burn area exceeds the donor site area. A number of manoeuvres have been established to facilitate coverage of these wounds by grafting, all of which are utilised in patients with the most extensive burn wounds. Techniques include serial episodes of grafting surgery, harvesting very thin autografts (to allow more rapid re-epithelialisation of the donor sites, facilitating earlier reharvest and allowing a greater number of harvests from the same donor site), widely meshing the grafts or using a Meek–Wall technique (Meek, Humeca, Enschede, the Netherlands). This latter technique involves using small pieces of graft, placed in a specialised holder on a cork board and run through a series of blades perpendicular to each other, to create small squares of graft each 3 mm × 3 mm. Once cut, the holding platform can be pulled apart (to differing distances – the 'mesh ratio'), separating the tiny grafts. Although 'fiddly' and laborious, this technique minimises graft wastage, since even small pieces of graft can be meshed in this way.

The use of cadaver skin to cover the non-grafted wounds pending donor site re-epithelialisation and 'reharvestability' gained popularity in the late twentieth century as issues of consent and techniques for harvest and storage (banking) were refined. The use of cadaver skin has a number of limitations. Skin banks are frequently short, or devoid, of stock. Its presence 'passively' temporises the wound, 'buying time' but not improving the wound bed, merely allowing undirected granulation. It cannot be used unless the patient is pathologically immune suppressed.

The dermal matrix strategy, pioneered by Jack Burke, sought to redress some of these issues. In producing a 'scaffold' to allow autologous tissue in-growth and establish a 'neodermis' ('active' temporisation), he improved the outcome of the thin, meshed skin graft. A completely synthetic, biodegradable polymer version has also been developed (***Figures 46.9 and 46.10***).

Figure 46.9 Day 28 post-full-thickness burns treated with early skin grafting using the Biodegradable Temporising Matrix (BTM) (a synthetic, biodegradable polyurethane dermal matrix) on the arms and immediate skin graft to chest.

Cicero Parker Meek, 1914–1979, general practitioner with a special interest in the treatment of burn patients, Aiken County Hospital, SC, USA.
SP Wall Jr, engineer, developed the Meek–Wall microdermatome with CP Meek in 1963.
John F Burke, 1922–2011, medical researcher, Harvard University, Boston, MA, USA, widely known for his co-invention of synthetic skin substitute in 1981 with Ioannis V Yannas.

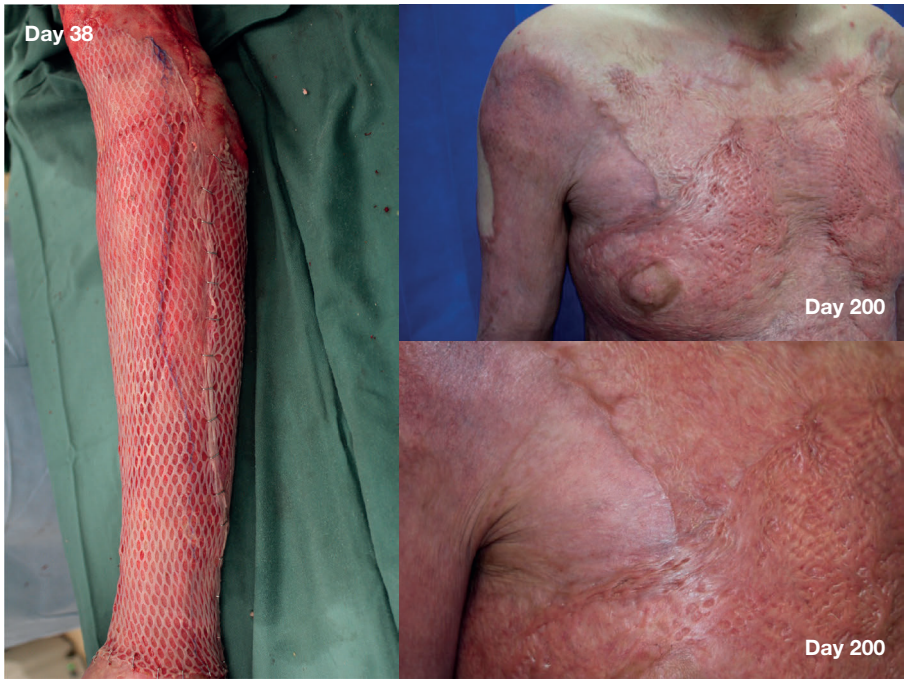

Figure 46.10 Day 38 picture shows a mesh graft on the arm after the dermal substitute has been removed. The day 200 pictures show the difference in scar outcome between the immediate skin graft to the chest and a Biodegradable Temporising Matrix (BTM) and skin graft to the arm and axilla. Both skin grafts had the same mesh ratio.

ADDITIONAL ASPECTS OF TREATING THE BURNED PATIENT

Analgesia

Acute

Analgesia is a vital part of burns management. Small burns, especially superficial burns, respond well to simple oral analgesia, paracetamol and non-steroidal anti-inflammatory drugs. Topical cooling is especially soothing. Large burns require intravenous opiates for the initial management; intramuscular administration should be avoided as uptake is variable.

Subacute

In patients with large burns, continuous analgesia is required, beginning with infusions and continuing with oral tablets. Powerful, short-acting analgesia should be administered before dressing changes. Administration is guided by anaesthetists, as in the case of general anaesthesia or midazolam and ketamine, or less intensive supervision, as in the case of morphine and nitrous oxide. Early support by colleagues from the pain team is beneficial in controlling pain.

Energy balance and nutrition

Any adult with a burn greater than 15% (10% in children) of TBSA has an increased nutritional requirement. All patients with burns of 20% of TBSA or greater should receive a nasogastric or nasojejunal tube and feeding should start within 6 hours of the injury to reduce gut mucosal damage. The advantage of the nasojejunal tube is that fasting is not necessary for trips to theatre. A number of different formulae are available to calculate the energy requirements of patients. This should be managed by a specialist dietician as part of the multidisciplinary team.

Burn injuries are catabolic in the acute episode. Successful management of the patient's energy balance involves a number of strategies. The catabolic drive continues while the wound remains unhealed and, therefore, rapid excision of the burn and stable coverage of the wound are the most significant factors in reversing this. Obligatory energy utilisation must be reduced to a minimum by keeping the patient warm with good environmental control. The excess energy requirements must be provided for and the nutritional balance monitored by measuring weight and nitrogen balance.

Monitoring and control of infection

Patients with major burns steadily become immunocompromised, having large portals of entry to pathogenic and opportunistic bacteria and fungi via the burn wound. They have compromised local defences in the lungs and gut owing to oedema, and usually have monitoring lines and catheters, which themselves represent portals for infection. Control of infection begins with policies on handwashing and other cross-contamination prevention measures. Bacteriological surveillance of the wound, catheter tips and sputum helps to build a picture of the patient's flora. If there are signs of infection, then further cultures need to be taken and antibiotics started. This is often initially on a best guess basis, hence the usefulness of prior surveillance; close liaison with a microbiologist is essential. In patients with large burns who remain

Figure 46.11 (a) Scar band contracture marked with multiple Z-plasties. **(b)** Release of the scar intraoperatively. **(c)** Reorientation of the scar when the Z-plasties are sutured.

catabolic, the core temperature is usually reset by the hypothalamus above 37°C. Significant temperatures are those above 38.5°C, but often other signs of infection are more useful to the clinician. These include significant rise or fall in the white cell count, thrombocytosis, increasing signs of catabolism and decreasing clinical status of the patient.

Nursing care

Burns patients require particularly intensive nursing care. Nurses are the primary effectors of many decisions that directly affect healing. Bandaged hands and joints that are stiff and painful need careful coaxing. Personal hygiene, baths and showers all become time-consuming and painful, but are vital parts of the patient's physiotherapy. Their success or failure has a powerful psychological impact on the patient and his or her family.

Physiotherapy and occupational therapy

All burns cause swelling, especially burns to the hands. Elevation, splintage and exercise reduce swelling and improve the final outcome. The physiotherapy needs to be started on day 1, so that the message can be reinforced on a daily basis. As the burn wounds heal scar management and rehabilitation to previous activities of daily living become increasingly important.

Psychological

A major burn is an overwhelming event, outside the normal experience, which stretches the patient's coping ability, suspends the patient's sense of safety and causes post-traumatic reactions. These are normal and usually self-limiting, receding as the patient heals. The features of this intensity of experience are of intrusive reactions, arousal reactions and avoidance reactions. Early intervention with psychology and development of coping strategies is of vital importance.

Delayed reconstruction and scar management

Delayed reconstruction of burn injuries is common for large full-thickness burns. These techniques were pioneered by McIndoe and Gillies. In the early healing period, acute contractures around the eye need particular attention. Eyelids must be grafted at the first sign of difficulty in closing the eyelids, and this must be done before the patient has any symptoms of exposure keratitis. Other areas that require early intervention are any contracture causing significant loss of range of movement of a joint. This is particularly important in the hand and axilla.

An established contracture can be treated in a number of ways. Burn alopecia is best treated with tissue expansion of the unburned hair-bearing skin. Tissue expansion is also a useful technique for isolated burns and other areas with adjacent normal skin. Z-plasty is useful where there is a single band and a transposition flap is useful in wider bands of scarring (*Figure 46.11*). In areas of circumferential or very broad areas of scarring, the only real treatment is incision and replacement with tissue. By far the best tissue for replacement is from either a full-thickness graft, dermal substitute with split-skin graft or vascularised tissue as in a free flap.

Summary box 46.18

Delayed reconstruction of burns

- Eyelids must be treated before exposure keratitis arises
- Transposition flaps and Z-plasties with or without tissue expansion are useful
- Full-thickness grafts and free flaps may be needed for large or difficult areas
- Hypertrophy is treated with pressure garments
- Pharmacological treatment of itch is important

The Guinea Pig Club. Sir Archibald McIndoe, 1900–1960, born in New Zealand, was appointed in 1938 as Consultant Plastic Surgeon to the Royal Air Force. He trained with his cousin, **Sir Harold Delf Gillies**, another internationally reputed plastic surgeon. McIndoe became world famous for his pioneering work on Battle of Britain pilots who were badly burnt. His work on these airmen, who needed several operations, and using his innovative technical and psychological methods, was the start of a lifelong service. The young fighter pilots were therefore referred to as 'guinea pigs' – thus was formed The Guinea Pig Club. McIndoe referred to his patients as 'the boys', who in turn called him 'the boss' or 'the maestro'. To this day, some of the members of the Guinea Pig Club from all over the world still meet on an annual basis in Sussex. McIndoe founded the British Association of Plastic Surgeons (BAPS).

Hypertrophy of many scars will respond to pressure garments. These need to be worn for a period of 6–18 months. Where it is difficult to apply pressure with pressure garments, or with smaller areas of hypertrophy, silicone patches will speed scar maturation, as will intralesional injection of steroid. Itching and dermatitis in burn scar areas are common. Pharmacological treatment of itch is an essential adjunct to therapy.

NON-THERMAL BURN INJURY

Electrical injuries

Electrical injuries are usually divided into low- and high-voltage injuries, the threshold being 1000 V.

Summary box 46.19

Electrical burns

- Low-voltage injuries cause small, localised, deep burns
- They can cause cardiac arrest through pacing interruption without significant direct myocardial damage
- High-voltage injuries damage by flash (external burn) and conduction (internal burn)
- Myocardium may be directly damaged without pacing interruption
- Limbs may need fasciotomies or amputation
- Look for and treat acidosis and myoglobinuria

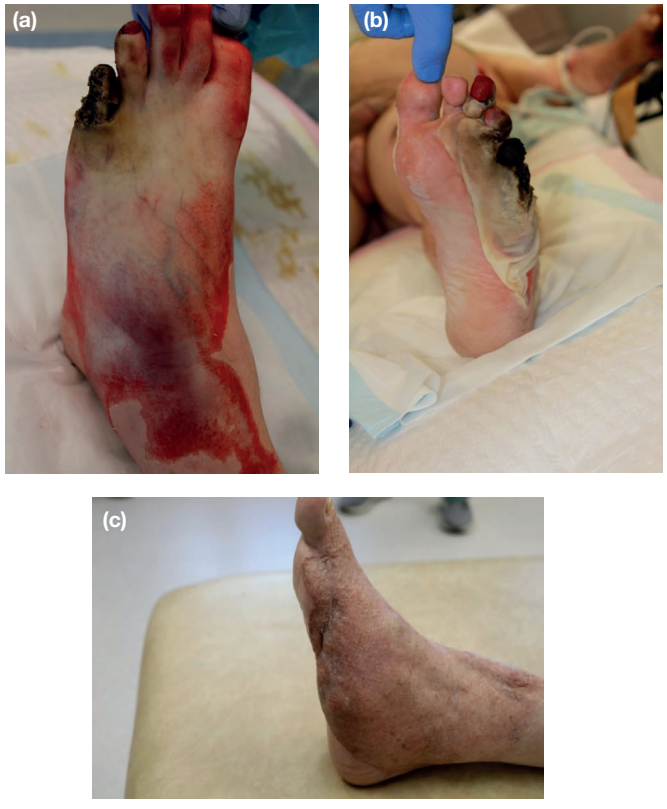

Figure 46.12 (a, b) High-voltage electrical injury resulting in amputation of the lateral three toes and the lateral foot. **(c)** One year post injury after treatment with a dermal substitute (Biodegradable Temporising Matrix [BTM]) and skin grafting.

Low-tension injuries

Low-tension or domestic appliance injuries do not have enough energy to cause destruction to significant amounts of subcutaneous tissues when the current passes through the body. The resistance is too great. The contact point, normally in the fingers, suffers small deep burns; these may cause underlying tendon and nerve damage, but there will be little damage between. The alternating current creates a tetany within the muscles, and thus patients often describe how they were unable to release the device until the power was turned off. The main danger with these injuries is from the alternating current interfering with normal cardiac pacing. This can cause cardiac arrest. The electricity itself does not usually cause significant underlying myocardial damage, so resuscitation, if successful, should be lasting.

High-tension injuries

High-tension electrical injuries (***Figure 46.12***) can be caused by one of three sources of damage: the flash, the flame and the current itself.

When a high-tension line is earthed, enormous energy is released as the current travels from the line to the earth. As the current travels through the air, the air is heated and expands in an explosive manner, which can propel the victim. A flash burn is the contact of superheated air with the skin for a short duration. The flash, however, can go on to ignite the patient's clothes and so cause a normal flame burn.

In accidents with overhead lines, the patient often acts as the conduction rod to earth. In these injuries, there is enough current to cause damage to the subcutaneous tissues and muscles. The entry and exit points are damaged but, importantly, the current can cause huge amounts of subcutaneous damage between these two points. These can be extremely serious injuries.

The damage to the underlying muscles in the affected limb can cause the rapid onset of compartment syndrome requiring urgent fasciotomies. The release of the myoglobin will cause myoglobinuria and subsequent renal dysfunction. Therefore, during the resuscitation of these patients, efforts must be made to maintain a high urine output of up to 2 mL/kg body weight per hour. Severe acidosis is common in large electrical burns and may require fluid and bicarbonate boluses. These patients are also at risk of myocardial damage as a result of direct muscle damage, rather than by interference with cardiac pacing. This gives rise to significant electrocardiogram changes, with raised cardiac enzymes. If there is significant damage, there is rapid onset of heart failure. In the case of a severe injury through a limb, primary amputation is sometimes the most effective management.

Chemical injuries

There are over 70 000 different chemicals in regular use within industry. Occasionally, these cause burns. Ultimately, there

are two aspects to a chemical injury. The first is the physical destruction of the skin and the second is any poisoning caused by systemic absorption.

The initial management of chemical burns is to ascertain whether it is in a solid powder or liquid state. Water irrigation should not be used for solid powders as this will result in further reaction, these substances require removal with forceps. Examples include phosphorous, a component of military devices and elemental sodium, which is occasionally present in laboratory explosions. It is rare that a medical practitioner will encounter these burns. The more common injuries are caused by either acids or alkalis. Alkalis are usually the more destructive and are especially dangerous if they have come into contact with the eyes. After copious lavage, the next step in the management of any chemical injury is to identify the chemical and its concentration and to elucidate whether there is any underlying threat to the patient's life if absorbed systemically.

Summary box 46.20

Chemical burns

- Damage is from corrosion and poisoning
- Copious lavage with water helps in most cases
- Then identify the chemical and assess the risks of absorption

One acid that is a common cause of acid burns is hydrofluoric acid, although generally a weak acid, it chelates calcium and magnesium in tissues. Burns affecting the fingers and caused by dilute acid are relatively common. The initial management is with calcium gluconate gel topically; however, severe burns or burns to large areas of the hand can be subsequently treated with Bier's blocks containing calcium gluconate 10% gel. If the patient has been burnt with a concentration greater than 50%, the threat of hypocalcaemia and subsequent arrhythmias then becomes high, and this is an indication for acute early excision. It is best not to split-skin graft these hydrofluoric acid wounds initially, but to do this at a delayed stage.

Ionising radiation injury

These injuries can be divided into groups depending on whether radiation exposure was to the whole body or localised. The management of localised radiation damage is usually conservative until the true extent of the tissue injury is apparent. Should this damage have caused an ulcer, then excision and coverage with vascularised tissue is required.

Whole-body radiation causes a large number of symptoms and may be fatal. A patient who has suffered whole-body irradiation and has acute desquamation of the skin has received a lethal dose of radiation, which can cause a particularly slow and unpleasant death. Non-lethal radiation has a number of systemic effects related to the gut mucosa and immune system dysfunction. Other than giving iodine tablets, the management of these injuries is supportive.

Summary box 46.21

Radiation burns

- Local burns causing ulceration need excision and vascularised flap cover, usually with free flaps
- Systemic overdose needs supportive treatment

Cold injuries

Cold injuries are principally divided into two types: acute cold injuries from industrial accidents and frostbite.

Exposure to liquid petroleum gas (LPG), liquid nitrogen and other such liquids will cause epidermal and dermal destruction. The tissue is more resistant to cold injury than to heat injury, and the inflammatory reaction is not as marked. The assessment of depth of injury is more difficult, so it is rare to make the decision for surgery early.

Frostbite injuries affect the peripheries in cold climates. The initial treatment is with rapid rewarming in a bath at 42°C. The cold injury produces delayed microvascular damage similar to that of ischaemia–reperfusion injury. The level of damage is difficult to assess, and surgery usually does not play a role in its management, which is conservative, until there is absolute demarcation of the level of injury.

RECENT ADVANCES

Advanced technology, newer drugs and skin substitutes are the major advances in burn care. The next steps will focus on cultured autologous skin incorporating the patient's own keratinocytes and fibroblasts. An intelligent use of these modalities is essential to make an effective case for cost–benefit ratios.

PART 6 | Skin, plastic and reconstructive

CHAPTER 47

Plastic and reconstructive surgery

Learning objectives

To be aware of:
- A variety of plastic surgical techniques used to restore bodily form and function

To know:
- The relevant anatomy and physiology of skin

To understand:
- The different types of skin grafts
- The principles and use of flaps
- The concept of microsurgical reconstructive surgery

WHAT IS RECONSTRUCTIVE PLASTIC SURGERY?

Reconstructive plastic surgery is a surgical specialty that aims to restore form and function. The word *plastic* derives from the ancient Greek *plassein* – to mould or shape. Unlike all other specialties, plastic surgery is not bound by anatomical or functional region. Instead, it involves the use of a wide array of surgical techniques to reconstruct tissues that have been damaged by congenital loss, infection, trauma, cancer or even the process of ageing. Hence the reconstructive plastic surgeon often works in collaboration with other specialists wherever necessary, including head and neck surgeons, oral surgeons, orthopaedic surgeons, ophthalmologists, urologists, paediatric surgeons, gynaecologists, general surgeons and dermatologists. Modern plastic surgery techniques enable clinicians to perform complex surgical procedures that would not have been previously possible, such as major oncological head and neck resections or skeletal fixation of open limb fractures with significant soft-tissue defects.

Since plastic surgery involves the restoration of form, it is necessarily closely related to aesthetic (or cosmetic) surgery, which has gained much attention in the media in recent decades. Many of the surgical techniques, including liposuction, fat grafting, scar management, tissue expansion and flap contouring, are shared between the two specialties. However, plastic surgery also aims to achieve restoration of function. An example would be the use of a free neurotised gracilis muscle transfer from the thigh to the face to restore a smile in facial palsy, or the use of a jejunal free flap to restore swallowing following a pharyngolaryngectomy for squamous cell carcinoma. Indeed, the microsurgical techniques developed to enable tissue transplantation within the same individual and the replantation of severed body parts (i.e. autografts) have, together with the discovery of immunosuppressive agents, heralded the field of composite tissue allotransplantation in the latter half of the twentieth century – including face, hand and abdominal wall transplants (i.e. homografts).

HISTORY

Although the evolution of plastic surgery as a surgical specialty is comparatively recent, with the 'masters' of the First World War years, including Sir Harold Gillies, a New Zealand otolaryngologist working in London, considered to be the founding fathers, its origins hark back to ancient times and were driven by the need to treat burns, congenital deformity and acquired injuries (whether judicial, vindictive or sustained in battle). The 'pre-scientific period' included a description by the pioneering Indian surgeon Sushruta in 600 BCE of numerous facial flaps (including a method to repair the split earlobe), which predated the forehead flap being used for nasal reconstruction by some 400 years. Anatomical understanding improved markedly from the mid-fifteenth century – the 'scientific period' – as human dissection became widely practised and the development of printing allowed anatomical drawings to be reproduced and disseminated. During this period the 'Italian rhinoplasty', which utilised a two-stage brachial flap technique, was popularised by Tagliacozzi. The 'modern period' – from the nineteenth century to the present day – witnessed a detailed appreciation of the anatomy of the cutaneous circulation, although the significance of the early research undertaken by Manchot took almost a century to be fully recognised, such that the random-pattern 'waltzed' tubed

Sir Harold Delf Gillies, 1882–1960, the 'father of plastic surgery', became the first President of the British Association of Plastic Surgeons in 1946.
Sushruta, *c.* 600 BCE, Indian surgeon; his eponymous Samhitá ('compendium') was translated into English in 1907.
Gaspare Tagliacozzi, 1545–1599, Professor of Surgery, University of Bologna, Bologna, Italy.
Carl Herman Manchot, 1866–1932, was born in Switzerland and studied medicine at the University of Strasbourg, Strasbourg, France.

pedicle flap was superseded by axial pattern flaps, including the musculocutaneous latissimus dorsi flap by Tansini (1896). This era of surgical discovery was greatly facilitated by the advent of antisepsis by Semmelweis (1847) and Lister (1883), the discovery of anaesthesia by Morton (1846), antibiotics by Fleming (1928) and immunosuppression by Hench (1949) and Calne (1962).

The past 50 years have seen an explosion in the complexity of microsurgical reconstructive techniques, culminating in vascularised composite tissue transplantation becoming part of routine clinical practice. A timeline of some of the key advances in the history of plastic surgical innovation is given in *Table 47.1*.

SURGICAL ANATOMY OF THE SKIN

Skin is the largest end organ, covering the body's entire external surface. Together with its derivatives, including hair, nails and sweat glands, it forms the integumentary system. The skin serves a number of functions that are critical for survival. It provides a protective barrier against mechanical, thermal and irradiation (ultraviolet) injury and infection. It also plays a role in homeostasis by preventing fluid loss and regulating temperature. As the primary interface with the external environment, it acts as a sensory organ and also produces vitamin D. Hence restoration of the skin is essential even if the underlying structures await delayed reconstruction.

TABLE 47.1 A selection of key advances in the history of plastic surgery innovation.

Year	Surgeon	Nationality	Innovation
c. 1800 BCE	–	Ancient Egypt	Wound care techniques
c. 600 BCE	Sushruta	India	Local flaps for nasal reconstruction
c. 25 CE	Celsus	Rome	Local flaps for lip reconstruction
c. 1000 CE	Al-Zahrawi	Spain	Introduced catgut sutures and developed numerous surgical instruments
c. 1400 CE	Branca	Sicily	Distant (arm) flap for nasal reconstruction
1789	Desault	France	Recognition of the importance of definitive wound debridement
1854	Hamilton	USA	Concept of flap 'delay' with the distant cross-leg flap
1862	Wood	UK	Concept of axial pattern flaps with the pedicled groin flap (*Figure 47.1*)
1889	Manchot	Germany	Cutaneous arterial supply using cadaveric arterial injection studies
1894	Dauriac	France	First description of a pedicled muscle (rectus abdominis) flap
1896	Tansini	Italy	Breast reconstruction using a pedicled musculocutaneous latissimus dorsi flap
1912	Carrel	France	Nobel Prize for the development of vascular anastomosis and its application to organ transplantation
1916–1917	Filatov and Gillies	Russian Empire and UK	Tubed pedicled flaps and concept of 'waltzing'
1954	Murray	USA	Nobel Prize for the first renal transplant between identical twins
1968	Cobbett	UK	Free toe-to-hand transfer
1973	Daniel and Taylor	Australia	Free groin flap to foot
1978	Taylor	Australia	Concept of the 'angiosome'
1979	Yang	China	Free radial forearm ('Chinese') flap
1989	Koshima	Japan	Perforator flaps (*Figure 47.2*)
1998	Dubernard	France	Hand transplant
2004	Chen	Taiwan	Vascularised lymph node transfer
2005	Devauchelle	France	Partial face transplant
2006	Barret	Spain	Full face transplant

Ignaz Philipp Semmelweis, 1818–1865, Professor of Obstetrics, University of Pest, Pest, Hungary.
Joseph Lister, Baron Lister of Lyme Regis, 1827–1912, Professor of Surgery, University of Glasgow, Glasgow, UK.
William Thomas Green Morton, 1819–1868, an American dentist.
Sir Alexander Fleming, 1881–1955, a Scottish microbiologist who discovered penicillin at St Mary's Hospital, London, UK, for which he was jointly awarded the Nobel Prize in 1945.
Philip Showalter Hench, 1986–1965, Professor of Medicine, Mayo Clinic, Rochester, USA, was jointly awarded the Nobel Prize in 1950 for his pioneering work on cortisone.
Sir Roy Yorke Calne, b. 1930, Emeritus Professor of Surgery, University of Cambridge, Cambridge, UK.

Figure 47.1 Pedicled groin flap. Full-thickness burn wounds over the dorsum of multiple digits. The exposed extensor tendons were covered by a pedicled groin flap. The pedicle was divided at 3 weeks and the digits were subsequently separated in stages.

The skin's structure consists of the outer epidermis (ectodermal in origin), the dermis and the inner hypodermis (of mesodermal origin). The deepest layer of the epidermis is the *stratum basale*, where stem cells differentiate into keratinocytes and migrate upwards towards the outermost *stratum corneum*, an acellular layer made of dead keratinocytes acting as a barrier to fluid loss and protection against invasion by microorganisms. The epidermis regenerates from deeper follicular elements such as hair follicles and sweat glands.

The dermis is connected to the epidermis via the basement membrane and consists of the upper papillary layer, composed of loose connective tissue, and a deeper reticular layer, which is thicker and consists of dense connective tissue and collagen fibres. The dermis houses the hair follicles, sweat glands, sensory receptors and blood vessels.

The hypodermis contains the subcutaneous fat as well as skin appendages, including hair follicles, sensory receptors, neurones and blood vessels.

The relative composition of these layers varies depending on the functional requirements of the region concerned. Specialised areas such as hair-bearing scalp skin or glabrous heel skin can be challenging to reconstruct as there are limited donor sites. However, for non-specialised skin, the abdomen and groin make ideal donor sites as they are elastic and thin and, thus, amenable to primary closure.

Blood vessels are found in the dermis and hypodermis and are arranged in a number of plexuses between each anatomical layer (***Figure 47.3***). Ultimately, they all originate from a main feeding or source vessel, via fine perforating vessels ('perforators') either directly or indirectly by traversing through fascia, muscle or bone. This observation gave rise to Taylor's 'angiosome' concept, in which angiosomes refer to three-dimensional blocks of tissue including skin and deeper tissue layers that are supplied by specific source arteries. Thus, any skin or other tissue types can be detached as a 'flap' provided the vessel course from the source vessel to the end organ that is to be transferred is kept intact.

Cutaneous nerves tend to run axially out of the major nerve trunks but are less defined than most perforating blood vessels. It is possible to coapt nerve ends between a cutaneous nerve within a flap and one at the recipient site, so-called 'neurotisation', to regain some sensation in the flap.

WOUND HEALING

There are various ways in which a wound can heal (see ***Chapter 3***). Plastic surgeons can affect the way in which wounds heal. Primary healing, or 'healing by primary intention', occurs when the wound is closed soon after the injury by reapproximating the wound edges. This is typically achieved with sutures, although glue, tape and staples can also be used. Incisions are designed so that they lie along the lines of relaxed

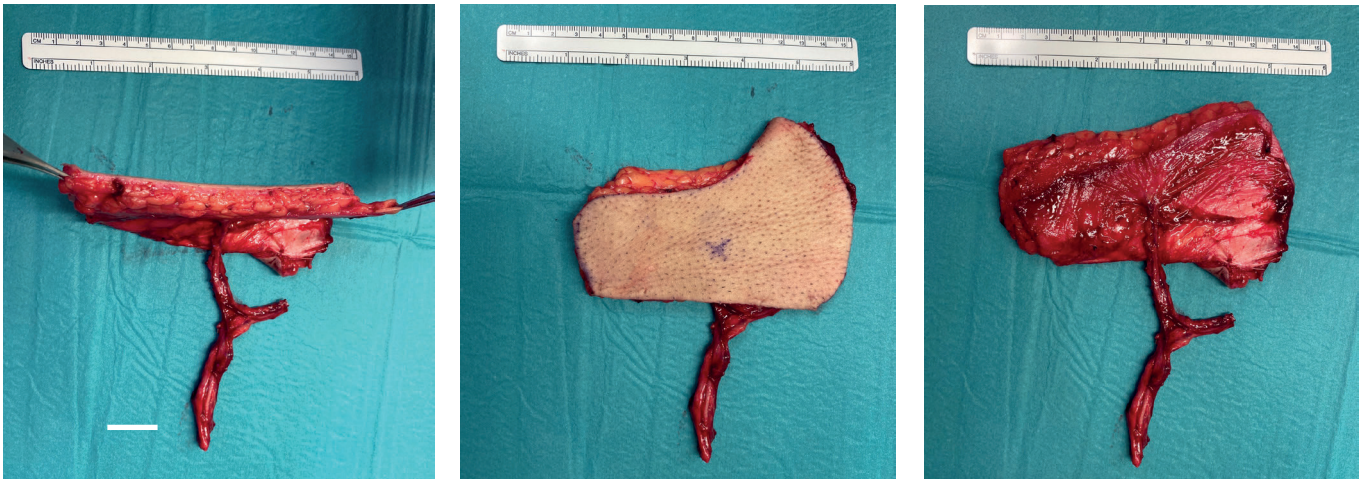

Figure 47.2 Three views of an anterolateral thigh flap on detachment from the donor site prior to anastomosis at the recipient site. Pedicle (arrow) consisting of one perforator artery and two vena comitans.

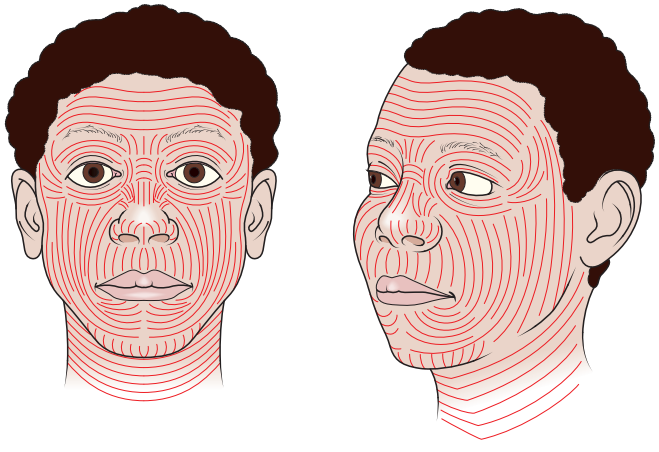

Figure 47.4 Lines of relaxed skin tension.

skin tension to reduce the appearance of the scar, particularly on the face and in areas of tension (***Figure 47.4***). Secondary healing, or 'healing by secondary intention', occurs when the wound is left to heal from its base. The wound is typically kept clean with sterile non-adherent dressings. Over the course of days and weeks, the wound contracts and skin cells migrate across the wound through a process called epithelialisation. Secondary healing is typically employed for wounds that have poor healing potential, such as leg and pressure ulcers, in which surgery risks exacerbating the wound-healing burden.

Every reconstructive procedure depends on the potential for wound healing. Furthermore, much of reconstructive plastic surgery involves the creation of wounds to heal other wounds – hence the aphorism 'rob Peter to pay Paul'. Therefore, the plastic surgeon must consider how to maximise the chances of success and adopt their approach accordingly. For example, in genetic conditions such as Ehlers–Danlos syndrome and epidermolysis bullosa (for which there is currently no cure), the surgeon is required to be less aggressive in their approach as surgical intervention risks creating additional iatrogenic wounds that may fail to optimally heal, thus potentially worsening the patient's situation (Hippocrates: *primum non nocere*; first, do no harm). Systemic comorbidities including diabetes, peripheral vascular disease, renal failure, corticosteroid use and immunodeficiency are significant causes of delayed wound healing and must be addressed preoperatively. For example, diabetic control may be optimised with the help of an endocrinologist, and preoperative angioplasty may augment blood flow in a chronically ischaemic lower limb. Nutrition is essential for wound healing; vitamin and protein deficiencies should be addressed preoperatively with the guidance of a dietician. Smoking is particularly detrimental as it causes vasoconstriction and decreases local oxygen delivery to tissues, thus impairing healing; patients are therefore advised to cease smoking at least 6 weeks prior to elective surgery if possible.

Furthermore, it is crucial to optimise a wound bed to promote healing. For example, the wound may require formal debridement and washout to minimise bacterial colonisation and hence the risk of surgical site infection. Perioperative antibiotics may also be necessary.

ABERRANT HEALING

Scarring can be aberrant owing to a combination of genetic predisposition and environmental factors. The two main types of abnormal scarring are hypertrophic and keloid scars.

Hypertrophic scars are elevated within the borders of the original scar and affect up to 15% of wounds. They tend to occur soon after injury, subsiding over time, and arise in areas of tension, particularly flexor surfaces. They may be successfully

Edward Ehlers, 1863–1937, Professor of Clinical Dermatology, Copenhagen, Denmark.
Henri Alexandre Danlos, 1844–1912, dermatologist, Hôpital St Louis, Paris, France, gave his account of this condition in 1908.
Hippocrates of Kos, *c.* 460–375 BCE, was a physician in Ancient Greece and considered to be the 'father of medicine'.

Figure 47.5 Pyogenic granuloma following a glass laceration to the base of the right middle finger.

treated with topical silicone, intralesional corticosteroid injection, compression therapy or surgical excision.

Keloid scars, by contrast, extend beyond the original wound borders and can be locally destructive; in extreme cases, they are debilitating. They occur more commonly in darker skin types and may arise some months after the injury, most commonly affecting the face, earlobes, deltoid area and presternal region. They are more resistant to treatment and may require repeated excision with adjuvant radiotherapy.

Scars may also be widened, thin and depressed owing to excess tension across the wound. Scars may also be unstable and prone to recurrent ulceration and breakdown; this is most frequently seen at mobile sites (such as overlying major joints or the neck) when healing has been achieved secondarily. These scars can be excised (serially if necessary) or resurfaced with a flap in order to provide more robust coverage.

Wounds that fail to heal properly may become populated with unstable and highly vascular granulation tissue ('over-granulated') that is fragile and prone to intermittent bleeding. These may be treated with topical silver nitrate or corticosteroid or may require formal excision and reconstruction.

A traumatic wound can lead to the development of a pyogenic granuloma. This is a benign proliferation of capillary blood vessels of the skin and presents as a painless red fleshy nodule that grows rapidly over several weeks and bleeds intermittently (***Figure 47.5***). It may be treated topically as per over-granulation tissue but frequently requires surgical excision.

In chronic wounds, such as in pressure sores, burns or osteomyelitis, the chronicity of the inflammatory environment can lead to the development of a Marjolin ulcer. This is a rare but aggressive form of squamous cell carcinoma that has a high propensity for distant metastasis. A low index of suspicion must be observed in chronic wounds that undergo sudden phenotypic change, so early biopsy is advocated.

WOUND DRESSINGS

These are a vital part of wound care and are used to optimise healing. The most suitable dressing is selected based on the type of wound being treated. The 'ideal dressing' should provide a moist environment to facilitate epidermal migration, enable gas exchange between the wound and environment, provide protection against bacterial infection and be non-adherent (to avoid trauma on removal). Furthermore, the dressing should be sterile, non-toxic, non-allergenic and readily available at minimal expense.

One of the most traditional dressings in regular use is gauze (tulle) impregnated with petroleum jelly (e.g. Jelonet®); it is ideal for clean wounds with minimal exudate. Semipermeable foam dressings (e.g. Allevyn®) are suitable for moderately to highly exudating wounds such as leg ulcers. Hydrocolloid dressings (e.g. Duoderm®) contain an inner colloidal layer with an impermeable outer layer and are ideal for moderately exudating wounds such as minor burns. Alginate dressings (e.g. Kaltostat®) are derived from seaweed and contain calcium salts that facilitate haemostasis; they can be used on moderate to heavily exudating wounds such as split-thickness skin graft donor sites. Mepitel® is a non-adherent dressing comprising a perforated silicone sheet that is designed for prolonged applications of up to 2 weeks; it is therefore popular in paediatric wounds. Some dressings contain antimicrobial agents such as ionic silver (e.g. Aquacel Ag®) or povidone iodine (e.g. Inadine®) that may have additional functionality in contaminated wounds.

Negative-pressure wound therapy (e.g. vacuum-assisted closure; VAC®) uses intermittent or continuous topical negative pressure (up to –125 mmHg) through a sealed foam dressing in order to stimulate the formation of granulation tissue, reduce local oedema and tissue exudate and reduce bacterial load. The technique has numerous applications, including as a dressing to secure a skin graft to its recipient bed, temporary coverage of a complex acute wound (e.g. an open abdomen; ***Figure 47.6***) until definitive cover can be achieved or to manage chronic wounds such as pressure ulcers.

RECONSTRUCTIVE TECHNIQUES

These range from the simple, including healing by secondary intention or skin grafting, to the complex, including free tissue transfer or vascularised composite allotransplantation. They also include the use of autologous tissue, allograft material, biocompatible materials such as skin substitutes, internal and external fixators and tissue expanders. Improved understanding of the blood supply to different tissue types including skin has vastly expanded the number of flap options (see below) available to reconstruct different parts of the body. The introduction of the operating microscope has ushered in the era of microsurgical reconstruction that has enabled free tissue transfer and replantation, procedures whereby the blood supply to a flap is detached from the donor site and re-established through vessel anastomosis to local source vessels at the recipient site.

Reconstructive plastic surgery is almost always undertaken to improve healing. Without it, wounds may heal poorly with unacceptable consequences, including chronic or non-healing wounds, unsightly and debilitating scars or the risk of deep infection. A common scenario is a skin defect that is too large

Jean-Nicolas Marjolin, 1780–1850, Professor of External Pathology, Hôtel-Dieu de Paris, Paris, France.

Figure 47.6 Negative-pressure wound therapy to promote wound healing in an open abdomen. The system consists of a non-adherent dressing overlaid by a sponge that is sealed with an airtight membrane and connected to a suction device.

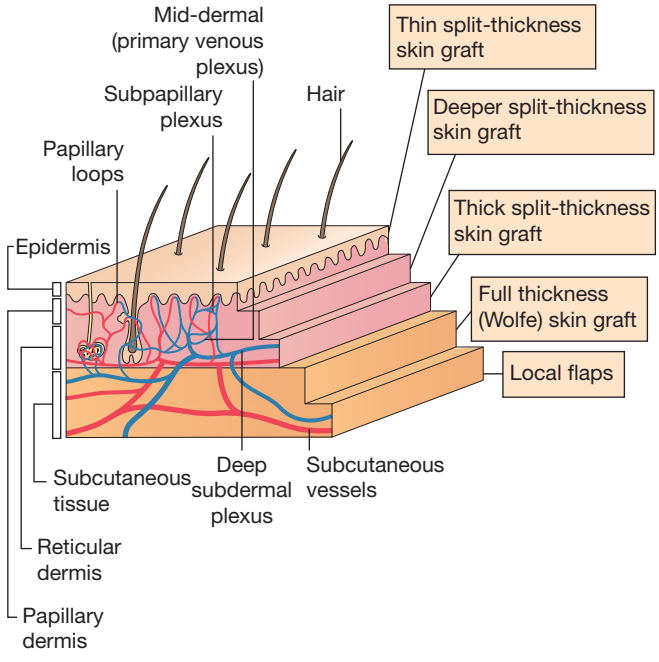

Figure 47.7 Schematic anatomy of the skin and its relationship to harvesting skin grafts (of varying thicknesses) and raising local flaps.

to be closed primarily, thus requiring surgical techniques or adjuncts to achieve wound closure. Several conceptual frameworks exist for the appropriate selection of techniques, including the now obsolete reconstructive ladder which advocates using the simplest methods first, and the patient-centred 'reconstructive elevator'. In essence, the modern patient-centred reconstructive technique employed must be considered in the context of each individual case, including patient factors, available skills, resources and the consequences of success and failure to achieve the best long-term outcome.

In acute burns, for example, split-thickness skin grafting is almost always used to restore skin as soon as possible in order to preserve life. Following facial tumour excision, a local flap is often superior to a skin graft in terms of contour and aesthetics such as skin quality and colour match. For pressure sore reconstruction, a local flap comprising both skin and muscle (for dead-space obliteration) would be more durable than a skin graft or primary closure, both of which would place the scar at the site of greatest pressure. For open lower limb fractures, free tissue transfer is often required as there is a lack of local tissue availability; this option provides healthy vascularised tissues to cover the fracture site (including any orthopaedic metalwork), thus significantly reducing the risk of limb-threatening deep infection or osteomyelitis.

Grafts

Grafts are tissues that are transferred without their blood supply and therefore need to be revascularised through the recipient wound bed. To maximise the success of this procedure, the wound bed must be healthy with a good blood supply such that angiogenesis into the graft tissue can occur. Graft failure occurs most commonly as a result of shear forces disrupting the graft from the wound bed, infection (particularly with group A β-haemolytic *Streptococcus* spp.) and haematoma or seroma formation (which can lift the graft away from the underlying wound bed).

Skin grafts are used to achieve wound closure in situations where the skin defects are too large for primary closure and healing by secondary intention may be inappropriate or lead to an unreasonable delay in complete healing. There are two types of skin grafts, depending on the depth at which they are taken (***Figure 47.7***):

- **Split-thickness skin grafts** consist of epidermis and a variable amount of dermis and are sometimes referred to as Thiersch grafts. They are commonly harvested from the thigh using a dermatome or graft knife to achieve a consistent depth (***Figure 47.8***). It is relatively simple to harvest large areas of skin to reconstruct sizeable defects such as those following a significant burn injury (see ***Chapter 46***). The grafted skin can then be meshed or fenestrated to

Karl Thiersch, 1822–1895, Professor of Surgery, Leipzig University, Leipzig, Germany.

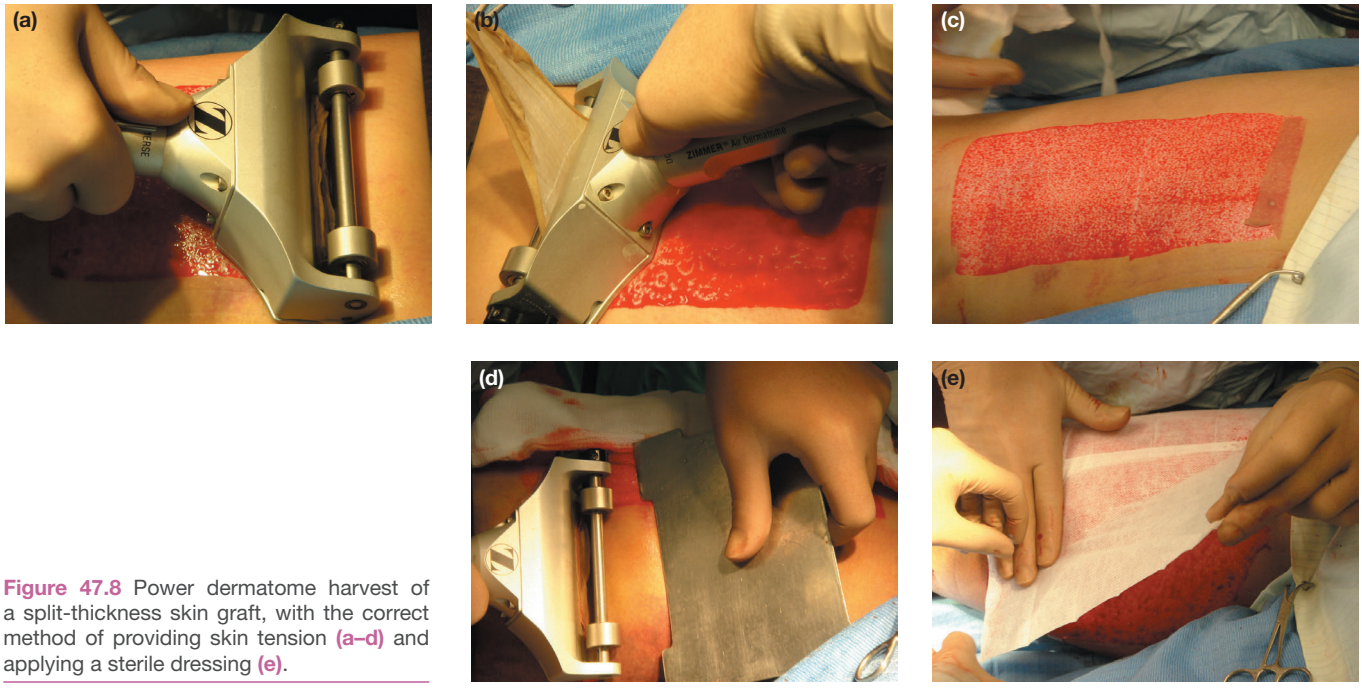

Figure 47.8 Power dermatome harvest of a split-thickness skin graft, with the correct method of providing skin tension **(a–d)** and applying a sterile dressing **(e)**.

expand and cover a wider surface area as well as avoid the accumulation of an underlying haematoma. The graft is typically sutured, glued or stapled to the recipient site. However, grafts are not entirely robust, for example they can shear off, and may contract significantly over time. The donor area usually heals by secondary intention within 2 weeks by means of simple dressings (***Figure 47.9***).

- **Full-thickness skin grafts** consist of epidermis and dermis. As they include the entire thickness of the dermis, they retain their elasticity and are less prone to secondary scar contracture. However, this also means that the area harvested is limited by the ability to primarily close the donor site. The common sites for harvest include the supraclavicular skin, groin crease and posterior auricular region (known as a Wolfe graft), where there is adequate skin laxity. Full-thickness grafts are commonly used for syndactyly release in the hand, reconstruction of facial defects following skin cancer excision or contracture releases following burns (***Figure 47.10***).
- **Composite skin grafts** are a combination of skin and another tissue type, such as fat or cartilage. A commonly used composite skin graft is to harvest a skin/cartilage graft from the helical root of the ear to reconstruct the alar of the nose following skin cancer excision. A hair-bearing composite scalp graft can be used to reconstruct an eyebrow.

Nerve grafts are used to reconstruct peripheral nerves (including the brachial plexus) and in the surgical management of facial palsy (by utilising a cross-facial nerve graft) and corneal paraesthesia. Common donor nerves include the sural nerve, medial antebrachial cutaneous nerve and the sensory branch of the posterior interosseous nerve (ideal for digital nerve grafts). Whereas vessels are 'anastomosed', nerves are 'coapted' – typically using epineurial sutures with or without fibrin glue in a tension-free manner.

Tendon grafts are utilised for the reconstruction of tendons in the upper and lower extremities as a result of trauma, infection (e.g. leprosy) or neurological injury (peripheral nerve or spinal transection). Commonly used donor tendons include palmaris longus, extensor digitorum longus and plantaris.

Autologous cartilage grafts can be used for support and augmentation (such as the cartilaginous framework of a staged reconstruction for microtia, a congenital deformity of the outer ear), to correct contour irregularities (such as the nasal dorsum) or to repair or resurface damaged joints (such as the temporomandibular joint or small joints of the hand).

Figure 47.9 Typical appearance of a split-thickness skin graft donor site on the left lateral thigh 6 months after harvest. The mild hyperpigmentation is expected to fade over time.

John Reissberg Wolfe, 1824–1904, Professor of Ophthalmology, University of Glasgow, UK.

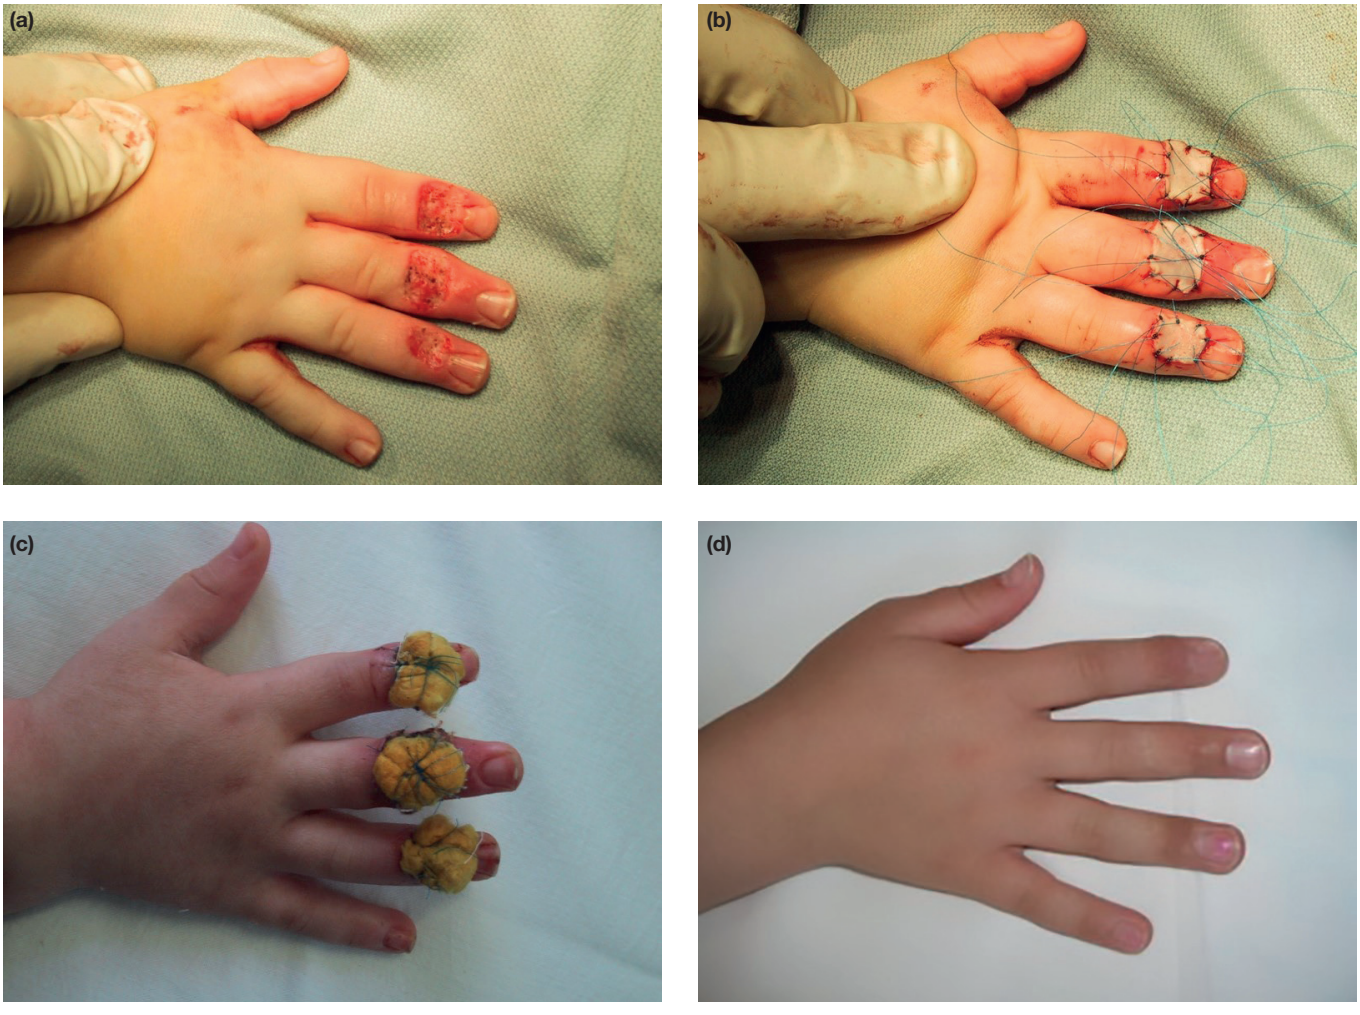

Figure 47.10 Full-thickness skin graft reconstruction of a contact burn to the dorsum of the digits. **(a)** Post excision of burn wounds. **(b)** Full-thickness skin grafts from the groin sutured to the wounds. **(c)** Tie-over dressings applied to avoid shearing of the graft off the wound bed. **(d)** Postoperative appearance at 1 year.

Common donor sites include the conchal bowl of the ear (elastic cartilage), the nasal septum (which provides rigid hyaline cartilage) and costal cartilage (a plentiful source of hyaline cartilage).

Whereas autograft (i.e. graft harvested from the same individual) is considered the 'gold standard' for most elective surgical indications, there are certain circumstances when allografting (i.e. from another individual of the same species) or xenografting (i.e. from another species) might be necessary to minimise donor site morbidity or because of a lack of donor tissue. For example, cadaveric allograft or porcine xenograft may be used as a temporising 'dressing' following the initial debridement of an extensive burn or necrotising fasciitis.

Skin substitutes are engineered dressings that are designed to facilitate wound healing by replicating as many of the key functions as possible. They can either replace the epidermal or dermal components (or both) and can have either a cellular or acellular dermal matrix. Dermal substitutes include Alloderm® (human dermal matrix) or Integra® (bovine collagen with chondroitin and a silastic membrane) whereas Epicel® is an example of an epidermal substitute derived from autologous keratinocytes. Apligraf® is a double-layered bioengineered skin substitute derived from human fibroblasts and keratinocytes and is licensed for the treatment of diabetic and venous ulcers. Their advantage is one of ready availability (in large quantities if required) without the creation of a donor site defect; however, they are expensive and must be employed using a meticulous surgical technique to avoid failure.

Tissue expansion is the creation of extra skin and soft tissue by using a subcutaneous silicone balloon in order to reconstruct locoregional defects. The tissue expander is placed within a subcutaneous pocket and then inflated with saline solution at regular (e.g. weekly) intervals via a filling port (which can be buried or externalised). The overlying skin and soft tissue have viscoelastic properties; in response to the underlying mechanical force, they permanently elongate through the processes of 'creep' and stress relaxation. Angiogenesis leads to increased vascularity within the expanded skin flap and the local response to a 'foreign body' creates a fibrous capsule. Thus large flaps can be created that have similar physical and mechanical properties to the skin that is to be replaced. Common indications include scalp reconstruction following skin cancer excision

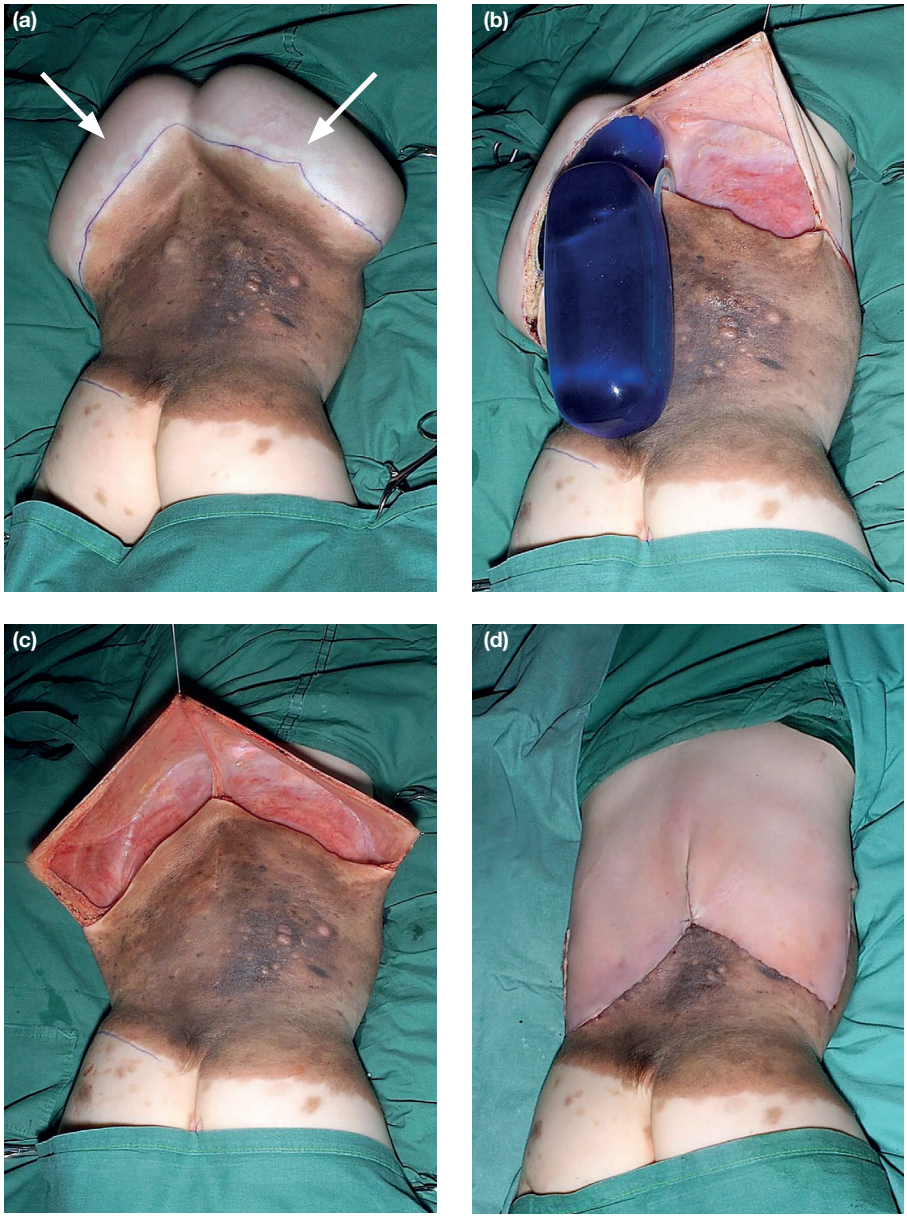

Figure 47.11 Tissue expansion provides local autologous tissue for reconstruction of large defects. **(a)** Extensive congenital melanocytic naevus of the back with tissue expanders *in situ* (arrows). **(b)** Explantation of inflated tissue expanders. **(c)** Advancement of expanded skin flaps to determine the extent of naevus excision. **(d)** Immediate postoperative appearance after partial excision of the naevus and skin flap closure. The flaps were subsequently re-expanded to facilitate excision of the residual naevus.

(ideal for reconstructing hair-bearing skin), breast reconstruction following mastectomy and auricular reconstruction. Occasionally, more than one expander is used to reconstruct complex or large defects, such as giant congenital melanocytic naevi (***Figure 47.11***). Caution must be exercised when considering expansion of irradiated tissue or in patients with comorbidities including diabetes or connective tissue disorders as wound healing is impaired in these scenarios.

Prosthetics are widely used in plastic surgery – ranging from ocular, nasal and auricular to hand prostheses. Alloplastic implants are routinely employed in reconstructive plastic surgery, including titanium plates for cranioplasties (replacing lost calvarial bone), porous polyethylene (Medpor®) onlay implants to augment the facial skeleton (e.g. cheek bones or chin tip) and breast implants. Breast implants comprise an outer shell (typically a silicone elastomer that may be smooth or textured) and a filling material (saline or silicone gel) and come in a variety of shapes (round or anatomical) and a vast array of volumes. Implants are prone to capsular contracture, may interfere with mammographic cancer surveillance and are associated with the development of anaplastic large-cell lymphoma in a small percentage of cases.

Lipotransfer

Lipotransfer, or autologous fat grafting, is a useful reconstructive technique to achieve soft-tissue augmentation, i.e. increase the volume in a specific region, hence it is sometimes referred to as 'lipomodelling'. Common indications include facial defects in progressive hemifacial atrophy (Parry–Romberg syndrome)

Caleb Hillier Parry, 1755–1822, physician, Bath General Hospital, Bath, UK.
Moritz Heinrich Romberg, 1795–1873, German neurologist, Director of the University Hospital, Berlin, Germany.

and breast reconstruction, although the greatest demand comes from the aesthetic industry for facial rejuvenation and buttock/breast augmentation. Lipotransfer is also used to improve scar remodelling, particularly after radiotherapy, the rationale being that adipose tissue contains adipose-derived stromal cells, which can modulate the healing process.

Autologous fat is an ideal filler material for soft-tissue reconstruction as it is biocompatible, non-immunogenic, inexpensive and can be easily and repeatedly harvested. This technique was systematised and popularised by Coleman in the late twentieth century. The stages of lipotransfer include: (i) harvesting or 'liposuction', whereby adipose tissue is suctioned from a body part, usually the abdomen , thigh or buttock, using local anaesthetic and a cannula; (ii) fat preparation, including centrifugation of the fat aspirate; and (iii) injection, using a specialised cannula, at the recipient site. One disadvantage is that the grafted fat undergoes an unpredictable amount of fat resorption (typically approximately 20% but may reach 80%). Current research is focused on how to improve the survival of the grafted fat, including through enrichment with a freshly isolated stromal vascular fraction. Although generally safe, there is a small risk of fat embolism, which can have serious complications (including blindness and stroke) and can be fatal.

Flaps

A flap is a block of tissue that contains an innate blood supply that may be transferred from a donor site to reconstruct a secondary defect; the pedicle is the 'base' of the flap that contains the blood supply. Unlike a graft, a flap can therefore be used to reconstruct a defect that does not have a vascularised wound bed, such as exposed tendon, cortical bone or a prosthesis. There are numerous methods of classifying flaps: according to their blood supply, their proximity to the defect, the method by which they are transferred and the tissue that they contain.

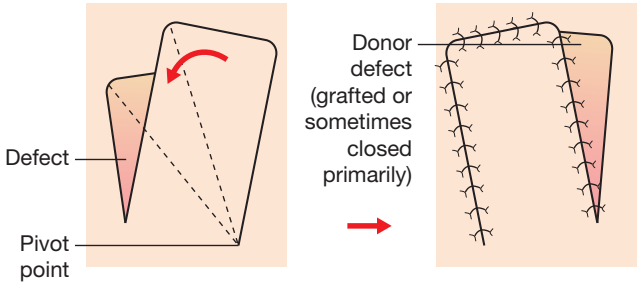
The five Cs methodology is a useful flap classification system based on their circulation, composition, contiguity, contour and conditioning (***Figure 47.12***).

1 **Circulation**: random pattern flaps have no dominant blood supply whereas axial flaps have a dominant feeding vessel.
2 **Composition**: cutaneous, fasciocutaneous, fascial, musculocutaneous, muscle, osseocutaneous, osseous, omentum/bowel.
3 **Contiguity**: local (where the flap shares a side with the defect) (***Figure 47.13***), regional (where the flap is near but not immediately adjacent to the defect) (***Figures 47.14 and 47.15***) and distant (where the flap is far from the defect and can be either pedicled or free) (***Figures 47.16 and 47.17***).
4 **Contour**: the method by which the flap is transferred into the defect – advancement (***Figures 47.18 and 47.19***), transposition (***Figure 47.20***), rotation (***Figure 47.21***), interpolation, waltzing, crane principle and free.
5 **Conditioning**: whether the flap is delayed by partially elevating and resetting the flap prior to definitive elevation and transfer. Delay enables a larger flap to be harvested by improving its blood supply.

Fasciocutaneous flaps comprise a fascial component that augments the flap blood supply owing to a network of subfascial, fascial and suprafascial vessels. Fasciocutaneous flaps may be classified according to Cormack and Lamberty (1984) (***Figure 47.22***):

- Type A: multiple perforators that can be direct or indirect (e.g. Pontén flap).
- Type B: single perforator that is usually direct and runs along the axis of the flap (e.g. the scapular or parascapular flaps).
- Type C: segmental perforators that arise from the same source vessel (e.g. the radial forearm and lateral arm flaps) (***Figure 47.23***).
- Type D: similar to type C; however, the flap is raised as an osteomyofasciocutaneous flap (e.g. the free fibular flap).

In muscle and musculocutaneous flaps the motor nerve is always accompanied by a vascular pedicle, which is often the major source of the flap circulation. A dominant pedicle can sustain an entire muscle whereas a minor pedicle can normally only sustain a portion of the flap. The skin in a musculocutaneous flap is supplied by perforators. Muscle flaps are classified by Mathes and Nahai (1981) (***Figure 47.24***):



- Type I: single vascular pedicle (e.g. tensor fascia lata and gastrocnemius).
- Type II: one dominant pedicle with one or more minor pedicles (e.g. gracilis, biceps femoris, sternocleidomastoid, soleus and trapezius); the flap cannot survive on the minor pedicle(s) alone.
- Type III: dual dominant pedicles (e.g. gluteus maximus, pectoralis minor, rectus abdominis, serratus anterior and temporalis).
- Type IV: segmental pedicles (e.g. flexor hallucis longus, sartorius and tibialis anterior).
- Type V: dominant pedicle with several smaller segmental pedicles (e.g. latissimus dorsi and pectoralis major) (***Figures 47.25 and 47.26***); the flap can survive on the minor pedicles alone.

A chimeric flap consists of multiple otherwise spatially independent flaps, each of which has an independent vascular supply, with all pedicles linked to a common source vessel. For example, the descending branch of the lateral femoral

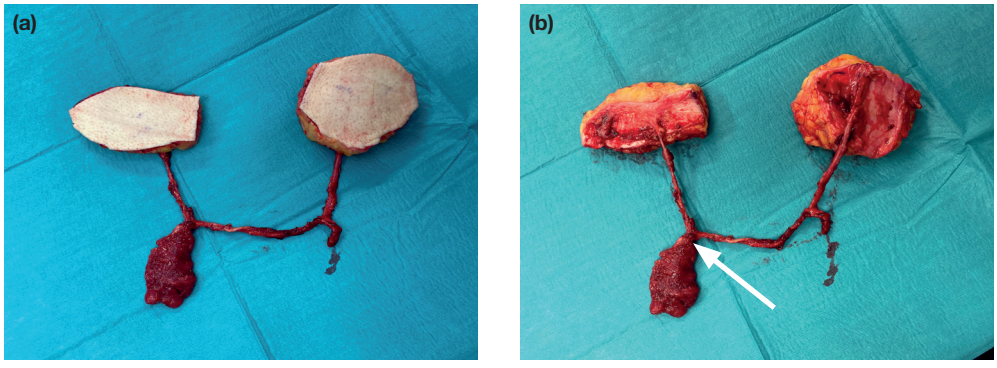

Figure 47.27 (a, b) Chimeric anterolateral thigh flap comprising spatially independent skin and muscle flaps with all pedicles linked to a common source vessel (arrow), the descending branch of the lateral femoral circumflex artery.

circumflex artery pedicle can support multiple skin and muscle flaps (***Figure 47.27***) or the subscapular vascular pedicle can support a scapular flap, a parascapular flap, a latissimus dorsi flap and a serratus anterior flap. This enables the reconstruction of complex composite defects involving different tissues. For example, following resection of a maxillary sinus tumour, a chimeric scapular flap can be used to reconstruct both the bony and skin defects.

Venous flow-through flaps are based on a venous rather than arterial pedicle so that the vein delivers both inflow and outflow of blood. These flaps are thin and pliable but prone to venous congestion and partial necrosis as there is no arterial input and the flap survives on deoxygenated blood. There is minimal donor site morbidity. Examples include the saphenous flap and those based on the superficial veins of the forearm.

MICROSURGERY

Microsurgery is a surgical subspecialty that makes use of magnification, precision tools and surgical techniques to enable the anastomosis of small blood vessels and coaptation of nerves. The diameter of a typical suture is between 0.01 and 0.03 mm. The advent of microvascular anastomotic techniques renders it feasible to transplant tissue to every region of the body, thus vastly expanding the reconstructive armamentarium as it is no longer necessary to rely on grafts that must revascularise from an underlying wound bed or on pedicled flaps that are limited by size, length or the distance they can 'travel'. Provided the course from the source vessel to the end organ is preserved, it is possible to transfer flaps from any region of the body to any recipient site provided an appropriate recipient vessel exists. This technique offers a highly versatile and flexible approach to reconstructive surgery.

Oncological reconstruction for head and neck cancer or mastectomy defects often requires the use of free flaps, providing superior functional and aesthetic outcomes. Typical flaps include the anterolateral thigh and deep inferior epigastric artery perforator flaps, based on the descending branch of the lateral circumflex femoral artery and the deep inferior epigastric artery, respectively. For complex limb injuries or osteomyelitis, microsurgical reconstruction has meant that limb salvage is now possible rather than amputation (***Figure 47.26***). Common flaps used in this context include the gracilis or latissimus dorsi muscle flaps.

Microsurgical flaps are not always used to reconstruct skin defects. Free functional muscle flaps are used to reanimate the face or the upper limb in facial and brachial plexus palsies, respectively. Free bone flaps such as the free fibular flap may also be used to reconstruct the mandible following oncological resection or to provide a strut following excision of an osteomyelitic segment of tibia.

Microsurgery has also made it possible to replant amputated digits and limbs, or reconstruct missing fingers with free vascularised functioning and sensate toes (***Figure 47.28***). Furthermore, the technique has also made vascularised composite allotransplantation possible, including of the hand and face.

Anastomoses are usually hand sewn (using specialist microinstruments with the aid of an operating microscope), although the adoption of mechanical coupler devices for venous anastomoses is becoming increasingly popular as they are often technically less demanding and faster than a hand-sewn approach.

Supermicrosurgery involving microneurovascular anastomosis of vessels and coaptation of single nerve fascicles of the order of 0.3–0.8 mm has further expanded the field. It has enabled the reconstruction of fingertip injuries, which traditionally would have been treated with amputation, and the creation of lymphaticovenous anastomosis for the treatment of chronic lymphoedema.

FLAP MONITORING

Following microvascular free-flap reconstruction, patients may be monitored in a high-dependency unit setting as it is crucial to keep the patient physiologically optimised in order that the flap remains well perfused at all times. The traditional adage is that the patient should be kept 'wet, warm and comfortable'. Strict fluid balance is monitored with the aim of keeping the circulation hyperdynamic; the flap is kept warm with a Bair Hugger® device and analgesia is carefully controlled to minimise excessive catecholamine production as a result of pain. The flap is monitored regularly by specialist nurses who assess the colour, warmth and turgor of the flap. Pressure applied to the skin of a musculocutaneous flap enables the capillary refill time to be assessed; if necessary the flap can be pricked with a

hypodermic needle to assess bleeding. The arterial and venous flow to a flap can often be monitored with a hand-help Doppler device, whereas some surgeons use an implantable Doppler (attached to the venous outflow of the flap), which is especially useful for muscle flaps (without the benefit of a skin paddle to monitor) or those flaps that are buried and thus not accessible for direct visual monitoring.

The survival of a free flap is usually threatened by an interruption to arterial inflow or venous drainage; rapid identification of a problem is essential as an immediate return to theatre is required to salvage the flap. Approximately 5% of free flaps will require exploration in theatre for vascular compromise; of these, more than 60% can be salvaged. The earlier a flap is explored the greater the likelihood of salvage success. Approximately two-thirds of cases of vascular compromise are venous in aetiology, with one-third being arterial; combined inflow and outflow issues are sometimes seen, and in some situations the vessels may be patent but compromised by external pressure (such as a haematoma or an excessively tight dressing). Thus, when assessing a compromised flap at the bedside, the surgeon must ensure that the dressings are loosened and any overly tensioned sutures released. Close flap monitoring is of most value in the first 48 hours with rapid detection of vascular compromise facilitating early salvage and improved flap survival.

A free-flap survival rate in excess 95% is typical in routine elective reconstructive cases such as breast reconstruction using a transverse rectus abdominis (TRAM) or deep inferior epigastric perforator (DIEP) flap. Flap survival rates are slightly lower in, for example, cases of complex polytrauma or head and neck reconstruction.

LEECH THERAPY

The European medicinal leech (*Hirudo medicinalis*) is an invertebrate annelid; its saliva contains hirudin (an anticoagulant), hyaluronidase (which facilitates anticoagulant penetration into the wound) and histamine (to maintain vasodilatation). The primary indication for leech therapy is to improve drainage from flaps that are venously congested, i.e. those that are dusky blue with a brisk capillary refill and a rapid, dark pinprick. Such congestion may result from a particular vein being too small or not present or a venous anastomosis not being technically possible (e.g. a distal digital replant where an artery is reconstructed but not the vein). Leeches are not normally used in cases of suspected venous obstruction of a free flap as immediate surgical exploration is required; likewise they are of no benefit in an arterially compromised flap as, again, immediate surgical exploration is mandated.

As leeching is used for venous (as opposed to arterial) insufficiency, a typical course of treatment may last for up to 2 weeks – until new vein formation occurs at the margins of the flap (***Figure 47.29***). The anticoagulant effect persists once the leech has detached from the patient, with bleeding occurring for some hours; each leech will imbibe up to 5 mL of blood and up to 150 mL of blood may be lost in the subsequent ooze; thus, all patients must have their haemoglobin level monitored regularly and blood transfusion may be necessary.

Figure 47.29 Leeching used for a venously congested replanted right external ear.

Leeches contain *Aeromonas hydrophila*, so patients require prophylactic antibiotics (typically a quinolone) until wound closure is complete.

FUTURE DIRECTIONS

Anatomical discoveries, such as a detailed understanding of the blood supply to the skin as well as technical and engineering innovations that brought about microsurgery, have enabled the field of reconstructive plastic surgery to blossom. As populations age and life expectancies continue to improve, the demand for reconstructive surgery, particularly among the elderly population for chronic degenerative and neoplastic conditions, will continue apace. The key to the next phase of reconstructive plastic surgery advances will likely be a combined approach across multiple scientific and surgical disciplines.

The scientific areas that will lead to significant breakthroughs include wound healing, bioengineering, cancer treatment and immunotolerance for vascularised allotransplantation. Recent discoveries of the genetic, epigenetic and molecular mechanisms that underlie conditions such as craniosynostosis, cleft lip and palate, Dupuytren's disease and delayed wound healing now provide a rational basis for the development of therapeutic interventions. Bioengineering and tissue engineering will certainly play a major role in modern reconstruction; for example, smart tissue expansion for cleft palate reconstruction and biocompatible scaffolds that simultaneously promote *in situ* tissue regeneration as well as deliver treatment by eluting antibiotics or chemotherapeutic agents for musculoskeletal and cancer reconstruction. Furthermore, as the cultural and political landscapes evolve, new areas of reconstructive surgery have emerged, including gender-affirming surgery. One of the most exciting areas of reconstructive plastic surgery has been the increasing success of vascularised composite allotransplantation, including of the face and upper limb. Outcomes are expected to continue to improve with better understanding of immunological tolerance and increasing social acceptance of the donation of body parts.

The field of robotic surgery continues to expand. It is particularly useful to assist in surgical approaches where access is limited, such as cleft surgery. The latest devices are able to eliminate hand tremor, increase dexterity and range of motion, provide haptic feedback and three-dimensional views that assist greatly in challenging dissections, and have been successfully adopted in oncological head and neck reconstruction.

Reconstructive plastic surgery is unique in its creativity, breadth and variety of reconstructive techniques. While this affords the specialty powerful means to serve the patient, it does also mean the practice of evidence-based surgery is challenging. There are often numerous techniques to treat the same conditions with a lack of high-quality evidence. Moreover, there are often situations where surgery may be technically feasible but not in the best interest of the patient. For example, patients with complex multifragmentary open tibiofibular fractures and neurovascular compromise may have a better quality of life with a below-knee amputation than with a salvage reconstruction with free tissue transfer. Hence, well-designed pragmatic clinical trials and the development of rigorous tools to capture the most relevant data, such as patient-reported outcome measures, together with the building of large-scale clinical research networks at both national and international levels will be crucial to drive complex shared decision making between surgeon and patient.

PART 7 | Head and neck

CHAPTER 48

Cranial neurosurgery

Learning objectives

- To understand the physiology of raised intracranial pressure, cerebrospinal fluid circulation and intracranial blood flow
- To recognise central nervous system infection, and understand the acute management
- To be familiar with causes of spontaneous intracranial haemorrhage and the principles of management of subarachnoid haemorrhage
- To recognise common intracranial tumours, their presentation, investigation and treatment
- To be aware of common developmental and other pathologies encountered in paediatric neurosurgical practice and emergency paediatric care
- To understand the indications and approaches available for the management of epilepsy, pain syndromes and movement disorders
- To note key practical and ethical issues relating to consent and risks, Creutzfeldt–Jakob precautions and the diagnosis of brainstem death

RAISED INTRACRANIAL PRESSURE

The importance of intracranial pressure (ICP) management in the context of head injury has been discussed elsewhere (see ***Chapter 28***). Likewise ICP is key to presentation and management across the spectrum of cranial neurosurgery.

Clinical features of raised intracranial pressure

Symptoms of raised ICP include a 'high-pressure headache' that is worse on coughing or bending forward. By contrast, low-pressure headaches, typically associated with excessive cerebrospinal fluid (CSF) drainage, are worse on standing. High-pressure headaches may be accompanied by nausea and vomiting, blurred vision and double vision: cranial nerve compression can result in eye movement and pupil abnormalities. Fundoscopy can detect papilloedema (***Figure 48.1***), but this takes time to develop so may be absent in the acute phase.

Before closure of the skull sutures in infancy, raised ICP presents differently with an increase in head circumference, prominent scalp veins and a tense bulging fontanelle. In infants and older children, raised CSF pressure results in dorsal midbrain compression with a loss of upgaze known as sunsetting, a feature of Parinaud's syndrome (***Figure 48.2***).

Raised ICP requires urgent evaluation and management: delay risks progression to cerebral herniation resulting in cardiovascular instability, neurological deficit and death. Vision may also deteriorate rapidly and irreversibly. Where there are pupil changes or a deterioration in conscious level, anaesthetic and

Figure 48.1 Papilloedema. The optic disc is swollen with blurred margins.

Figure 48.2 Parinaud's syndrome with sunsetting.

Henri Parinaud, 1844–1905, French ophthalmologist and pioneer in neuro-ophthalmology.

neurosurgical help may be needed: raise the head of the bed, administer hypertonic saline or mannitol and arrange urgent computed tomography (CT) imaging.

Investigation of raised intracranial pressure

CT is a first-line investigation to identify causes of raised ICP, including mass lesions, bleeds, cerebral oedema and hydrocephalus, and to guide treatment. Outside the emergency setting many pathologies, as well as the anatomy relating to potential treatments such as third ventriculostomy, may be better visualised on magnetic resonance imaging (MRI). The gold standard for quantifying ICP and monitoring in real time is by transducing CSF pressure through an external ventricular drain or insertion of a pressure monitor into the brain substance (***Figure 48.3***).

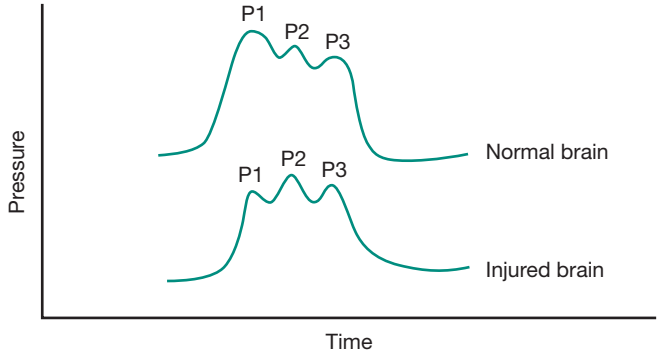

Figure 48.3 The intracranial pressure waveform. The P1 percussion wave corresponds to arterial pulsation. Reduced brain compliance in the setting of traumatic brain injury among others is associated with a prominent P2 tidal wave. The P3 dicrotic wave represents venous pulsation.

Summary box 48.1

Raised ICP

Acutely raised ICP is a neurosurgical emergency. Clinical features include:

- Headache
- Nausea and vomiting
- Diplopia and blurred vision
- Drowsiness then coma

HYDROCEPHALUS

The total volume of CSF is normally about 150 mL. Production from the walls of the ventricles and the choroid plexus is about 20 mL/h. Hydrocephalus refers to an increase in CSF volume with ventricular enlargement, often presenting symptoms of raised ICP.

Physiology of cerebrospinal fluid flow

CSF flows from the lateral ventricles through the foramen of Monro to the third ventricle, then down the cerebral aqueduct to the fourth ventricle, where it exits to the subarachnoid space via the midline foramen of Magendie and the lateral foramina of Luschka (***Figure 48.4***). CSF is reabsorbed into the arachnoid villi along the superior sagittal sinus.

Obstructive and communicating hydrocephalus

Hydrocephalus (***Figure 48.5***) almost always reflects obstruction to circulation (an obstructive hydrocephalus; ***Figure 48.6***) or failure of reabsorption (a communicating hydrocephalus; ***Figure 48.7***) (***Table 48.1***). The distinction is important since obstructive hydrocephalus especially can cause very sudden

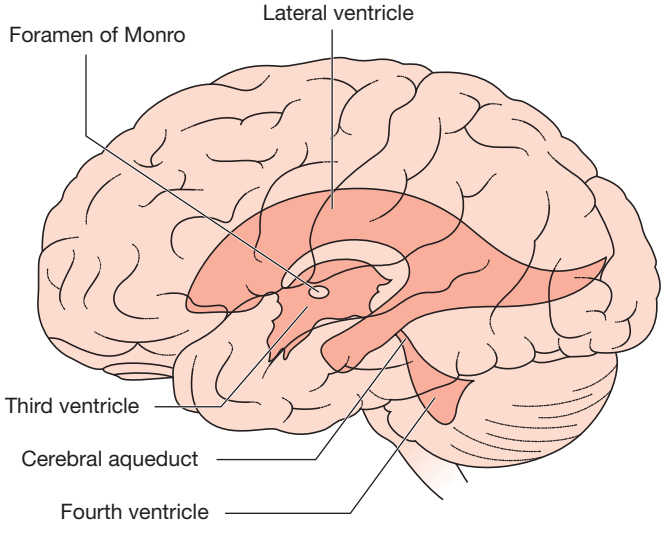

Figure 48.4 'CSF pathways'. Cerebrospinal fluid (CSF) is produced by the choroid plexus of the lateral ventricles and flows through the ventricular system to exit into the subarachnoid space through the foramina of Magendie and Luschka in the fourth ventricle.

TABLE 48.1 Aetiology of hydrocephalus.

Obstructive hydrocephalus	• Lesions within the ventricle • Lesions in the ventricular wall • Lesions distant from the ventricle but with a mass effect
Communicating hydrocephalus	• Post haemorrhagic • CSF infection • Raised CSF protein
Excessive CSF production (rare)	Choroid plexus papilloma/carcinoma

CSF, cerebrospinal fluid.

Alexander Monro, 1733–1817, Professor of Anatomy, The University of Edinburgh, Edinburgh, UK, a post also held by his father, Alexander Monro (primus), and son, Alexander Monro (tertius).
Francois Magendie, 1783–1855, Physician and Professor of Pathology and Physiology, Paris, France. Also described the Magendie sign, a downward and inward rotation of the eye due to a cerebellar lesion.
Hubert von Luschka, 1820–1875, anatomist, University of Tübingen, Tübingen, Germany.

deterioration with coma and death, and because lumbar puncture in this context carries a risk of herniation of the brainstem and cerebellar tonsils owing to the resulting differential pressure changes (sometimes termed 'coning'). For communicating hydrocephalus, lumbar puncture is of diagnostic value, deriving an opening pressure and assessment of the CSF contents. It is also therapeutic: drainage of typically between 10 and 30 mL of CSF can relieve hydrocephalus temporarily.

Treatment of hydrocephalus in the emergency setting usually involves CSF diversion, for example using an external ventricular drain. Disorders of CSF flow with poorly understood mechanisms manifest in two syndromes: normal pressure hydrocephalus and idiopathic intracranial hypertension (IIH).

Figure 48.5 Pathological specimen of a hydrocephalic brain.

Normal pressure hydrocephalus

Normal pressure hydrocephalus is an important cause of dementia since it is readily reversible. It may be idiopathic or develop in the context of previous brain insults, including subarachnoid haemorrhage (SAH), head injury, meningitis and tumour. The CSF pressure at lumbar puncture is typically normal, but it is believed that reduced brain compliance in this condition results in transient spikes of ICP that contribute to clinical deterioration. Patients typically present with the triad of gait disturbance, incontinence and cognitive decline. Ventriculomegaly is evident on imaging, but this can also be the result of cortical atrophy due to other dementia pathologies. Diagnosis typically depends on lumbar infusion and/or drainage studies to demonstrate altered compliance and/or clinical improvement associated with CSF drainage. Treatment is typically by insertion of a ventriculoperitoneal shunt.

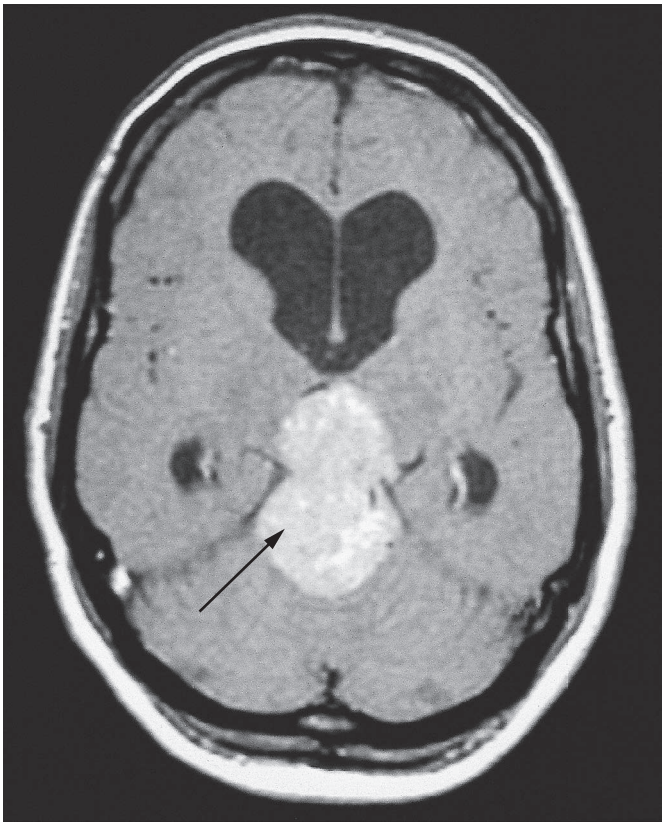

Figure 48.6 Pineal region tumour (arrow) causing obstructive hydrocephalus.

Figure 48.7 Gross hydrocephalus in a neonate with very prominent temporal horns (arrows) and fourth ventricle.

Idiopathic intracranial hypertension

Patients with IIH develop raised ICP without an underlying mass lesion. Patients are classically young overweight women with high-pressure headaches and visual deterioration. Examination may reveal papilloedema, and occasionally cranial nerve palsies. Imaging is unremarkable, but lumbar puncture demonstrates a raised opening pressure >25 mmHg. The diagnosis is one of exclusion, and the aetiology is not well understood. Impaired CSF resorption may reflect raised venous pressure, either as a result of sinus thrombosis or secondary to raised intra-abdominal pressure in obese patients. Weight loss and cessation of certain medications, including the oral contraceptive pill, is often effective. This is combined with medical therapy using acetazolamide to reduce CSF production. For patients with visual field loss or visual failure despite medication, lumboperitoneal or ventriculoperitoneal shunting is offered. There may be a role for optic nerve sheath fenestration or venous sinus stenting in select cases.

Summary box 48.2

Hydrocephalus and disorders of CSF flow

- Obstructive or communicating hydrocephalus may occur as a result of neurosurgical pathology or its treatment
- CT is the first line of investigation. Lumbar puncture can confirm raised CSF pressure in communicating hydrocephalus and relieve it temporarily, but is dangerous in obstructive hydrocephalus
- Normal pressure hydrocephalus is a potentially reversible cause of dementia, presenting with gait disturbance, incontinence and cognitive decline
- IIH causes headaches and even visual loss in young people; it can be managed with weight loss, acetazolamide, serial lumbar puncture and CSF diversion as a last resort

Treatment of hydrocephalus

Acute obstructive hydrocephalus is an emergency because of the risk of rapid progression to coma and death, sometimes with very sudden deterioration, a 'hydrocephalic attack'. It may be relieved by addressing the underlying pathology, for instance by excision of a tumour responsible for an obstructive hydrocephalus. Most often, however, temporary ventricular drainage is required as a precaution in the preoperative and perioperative period or as an emergency in an obtunded or deteriorating patient.

External ventricular drain

External ventricular drains (EVDs) are an effective temporary measure to relieve hydrocephalus. Most commonly they are inserted through a burr hole at Kocher's point (right of midline, anterior to the coronal suture), perpendicular to the brain surface, so that the catheter tip rests adjacent to the foramen of Monro in the lateral ventricle. Intrathecal antibiotics may also be delivered through the EVD. Lumbar drains are an alternative means of temporary CSF diversion.

Ventriculoperitoneal shunts

Ventriculoperitoneal shunting comprises the insertion of a proximal or ventricular catheter into the lateral ventricle, while a distal catheter is tunnelled subcutaneously to the abdomen. Ventriculoatrial, ventriculopleural and lumboperitoneal shunting are also occasionally employed. A shunt valve inserted between the proximal and distal catheters regulates flow through the system by opening at a predetermined pressure (***Figure 48.8***); the shunt valve typically incorporates a CSF reservoir, which allows for percutaneous sampling. An anti-siphon system may also be incorporated to prevent excessive drainage in the standing position. Programmable valves offer variable opening pressures, adjusted magnetically using a device applied externally over the valve.

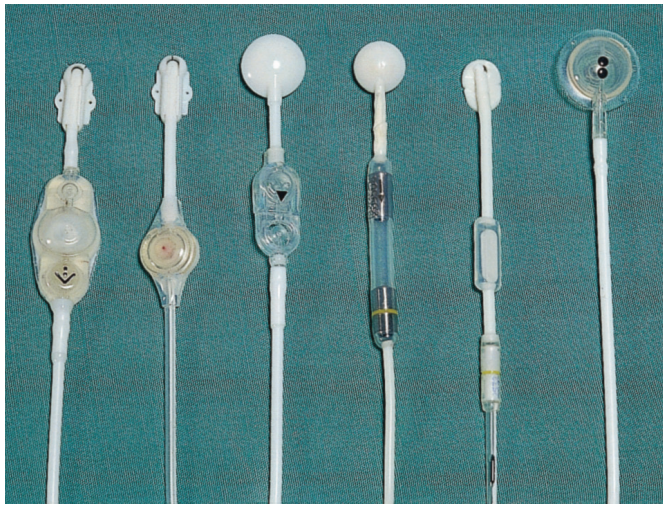

Figure 48.8 Examples of ventriculoperitoneal shunt valves.

Shunt complications

Shunts are vulnerable to disconnection, infection, blockage and overdrainage, so that 15–20% require replacement within 3 years.

Features of shunt infection typically include fever, headache and meningism; 75% of infections present within 1 month, reflecting introduction at the time of insertion. The diagnosis can be confirmed by CSF tap from the shunt reservoir or lumbar puncture if safe to do so. The shunt is removed and external ventricular drainage or serial lumbar punctures instituted to cover a course of antibiotic therapy. Once CSF sampling confirms resolution of the infection and a normal protein concentration, a shunt can be inserted at a new site.

Patients with blocked shunts present clinical features of hydrocephalus, which can be confirmed on CT, and the shunt reservoir may be difficult to compress or refill only slowly. The majority of blockages are attributable to cellular and proteinaceous debris, especially due to infection, but choroid plexus adhesion, blood clot or failure of the valve mechanism may also be responsible. In the context of obstructive and congenital

Emil Theodor Kocher, 1841–1917, Professor of Surgery, Berne, Switzerland. In 1909, he was awarded the Nobel Prize in Physiology or Medicine for his work on the thyroid.

hydrocephalus especially, shunt blockage is an emergency because of the potential for rapid deterioration owing to uncontrolled rises in ICP.

Overdrainage can result in low-pressure headaches, which are typically worse on standing. Collapse of the ventricles can cause accumulation of fluid or blood in the subdural space, resulting in subdural hygroma or subdural haematoma. The slit ventricle syndrome describes the situation in children treated with shunts, whose ventricles and subarachnoid spaces are underdeveloped, resulting in poor brain compliance. In these patients normal fluctuations in ICP are exaggerated so that coughing and straining may cause symptoms of raised ICP. Any shunt blockage may not be evident on scan as the ventricles fail to enlarge.

Endoscopic third ventriculostomy

This procedure is especially useful in obstructive hydrocephalus due to aqueduct stenosis. A neuroendoscope is inserted into the frontal horn of the lateral ventricle and then into the third ventricle via the foramen of Monro. The floor of the ventricle is then opened between the mamillary bodies and the pituitary recess. Free drainage between the third ventricle and the adjacent subarachnoid cisterns is then possible, without the infection risk posed by implanted tubing. Reblockage of this route is common, however, and many patients will subsequently require a shunt. Rare but serious complications include damage to the basilar artery or forniceal damage, resulting in permanent memory impairment.

Summary box 48.3

Treating hydrocephalus

- Temporary CSF diversion can be achieved with an EVD
- In the long term a shunt, usually connecting the lateral ventricles with the peritoneal cavity in the abdomen (ventriculoperitoneal shunt), is the mainstay of management
- Shunt blockage and infection are common complications
- In certain cases, obstructive hydrocephalus can be managed by endoscopic third ventriculostomy

INTRACRANIAL INFECTION

Meningitis

Meningitis describes inflammation of the meninges of the brain and spinal cord, most commonly and most seriously due to bacterial infection. The clinical features of meningeal irritation or meningism are fever, headache, neck stiffness and photophobia. Community-acquired bacterial meningitis can progress rapidly without antibiotic treatment to subpial encephalopathy, venous thrombosis, cerebral oedema and death. Meningitis as a complication of head injury or surgery typically follows a more insidious course, but nonetheless remains a feared complication requiring prompt intervention.

TABLE 48.2 Principles of central nervous system antibiotic therapy.

- Treatment should be initiated as soon as feasible, allowing for sampling of collections or CSF first if the patient's clinical condition allows
- High-dose empirical intravenous antibiotics are administered according to local protocol, broad spectrum initially and then according to sensitivities of the organisms responsible once identified
- Extended treatment over 6 weeks or more is typically required, but a switch to oral therapy may be appropriate after an interval and in consultation with the microbiology team

Typical organisms are *Staphylococcus aureus*, Enterobacteriaceae, *Pseudomonas* and pneumococci.

Meningitis after head injury is common, affecting 25% of patients with base of skull fracture and CSF leak. Repair of the CSF leak may be required, and empirical antibiotics (***Table 48.2***) should have activity against commensal nasal organisms, including Gram-positive cocci and Gram-negative bacilli in the presence of symptoms/signs of clinical meningitis.

Summary box 48.4

Meningitis

- A feared complication of neurosurgery and of head injury
- CT head allows exclusion of raised ICP prior to lumbar puncture
- CSF should be sent for microscopy and culture, and for assay of protein and glucose levels
- Treatment, pending identification of an organism, is with broad -spectrum antibiotics, including anaerobic cover

Brain abscess and empyema

Abscesses arise when the brain is exposed directly, for example as a result of fracture or infection of an air sinus, or at surgery. They also result from haematogenous spread, typically in association with respiratory and dental infections or endocarditis. In 25% of cases, no underlying primary infection is found. The organisms involved are normally bacteria, but immunocompromised hosts in particular are vulnerable to a broad range of pathogens (***Table 48.3***).

Typical presenting features include low-grade fever, confusion, seizures and focal deficit, often with equivocal blood markers of inflammation; blood cultures should be obtained at an early stage. CT scan with contrast is the initial imaging modality of choice. Hypodense oedematous brain representing early cerebritis is visible in the first few days (***Figure 48.9***). The classic appearances of a smooth-walled, well-defined, ring-enhancing mass develop as the abscess matures (***Figure 48.10***). The distinction between abscess and tumour can be difficult and has important management implications since abscesses generally require urgent drainage. Restricted diffusion evident

Hans Christian Joachim Gram, 1853–1938, Professor of Pharmacology (1891–1900) and of Medicine (1900–1923), Copenhagen, Denmark, described this method of staining bacteria in 1884.

Figure 48.9 Axial computed tomography scan with contrast of a patient with frontal sinusitis presenting with seizures. Early cerebritis is evident in the left frontal region (arrow).

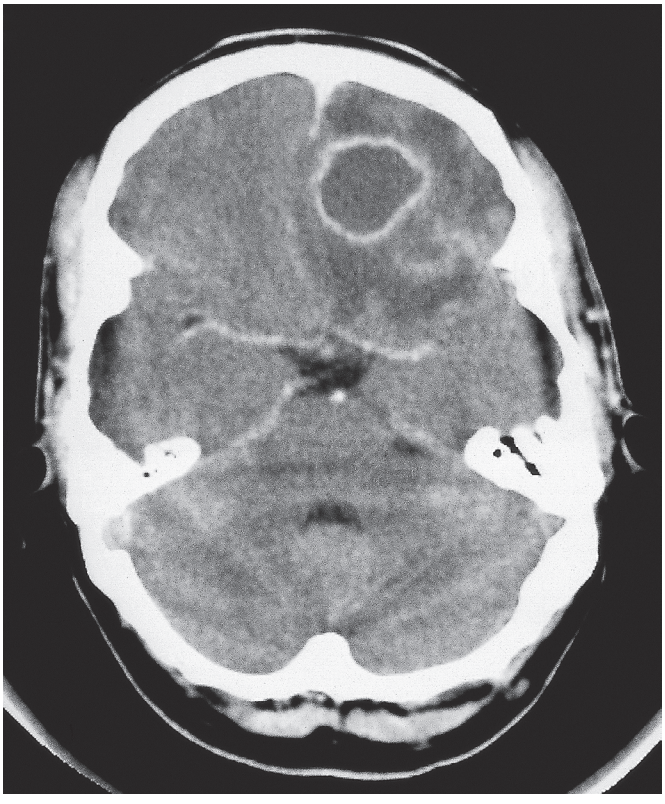

Figure 48.10 Axial computed tomography scan with contrast in the same patient as in **Figure 48.9** 2 weeks later. A ring-enhancing, smooth-walled lesion is evident; this is an abscess suitable for image-guided drainage.

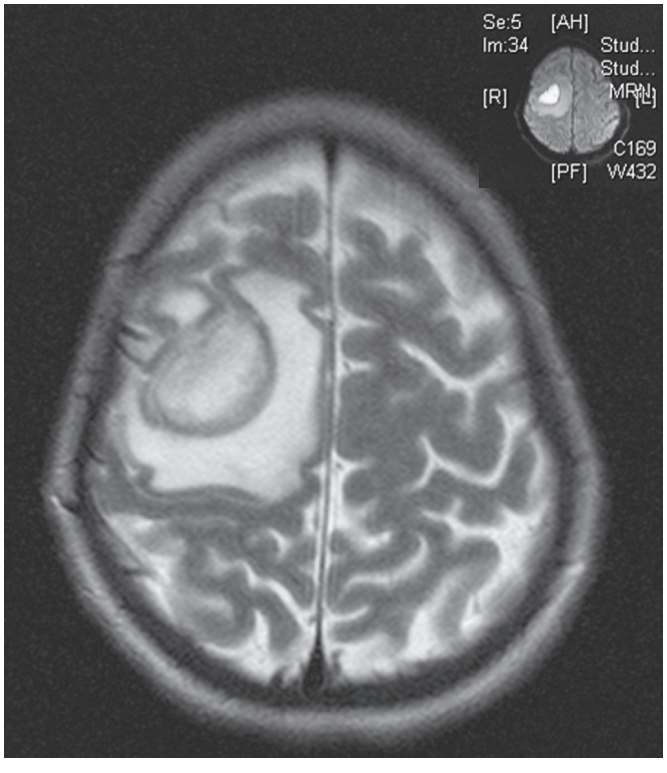

Figure 48.11 The right frontal lesion evident on T2-weighted magnetic resonance imaging (MRI) (main image) exhibits high signal on diffusion-weighted MRI sequences (top right inset) indicative of brain abscess.

on diffusion-weighted MRI sequences is a valuable indicator of infective pathology (***Figure 48.11***).

The mainstay of abscess management is early surgical drainage: mortality for patients treated in this way is about 4%, whereas it is greater than 80% in cases of ventriculitis due to rupture of an abscess into the ventricles. Up to 50% of patients with brain abscess will develop seizures at some stage, so that prophylactic anticonvulsants should be considered.

TABLE 48.3 Common causative organisms.

Condition	Organisms
Sinus/mastoid infection	Streptococci; *Bacteroides*; enterobacteria; staphylococci; *Pseudomonas*
Haematogenous spread	*Bacteroides*; streptococci
Penetrating trauma	*Staphylococcus aureus*; *Clostridium*; *Bacillus*; enterobacteria
Food contamination	*Toxoplasma*; pork tapeworm (neurocysticercosis)
Immunocompromise	HIV; *Toxoplasma* (protozoal); *Cryptococcus* (fungal); JC virus

HIV, human immunodeficiency virus; JC, John Cunningham.

Summary box 48.5

Brain abscesses

- Presenting features are those of infection and intracranial mass lesion
- Imaging reveals a 'ring-enhancing lesion', with tumour usually the main differential
- Early diagnosis, usually followed by drainage, is key for good outcome

Subdural empyema

Subdural empyema refers to an infected fluid collection in the subdural space. This may develop as a result of sinusitis, mastoiditis or meningitis, and can complicate trauma or surgery. ***Figure 48.12*** shows a subdural empyema associated with osteomyelitis of the frontal bone and associated scalp swelling – Pott's puffy tumour. In empyema, pus will generally collect in the parafalcine region and over the convexity, triggering inflammation and thrombosis in the cortical veins, which helps to explain the high mortality of 8–12%. Presentation mimics that of meningitis and cerebral abscess; typical CT appearances are of hypodense or isodense subdural collection, with contrast enhancement at the margins and often swelling and midline shift.

Summary box 48.6

Subdural empyema

- Presenting features are similar to those of meningitis or cerebral abscess
- Typically a crescentic collection with a contrast-enhancing rim is evident on CT
- Drainage is the mainstay of treatment

Tuberculosis

Tuberculosis (TB) infection of the central nervous system (CNS) represents haematogenous spread from primary pulmonary foci. A high index of suspicion is required, especially when population or individual risk factors are present. TB can result in a diverse but overlapping spectrum of pathology, including in the head:

- tuberculous meningitis – this commonly affects young children; CT demonstrates intense meningeal enhancement and hydrocephalus is a common complication;
- tuberculoma – discrete tumour-like granulomas at the base of the cerebral hemispheres, presenting with mass effect;
- tuberculous abscess – seen predominantly in immunocompromised hosts, this represents progression of a tuberculoma with prominent central caseating necrosis;

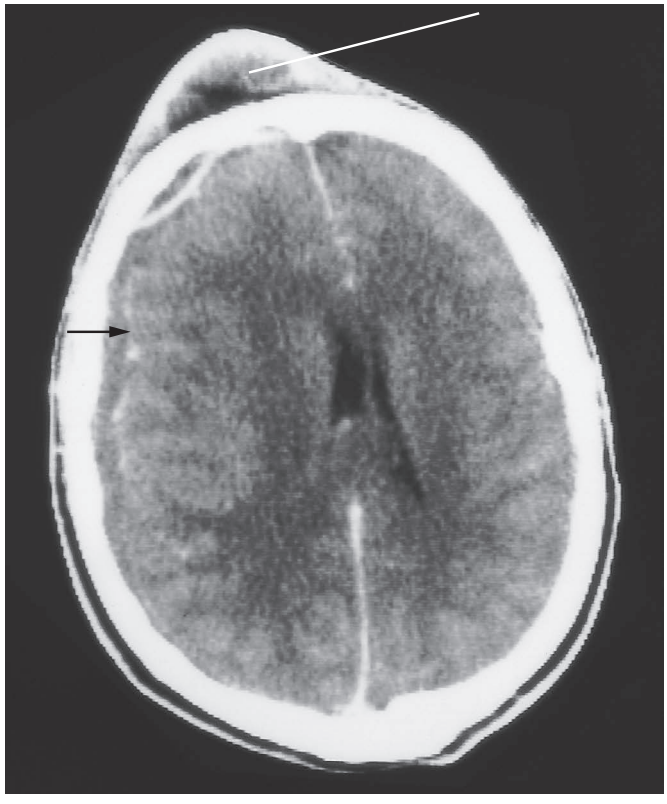

Figure 48.12 Axial computed tomography scan with contrast showing a right hemisphere subdural empyema (short arrow) and a right frontal Pott's puffy tumour (long arrow) (osteomyelitis of the frontal bone).

- miliary tuberculosis – describes a diffuse distribution of multiple small tuberculomas throughout the brain substance.

Where the meninges are involved, lymphocytes can be expected to predominate in the CSF, rather than the polymorphs seen with other bacterial meningitides. The increase in protein content and reduction in glucose concentration are also less marked. Ziehl–Neelsen staining for mycobacteria is frequently negative, and polymerase chain reaction (PCR) testing offers relatively rapid diagnosis compared with culture for acid-fast bacilli, which may take weeks. A 20- to 30-mL CSF sample allows spinning to increase the culture yield. Management is with antituberculous therapy; hydrocephalus may require shunt insertion.

VASCULAR NEUROSURGERY

Subarachnoid haemorrhage

'Spontaneous' SAH is usually the result of bleeding from a ruptured aneurysm (approximately 80% of SAH) or an arteriovenous malformation (AVM). Most ruptured aneurysms are located in the circle of Willis, at branch points in the arterial

Percival Pott, 1714–1788, surgeon, St Bartholomew's Hospital, London, UK. Besides the 'puffy tumour', described in 1760, Pott established the first association between a cancer and an environmental carcinogen, when he noted the high incidence of (squamous cell) scrotal cancers in chimney sweeps.
Franz Ziehl, 1857–1926, German bacteriologist and professor in Lübeck, Germany.
Friedrich Carl Adolf Neelsen, 1854–1894, German pathologist and professor at the Institute of Pathology, University of Rostock, Germany.

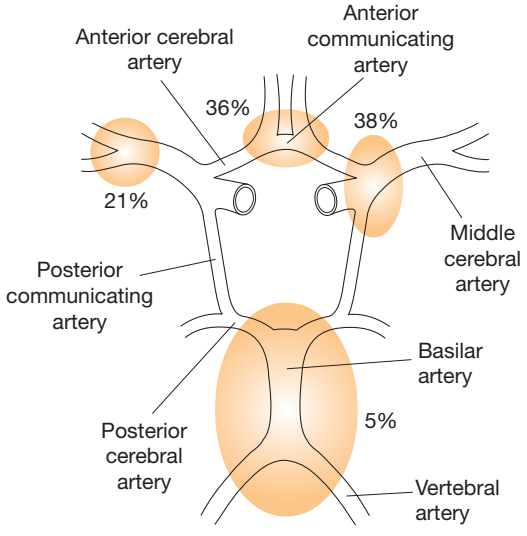

Figure 48.13 Common sites of aneurysm in the circle of Willis.

tree associated with turbulent blood flow (***Figure 48.13***). A distinct subgroup of patients with SAH suffer bleeds confined to the basal cisterns anterior to the midbrain and pons, without an underlying lesion evident on angiogram. This is termed perimesencephalic SAH, is believed to represent venous bleeding and has an excellent prognosis. Aneurysms may also develop as a result of infective infiltration of arterial walls in the context of bacteraemia (mycotic aneurysm), often in the setting of intravenous drug use or infective endocarditis. Pseudoaneurysms may also develop after trauma or after surgery.

Aneurysmal bleeding has an incidence of 10–15 per 100 000 population per year. Risk factors include age, female sex, hypertension, smoking, cocaine abuse and a family history with two first-degree relatives affected. A range of genetic disorders, in particular adult polycystic kidney disease, fibromuscular dysplasia, neurofibromatosis type 1, Ehlers–Danlos and Marfan syndrome, are known to predispose patients to this condition.

History and examination

The typical presentation of an SAH includes a 'thunderclap' headache, which is both sudden and severe and is outside the patient's normal experience. Some patients describe prodromal headaches preceding the event, potentially representing aneurysm growth or subclinical bleeds. The sudden onset occurs commonly but not exclusively during exertion, and may be associated with seizure (10%), unresponsiveness (50%) and vomiting (70%). Sometimes it is difficult to establish whether SAH has caused a fall or a fall with head injury is responsible for the SAH. Approximately one-third of SAHs are incorrectly diagnosed at initial presentation. Patients are then at high risk of succumbing to early complications, especially a rebleed.

Neurological examination may be normal ('good clinical grade') or the patient may have focal deficits and an impaired conscious level ('poor grade'). The World Federation of Neurosurgical Societies (WFNS) grading of SAH is measured against the condition of the patient after resuscitation rather than at the time of ictus (***Table 48.4***). A painful third nerve palsy is typically the result of compression from a posterior communicating artery aneurysm. Meningitic features of neck stiffness and photophobia often develop over hours. Intraocular haemorrhages, classically subhyaloid, may be visible on fundoscopy. The combination of SAH and vitreous haemorrhage is known as Terson's syndrome and occurs in 15–20% of patients. Papilloedema should be sought, but may not be evident early in the course of a developing hydrocephalus.

Investigation

CT scan is the imaging of first choice; when performed within 12 hours of ictus, it will confirm bleeding in more than 98% of cases. This makes a diagnostic lumbar puncture unnecessary (***Figure 48.14***).

TABLE 48.4 World Federation of Neurosurgical Societies (WFNS) grading of subarachnoid haemorrhage.

Grade	Glasgow Coma Scale	Focal deficits[a]
I	15	–
II	13–14	–
III	13–14	+
IV	7–12	±
V	3–9	±

[a]Focal deficit = dysphasia or limb weakness.

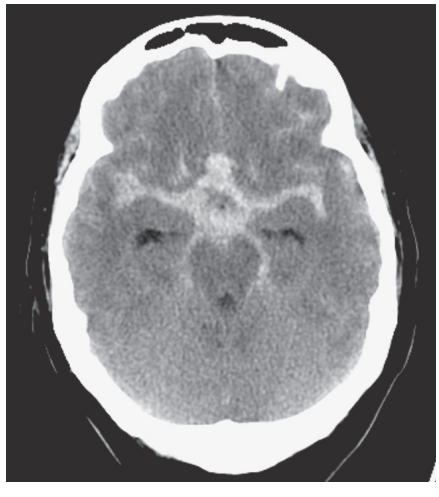

Figure 48.14 Diffuse subarachnoid bleeding from a ruptured anterior communicating artery aneurysm extends to the prepontine and ambient cisterns around the brainstem and into both Sylvian fissures.

Thomas Willis, 1621–1675, Sedleian Professor of Natural Philosophy at Oxford. Also the first anatomist to number the cranial nerves in the order used today.
Edward Ehlers, 1863–1937, Professor of Clinical Dermatology, Copenhagen, Denmark.
Henri Alexandre Danlos, 1844–1912, dermatologist, Hôpital St Louis, Paris, France, gave his account of this condition in 1908.
Bernard Jean Antonin Marfan, 1858–1942, physician L'Hôpital des Enfants-Malades, Paris, France, described this syndrome in 1896.
Albert Terson, 1867–1935, French ophthalmologist.
Franciscus Sylvius, 1614–1672, a Dutch physician, chemist, physiologist and anatomist.

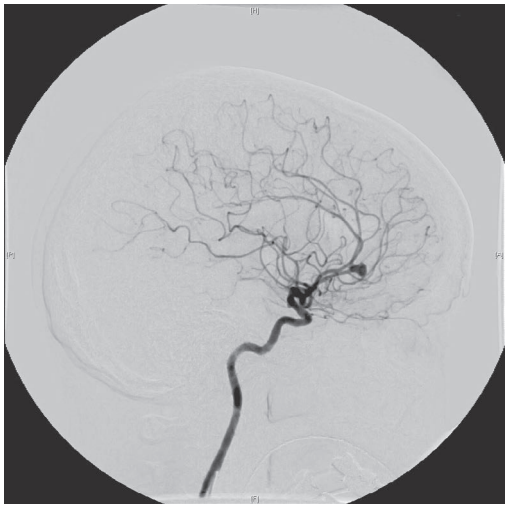

Figure 48.15 There is a small saccular aneurysm of the pericallosal branch of the anterior cerebral artery.

The sensitivity of CT scan, however, deteriorates to less than 50% at 1 week after a bleed. In light of this, patients with a suggestive history and negative CT scan will require lumbar puncture, especially where presentation is delayed. The CSF supernatant should be analysed by spectrophotometry (visual inspection is not reliable) for the spectra of haemoglobin breakdown products oxyhaemoglobin and bilirubin. These are present in samples taken at least 6 and preferably 12 hours after SAH, but not in CSF mixed with fresh blood due to traumatic puncture and analysed immediately. Failure to exclude SAH with an adequate lumbar puncture sample can result in diagnostic confusion and overtreatment.

Aneurysms can be visualised by CT and magnetic resonance angiography, but the gold standard remains digital subtraction angiography (DSA), which involves access to both vertebral and carotid arteries through the femoral artery under local anaesthetic. This allows visualisation of the vascular anatomy by injection of contrast medium with simultaneous radiographic screening (***Figure 48.15***). The serious potential risks include ischaemic stroke or arterial dissection (1–2%), and renal failure or allergic reactions attributable to contrast.

Surgical/interventional management

Aneurysms may be removed from the circulation surgically by craniotomy and 'clipping' or by endovascular embolisation, also known as 'coiling' (***Figure 48.16***). Sometimes mesh stents may also be used to help secure the metal coils within the aneurysm sac as part of this procedure. Class 1 evidence suggests that coiling has slightly better outcomes where feasible, but clipping remains necessary or preferable in many cases; these decisions are shared between surgeons, radiologists and the patient. A rebleed risk of 4% in the first 24 hours then 1.5% per day thereafter is quoted for untreated aneurysms; 80% of patients who rebleed have an eventual poor outcome. For this reason, and to permit optimal management of vasospasm, the current consensus favours early intervention, despite the surgical challenges presented by brain swelling and blood load.

Unruptured aneurysms represent a thorny management problem: incidentally detected small anterior circulation aneurysms represent a minimal bleeding risk. Screening, even in high-risk groups, is therefore of questionable benefit.

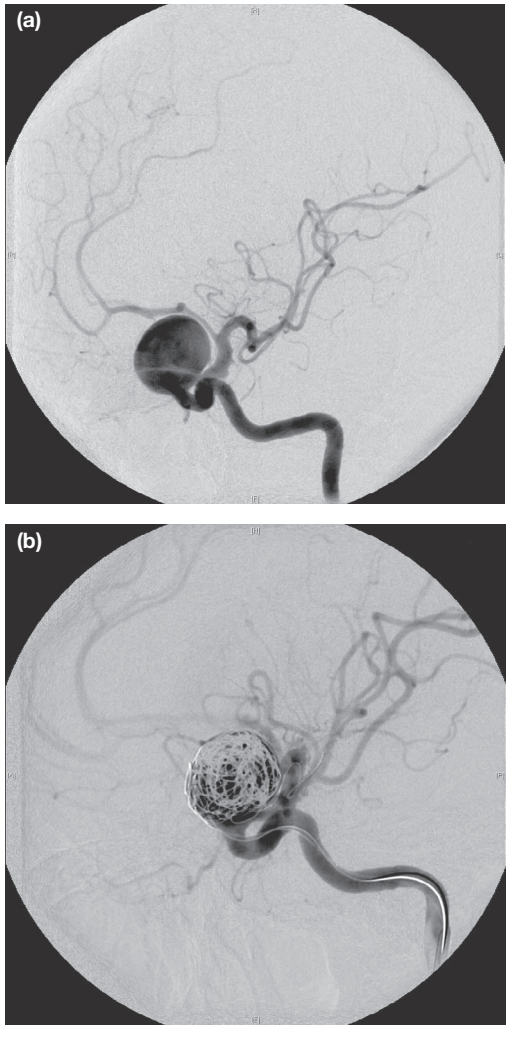

Figure 48.16 (a) A giant aneurysm of the internal carotid artery. **(b)** Angiographic embolisation (coiling) of the giant aneurysm. Note the single displaced coil passing into the distal internal carotid artery and then the middle cerebral artery.

Medical management

Patients should be placed on bed rest with hourly neuro-observations. They require strict input–output monitoring and intravenous fluid replacement with normal saline initially. Oral nimodipine at a dose of 60 mg every 4 hours is administered to reduce the incidence of vasospasm and delayed ischaemic neurological deficit. Analgesics, laxatives, antiemetics, gastric protection and compression stockings are also likely to be necessary. After resuscitation, the priorities in SAH are to:

1. prevent rebleeding by identifying and controlling any underlying lesion;
2. recognise and manage:
   - neurological complications, especially vasospasm, delayed ischaemic neurological deficit and hydrocephalus;

- systemic complications, including electrolyte imbalance, severe hypertension, cardiac infarct and arrhythmia, and neurogenic pulmonary oedema.

These goals are best served by early transfer of the patient to a neurosurgical centre. In elderly patients with a poor WFNS grade, a decision to offer only supportive management may be appropriate.

Neurological deterioration should prompt a repeat scan to exclude evidence of rebleeding and of hydrocephalus. This is typically the communicating type, which is a common complication of haemorrhage. Where these complications are not demonstrated, deterioration may reflect delayed ischaemic neurological deficit (DNID), which commonly develops 3–10 days after aneurysmal haemorrhage and can progress rapidly to infarction. The process is attributed to cerebral vasospasm in response to, and correlating with, the blood load. This process can be visualised angiographically or by perfusion CT, and the velocity of blood flow in the cerebral vasculature measured using transcranial Doppler ultrasound can also provide an indirect assessment of the degree of stenosis. Outcomes are optimised by the prophylactic administration of nimodipine and maintenance of fluid volume, typically with 2.5–3 L/day of normal saline. In established vasospasm, the goal is to maintain cerebral perfusion by administration of fluid and inotropes.

Hyponatraemia is a frequent complication of SAH, attributed to cerebral salt wasting in the context of fluid depletion and to the syndrome of inappropriate antidiuretic hormone secretion otherwise. This is associated with a higher incidence of DNID; practical management, irrespective of the underlying pathology, is based on sodium replacement with hypertonic infusions if necessary. Fluid restriction is not appropriate in these patients since this risks further compromising perfusion.

Summary box 48.7

Subarachnoid haemorrhage

- Most result from rupture of an aneurysm in the circle of Willis
- Plain CT and lumbar puncture are first-line investigations
- Even 'good grade' patients treated promptly have a significant morbidity owing to vasospasm, cardiac arrhythmias, neurogenic pulmonary oedema, etc.

Intracerebral haemorrhage

Intracerebral haemorrhage (ICH) typically presents with sudden focal deficit and a reduced conscious level. Following initial resuscitation, these patients will require CT scan to establish the diagnosis and the size and position of the bleed (***Figure 48.17***). They require reversal of anticoagulation, ongoing hourly neuro-observations and blood pressure monitoring. High blood pressure may be longstanding and associated with adaptations to autoregulation, so attempts at lowering it acutely with intravenous antihypertensives should be made only if the values are very high (e.g. mean arterial pressure >130 mmHg).

Spontaneous ICH accounts for 10–15% of strokes and has a mortality of 40% at 1 year. The majority occur in the context of hypertension or amyloid angiopathy, or as a complication of ischaemic stroke. Coagulation disorders, especially patients being treated with warfarin, are a major risk factor. In younger patients and where the pattern of bleeding is atypical, dedicated imaging to rule out an underlying vascular anomaly or tumour is required. For example it is critically important to identify ICH due to aneurysm rupture or AVM before considering surgical intervention.

Craniotomy and evacuation may be used to alleviate raised ICP. Importantly this surgery may be life-saving by relieving raised ICP but cannot reverse deficits resulting from the haematoma directly. Surgical evacuation would typically be a good option for younger, fitter patients with signs of raised ICP and haematomas close to the cortical surface or in the posterior fossa.

Summary box 48.8

Intracerebral haemorrhage

- These account for 10–15% of strokes
- Presentation is with headache, focal deficits and signs of raised ICP
- High blood pressure may be chronic so should only be reduced with care
- Anticoagulants should be reversed
- In fit patients, clot evacuation is an option to relieve raised ICP but not reverse deficits
- Further imaging may be required to exclude an underlying vascular or neoplastic lesion

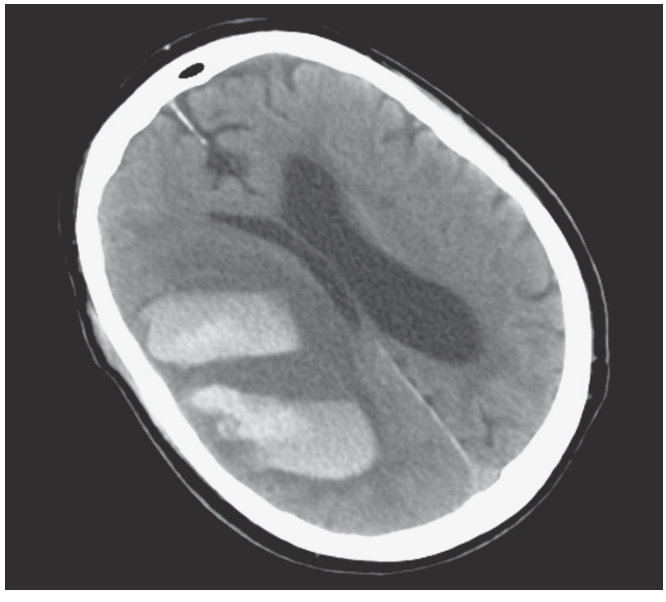

Figure 48.17 Large acute intracerebral haemorrhages in the right frontal and parietal lobes are evident, with surrounding oedema and midline shift.

Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the 'Doppler principle' in 1842.

Vascular malformations

Vascular malformations are usually congenital in origin, with certain key exceptions discussed below. They may present with headaches, pulsatile tinnitus, seizures or focal deficit, or else acutely with rupture and haemorrhage.

AVMs are responsible for a small proportion of SAHs and ICHs. Vessels and calcification may be apparent on CT or MRI and the lesion is confirmed on angiography (***Figure 48.18***).

Depending on the size, location and venous drainage patterns, surgery or radiosurgery are usually preferred treatment options. In some cases endovascular embolisation with tissue glue may have a role, and for many AVMs there is no treatment with a satisfactory risk–benefit ratio.

Vein of Galen malformations are AVMs feeding into an embryological venous remnant dorsal to the brainstem, presenting in childhood. High-flow malformations may cause cardiac failure. They may be treated by embolisation.

Dural arteriovenous fistulae (DAVFs) are shunts between dural arteries and veins or sinuses. They are proposed to arise as a result of vessel remodelling in response to dural sinus thrombosis and subsequent recanalisation. They may present with subarachnoid, intracerebral or subdural bleeding, or with headache and pulsatile tinnitus. A carotid cavernous fistula is a spontaneous or traumatic DAVF between the internal carotid artery and surrounding cavernous sinus, typically producing eye pain, ocular muscle palsies and exophthalmos. Angiography is diagnostic.

Cavernomas (***Figure 48.19***) are discrete venous anomalies within brain tissue, visible on MRI but not angiography, that can bleed repeatedly, causing progressive deficit. They can be removed surgically if required.

Related lesions, usually clinically silent, include developmental venous anomalies and capillary telangiectasia.

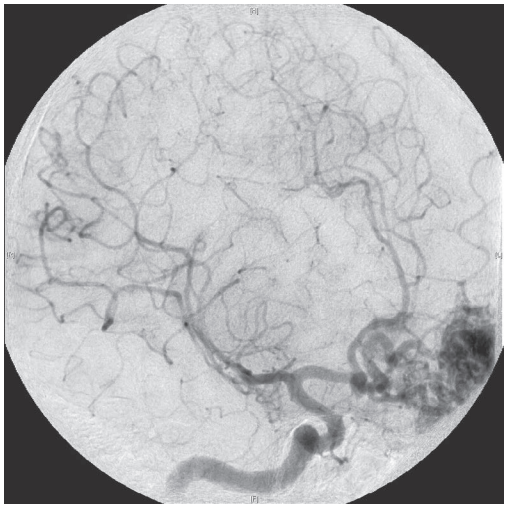

Figure 48.18 An arteriovenous malformation supplied by the anterior cerebral, middle cerebral and middle meningeal arteries is demonstrated at the 4 o'clock position in this angiogram.

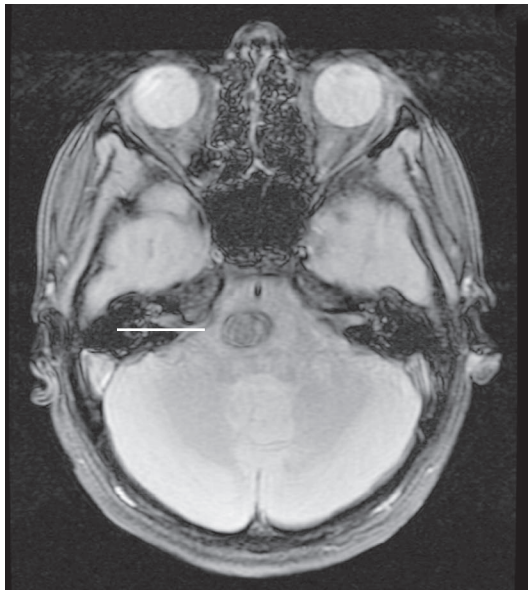

Figure 48.19 A brainstem cavernoma (arrow).

Neurosurgery in occlusive vascular disease

In a subgroup of patients with completed ischaemic strokes, generally in the middle cerebral artery territory or posterior fossa, there is a role for decompressive craniectomy in the 2–3 days after ictus to manage brain swelling and raised ICP associated with the infarct.

There is class 1 evidence for the role of carotid endarterectomy in reducing the risk of stroke in patients with symptomatic carotid stenosis, and a debatable role for the procedure in patients with no previous transient ischaemic episodes.

Moyamoya disease entails the progressive obliteration of one or both internal carotid arteries, thought to represent an autoimmune process. The development of external carotid circulation collaterals produces the angiographic 'puff of smoke' appearance from which the term derives. It presents in youth or early middle age with ischaemia or haemorrhage. Untreated, the majority of patients suffer major deficit or die within 2 years. Ischaemia may be addressed by a variety of bypass techniques, for example by anastomosing the superficial temporal artery (arising from the external carotid) to the middle cerebral artery.

BRAIN TUMOURS

The term 'brain tumour' applies to more than 100 distinct pathologies detailed in the World Health Organization (WHO) classification. Many are malignant, but even histologically benign tumours may carry a grave prognosis when they encroach on key structures that also limit surgical access. The commonest brain tumour is a metastasis. Primary brain

Galen, 130–200, Roman physician, commenced practice as Surgeon to the Gladiators at Pergamum (now Bergama in Turkey) and later became personal physician to the Emperor Marcus Aurelius and to two of his successors. He was a prolific writer on many subjects, among them anatomy, medicine, pathology and philosophy. His work affected medical thinking for 15 centuries after his death. (Gladiator is Latin for 'swordsman'.)

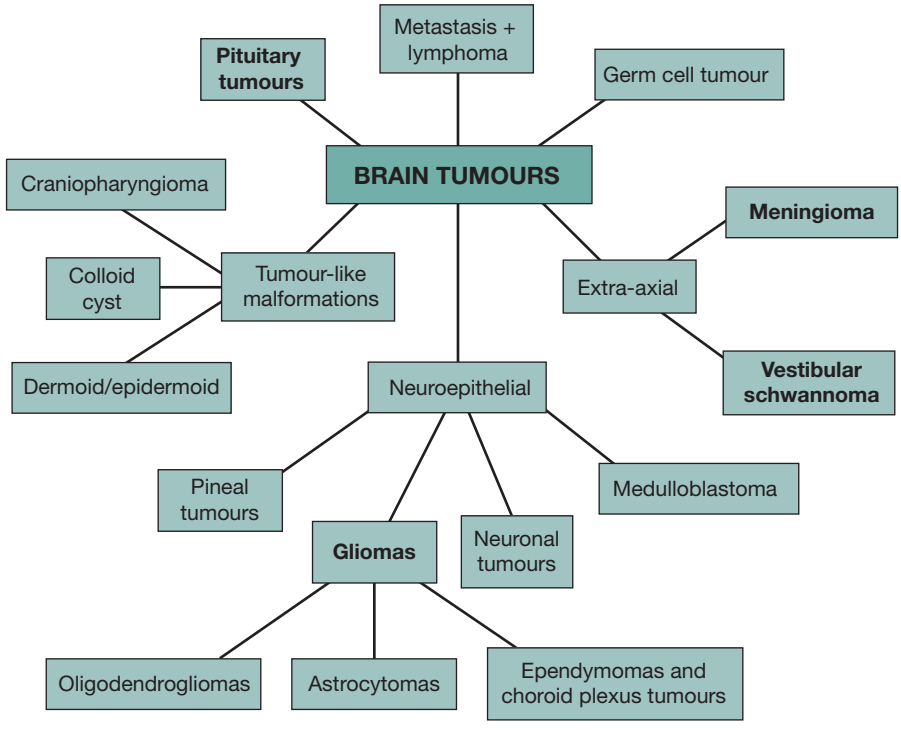

Figure 48.20 Brain tumour classification. A simplified schema encompassing some of the key brain tumour categories. Highlighted in bold are the pathologies discussed in more detail in this chapter.

tumours represent 1.5% of all cancers, with an incidence of 19 per 100 000 person-years. Nevertheless many, especially glial, tumours present commonly in younger age groups and are incurable, so that they are a leading cause of life-years lost to cancer.

Classification

WHO classifies primary brain tumours on the basis of cell of origin and histological grade (***Figure 48.20***), with the 2016 edition including a number of additional molecular classifications assigned in parallel to constitute an 'integrated' diagnosis.

Common adult primary brain tumours include gliomas, meningiomas (15–20% of total), pituitary adenomas (10–15% of total) and vestibular schwannomas.

Grade I is applied to 'benign' lesions, while grade IV implies high-grade malignancy.

TABLE 48.5 Chromosomal abnormalities associated with brain tumours.

Syndrome	Gene defect	Tumour
Neurofibromatosis type 1	*Neurofibromin* (chromosome 17)	Astrocytomas; neurofibromas
Neurofibromatosis type 2	*Schwannomin* (chromosome 22)	Acoustic neuromas (bilateral); meningiomas
Cowden's disease	*PTEN* (chromosome 10)	Astrocytomas
Hereditary non-polyposis colorectal cancer	Multiple	Astrocytomas
Li–Fraumeni syndrome	*p53* (chromosome 17)	Astrocytomas

PTEN, phosphatase and tensin homologue.

Aetiology

The common primary brain tumours mentioned above mostly occur sporadically. There is no proven risk due to environmental factors, except for radiation exposure, but germline genetic syndromes may also predispose (***Table 48.5***).

Presentation

Most tumours present with one or more features belonging to three cardinal categories: these are seizure, raised ICP and focal neurological deficit. Pituitary adenomas may also present with endocrine disturbance.

Theodor Schwann, 1810–1882, Professor of Anatomy, Louvain and Liège, Belgium. German physiologist who established the cellular basis of differentiated tissues including feathers.

One of the few clinical syndromes named for the patient rather than the clinician. **Rachel Cowden** was, in 1963, the first patient described with the syndrome. She died from breast cancer at the age of 20.

Frederick Pei Li, 1940–2015, Professor of Medicine, Harvard University Medical School, Boston, MA, USA.

Joseph F Fraumeni, b. 1933, Director of Cancer Epidemiology and Genetics, The National Cancer Institute, Bethesda, MD, USA.

Seizures

Seizures are a common presenting feature, especially of low-grade gliomas arising in the cortical hemispheres. Simple partial seizures, involving focal twitching or similar with preserved consciousness, are the rule, but temporal location will commonly produce complex partial seizures, and any seizure may progress to a secondary generalised tonic–clonic fit.

Patients who have had a seizure should be started on an antiepileptic drug, typically levetiracetam. Routine prophylaxis in patients with tumours who have no history of seizures is not recommended, although a short course at the time of craniotomy for tumour excision may be warranted.

Raised intracranial pressure

Headache is a presenting feature in only about 50% of patients. It is classically worse in the morning and on straining (high-pressure features) and is accompanied by nausea and vomiting. Pressure effects develop as a result of the tumour mass effect and surrounding oedema, especially in fast-growing metastases and high-grade gliomas (see main section on ***Raised intracranial pressure***). After excluding the possibility of brain abscess (see ***Brain abscess and empyema***), the mass effect is controlled initially using high-dose glucocorticoids (e.g. dexamethasone) and, especially in the case of posterior fossa tumours, early external ventricular drainage may be required to treat obstructive hydrocephalus.

Focal neurological deficit

A focal deficit that is progressive over time, as opposed to the sudden onset of a vascular accident, is suspicious of tumour. Lesions in specific locations can produce characteristic patterns of deficit due to compression of local structures (***Table 48.6***).

TABLE 48.6 Patterns of deficit generally associated with certain tumours.

Tumour location	Expected deficit
Pituitary (e.g. pituitary adenoma)	Bitemporal hemianopia; gaze palsies
Cerebellopontine angle (e.g. vestibular schwannoma)	Hearing loss; balance disturbance; tinnitus
Anterior skull base (e.g. olfactory groove meningioma)	Anosmia; ipsilateral optic atrophy; contralateral papilloedema (Foster Kennedy syndrome)
Occipital (e.g. glioma, metastasis)	Homonymous hemianopia with central sparing
Parietal (dominant hemisphere)	Acalculia; agraphia; left–right disorientation; finger agnosia (Gerstmann's syndrome)
Parietal (e.g. glioma)	Sensory inattention; dressing apraxia; astereognosis
Temporal (e.g. glioma)	Memory disturbance; contralateral superior quadrantanopia; dysphasia (dominant hemisphere)
Frontal (e.g. glioma)	Personality change; gait disturbance; urinary incontinence
Brainstem (e.g. brainstem glioma)	Multiple cranial nerve deficits; long tract signs; nystagmus
Posterior fossa (e.g. medulloblastoma)	Ataxia; hydrocephalus

Summary box 48.9

Brain tumours

Most brain tumours will present with one or more features related to the following triad:

- Raised ICP
- Seizures
- Focal deficit

Common brain tumours

Cerebral metastases

Cerebral metastases (***Figure 48.21***) are the most common intracranial tumours and are diagnosed in 25% of patients with cancer, a proportion that is increasing with extended survival associated with more effective treatment of primary cancers. The tumours of origin and their contribution to the burden of cerebral metastases are detailed in ***Table 48.7***. Traditionally

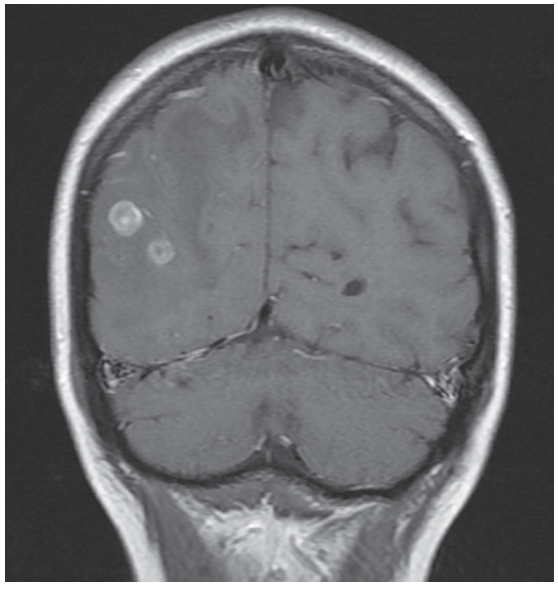

Figure 48.21 T1-weighted magnetic resonance imaging with contrast. Two right occipital lung metastases are demonstrated. They are well demarcated and enhance with gadolinium contrast.

Robert Foster Kennedy, 1884–1952, British Neurologist, awarded the Chevalier de la Légion d'honneur in recognition of his service in French front-line field hospitals in the First World War.

Josef Gerstmann, 1887–1969, Austrian neurologist who fled to America in 1938 to escape the Nazis.

patients with multiple cerebral metastases were deemed unsuitable for surgery. In patients with good functional status and well-controlled systemic disease, craniotomy for resection of a single focus, and in selected cases multiple lesions, may confer symptomatic and survival benefits. New molecular therapies can control systemic disease in many cancers; in these cases craniotomy and resection of one or more lesions responsible for the mass effect or hydrocephalus with medical treatment of the remaining lesions may be well warranted. Occasionally diagnostic biopsy may be warranted where the primary is unknown.

TABLE 48.7 Tissue of origin for brain metastases (approximate).

Origin	Percentage
Lung	40
Breast	15
Melanoma	10
Renal/genitourinary	10
Other/unknown	25

Glioma

These are intrinsic tumours with glial histology, with subtypes including astrocytomas, oligodendrogliomas, ependymomas and mixed tumours. This is a tissue diagnosis, but imaging often predicts both a glial origin and the grade of tumour (***Figure 48.22***). Low-grade glioma (WHO grade II) has a peak incidence in the fourth decade of life, and commonly presents with seizures initially. High-grade gliomas include anaplastic astrocytoma (WHO grade III) and glioblastoma (WHO grade IV), the commonest glial tumour (***Figure 48.23***). They typically present *de novo* with the peak incidence in the fifth and sixth decades of life, respectively, or arise by transformation of low-grade tumours.

Figure 48.22 Computed tomography with contrast demonstrates a heterogeneous right frontoparietal lesion with mass effect and midline shift, almost certainly a glioblastoma multiforme. A magnetic resonance imaging scan with and without contrast will aid evaluation.

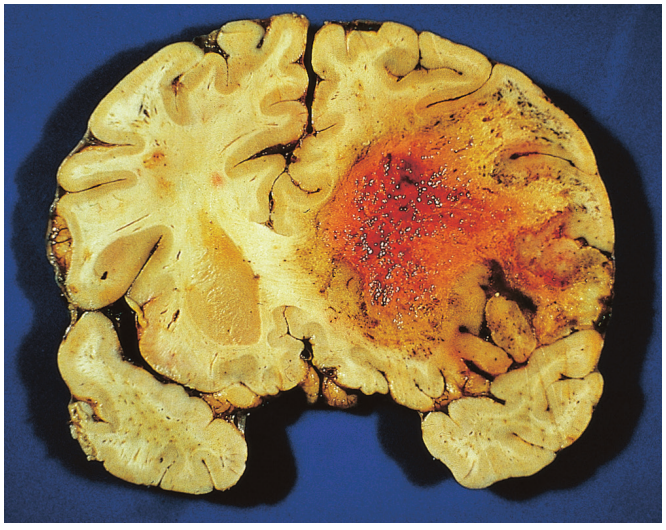

Figure 48.23 Pathological specimen of glioblastoma multiforme.

MRI of the head with and without contrast is the preferred modality, generally combined with CT of the chest, abdomen and pelvis to exclude an extracranial primary, since metastasis is usually the main differential diagnosis. Diffusion-weighted MRI sequences are valuable in excluding another key differential diagnosis – brain abscess, which is associated with prominent restricted diffusion in these images.

Initial management of these tumours should generally include high-dose steroids to alleviate any mass effect. Antiepileptics are administered when seizures are a presenting feature or are anticipated in view of the temporal location. Surgical resection is usually the primary treatment, with the aim of reducing disease burden and obtaining tissue for diagnosis. When tumours encroach on the eloquent cortex, especially the speech areas of the dominant hemisphere which are not consistently anatomically localised, awake craniotomy allows for mapping of speech function. Except for grade I pilocytic astrocytomas typically found in children, gliomas are notable for diffuse infiltration into the surrounding brain, so that recurrence after even macroscopically complete resection is the rule.

The classification of gliomas has been significantly updated with the recent addition of integrated molecular diagnostic categories to the WHO 2016 classification (***Figure 48.24***). Gliomas with low-grade histology often carry characteristic mutations; for example, point mutations in isocitrate dehydrogenase (*IDH*) enzymes and 1p/19q chromosomal co-deletion, the latter specific to oligodendrogliomas. Glioblastomas are WHO grade IV tumours and include *IDH* wild-type 'primary' glioblastoma and occasional *IDH* mutant 'secondary' glioblastomas. These are thought to arise from transformation of previously diagnosed, or clinically silent, low-grade gliomas. *IDH* wild-type status is a strong predictor of aggressive malignant behaviour, even in the absence of high-grade histological features. Active treatment consists of maximal surgical resection, typically with the assistance of intraoperative neuronavigation systems to accurately localise the tumour.

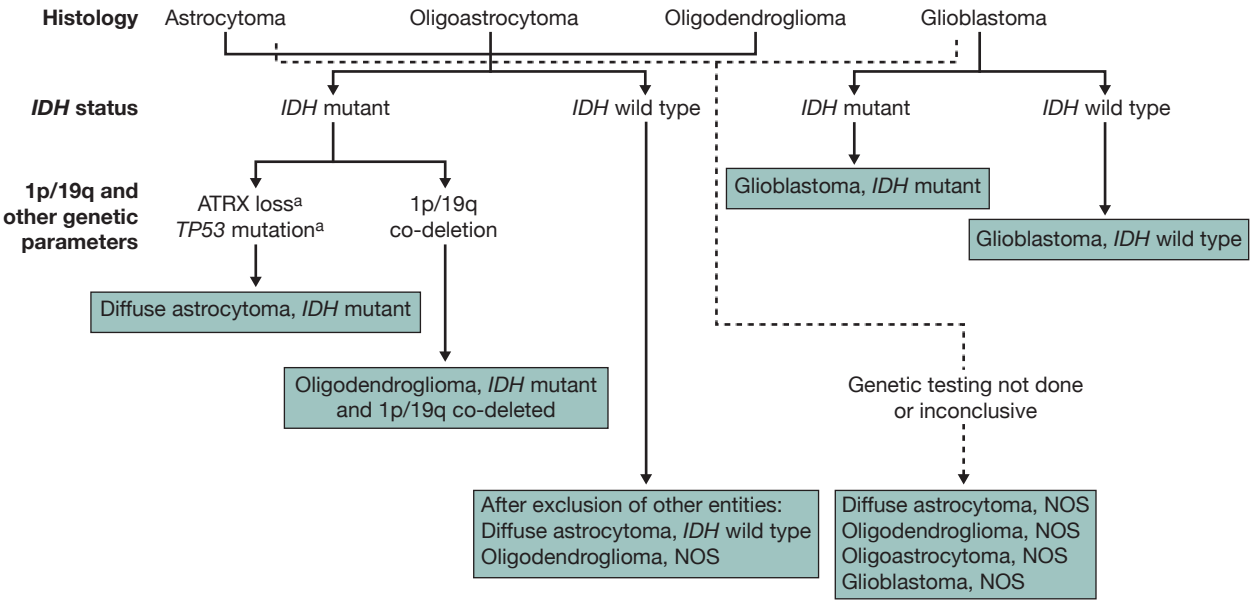

Figure 48.24 World Health Organization 2016 classification of gliomas. ATRX, α-thalassaemia/mental retardation syndrome X-linked; IDH, isocitrate dehydrogenase; NOS, not otherwise specified. [a]Characteristic but not required for diagnosis. (Reproduced from Louis DN, Perry A, Reifenberger G *et al*. The 2016 World Health Organization classification of tumors of the central nervous system: a summary. *Acta Neuropathol* 2016; **131**(6): 803–20, with permission from Springer.)

Patients can also be dosed with 5-aminolevulinic acid (5-ALA) preoperatively. Protoporphyrin IX, a fluorescent metabolite of this drug, accumulates selectively in glioma cells, causing them to glow pink under ultraviolet light, so providing a real-time assessment of tumour infiltration at the resection boundaries.

First-line adjuvant treatment in malignant glioma includes high-dose focused radiation therapy and alkylating chemotherapy with oral temozolomide. Median survival for glioblastoma remains just over 12 months.

Meningioma

Meningiomas are usually benign lesions, although anaplastic variants do occur. They arise from the meninges and typically present as a result of the mass effect from the tumour, compounded by vasogenic oedema in the adjacent brain and obstructive hydrocephalus where CSF drainage is impaired. Imaging will demonstrate a contrast-enhancing mass distinct from the brain with a dural base (***Figure 48.25***).

These are generally slow-growing lesions: smaller lesions, perhaps detected incidentally in an elderly patient, may well warrant a 'watch-and-wait' approach. If the lesion is large or positioned so as to impinge on key structures, the patient may require steroids and early surgery. The degree of resection predicts recurrence, with rates of 10% at 10 years for total excision with a clear dural margin and 30% at 10 years for subtotal excision. Lesions that are difficult to approach surgically may be managed with radiotherapy or stereotactic radiosurgery.

Summary box 48.10

Common supratentorial brain tumours

- Metastases and gliomas are common tumours arising within brain substance, appearing as 'ring-enhancing' lesions on contrast CT. Surgery is usually life-extending rather than curative
- Meningiomas arise from the meninges around the brain and typically enhance uniformly on contrast CT. Most are benign and amenable to curative resection
- MRI is usually the best modality for evaluating brain tumours. Diffusion-weighted sequences help to exclude abscess when glioma or metastasis is suspected
- Metastasis is the main differential diagnosis, and CT of the body is useful in identifying extracranial primary tumours
- Steroids, along with proton pump inhibitor treatment for gastric protection, are administered to control swelling and the mass effect in the short term

Pituitary tumours

Most tumours in the sellar region are benign pituitary adenomas, but pathology in this region can also include malignant variants as well as craniopharyngiomas, meningiomas, aneurysms and Rathke's cleft cysts (***Figure 48.26***).

Microadenomas are less than 10 mm in size and usually present incidentally or with endocrine effects. Macroadenomas are larger than 10 mm and often present with visual

Martin Heinrich Rathke, 1793–1860, German anatomist.

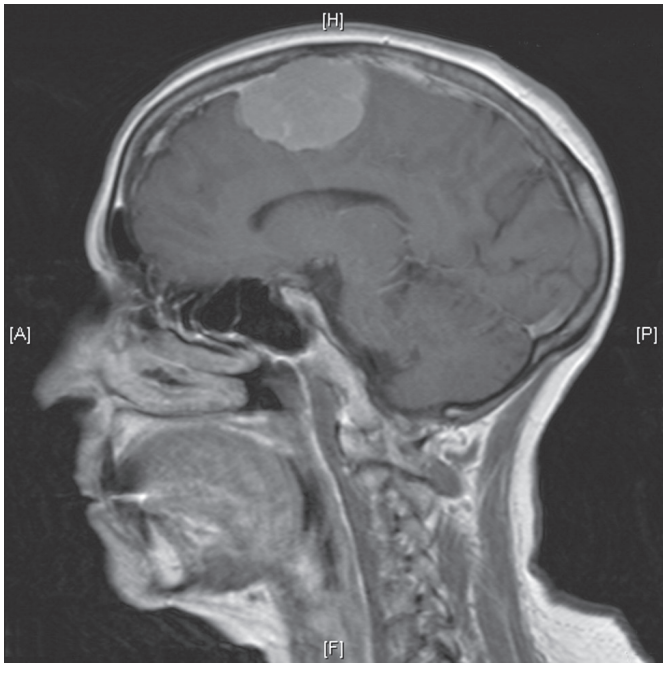

Figure 48.25 On T1-weighted magnetic resonance imaging an extra-axial, durally based lesion is seen to arise in the region of the falx. This is a meningioma.

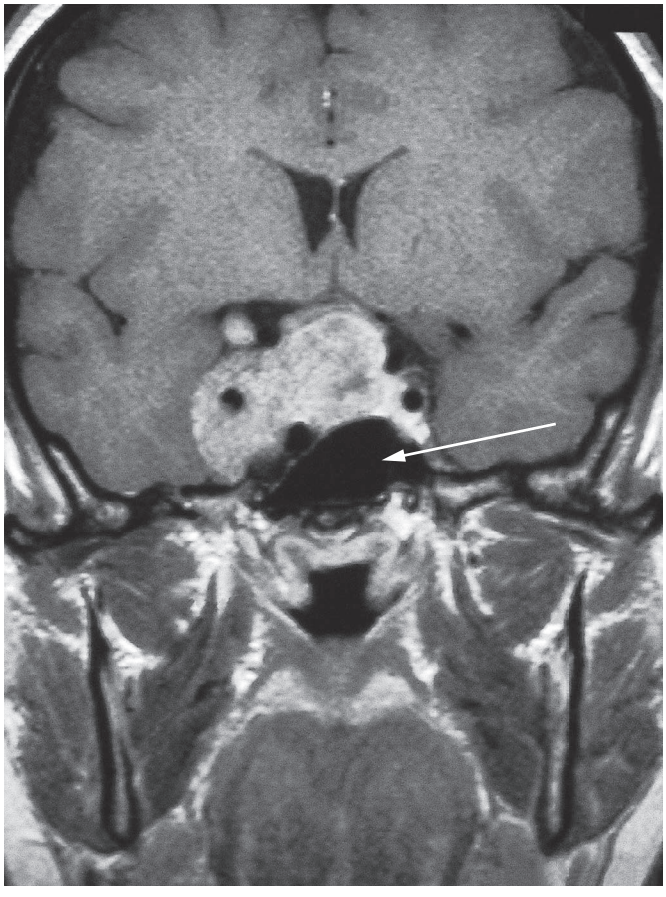

Figure 48.26 Non-functioning pituitary macroadenoma (arrow) compressing the optic chiasm superiorly, extending into the right cavernous sinus and encasing the right carotid artery.

field deficits. Thirty per cent of adenomas are prolactinomas, 20% are non-functioning, 15% secrete growth hormone and 10% secrete adrenocorticotropic hormone (ACTH).

Features of note in the initial assessment include any history of galactorrhoea (suggestive of prolactinoma) and Cushingoid or acromegalic features pointing to ACTH- or growth hormone-secreting tumours, respectively. Baseline assessment of pituitary function should include serum prolactin, follicle-stimulating hormone and luteinising hormone together with testosterone in males or oestradiol in females, thyroid function tests and fasting serum growth hormone and cortisol. Preoperative prolactin levels are crucial since prolactinomas may be managed with dopamine agonists such as bromocriptine and cabergoline rather than surgery. Growth hormone-secreting tumours may also respond to dopamine agonists or to somatostatin analogues such as octreotide. The cortisol level is also important since deficiency must be corrected, especially in the perioperative period. Diagnosis of ACTH-secreting tumours can be difficult and may require the use of specialised tests such as petrosal sinus sampling and the dexamethasone suppression test.

Effective treatment requires close cooperation between the neurosurgical team and an endocrinologist. Compression of the chiasm with any evidence of visual compromise is the main indication for urgent surgical intervention.

Surgical resection is usually performed by a transsphenoidal approach through the nose, using a microscope or endoscope. Sometimes large tumours also require a craniotomy. After operation patients are at risk of CSF leak and pituitary insufficiency. Diabetes insipidus resulting from manipulation of the pituitary stalk is possible in the immediate postoperative period and usually resolves spontaneously. Where it is suspected, the patient will require hourly measurement of urine output and blood and urine samples for calculation of sodium concentration and osmolality. If confirmed, the condition can be managed with desmopressin in consultation with endocrinology.

Pituitary apoplexy is a syndrome associated with haemorrhage or infarction in a pituitary tumour. It presents with sudden headache, visual loss and ophthalmoplegia with or without impaired conscious level. Endocrine resuscitation with intravenous steroids is the priority and surgical decompression may be required.

Vestibular schwannoma

These are nerve sheath tumours arising in the cerebellopontine angle (***Figure 48.27***) that present with hearing loss, tinnitus and balance problems. Facial numbness and weakness are less common, while large tumours may present with features of brainstem compression or hydrocephalus. The differential

Harvey Williams Cushing, 1869–1939, Professor of Surgery, Harvard University Medical School, Boston, MA, USA; credited as the father of modern neurosurgery; described the eponymous disease but also pioneered new techniques in bacteriology, blood pressure measurement and electrocautery.

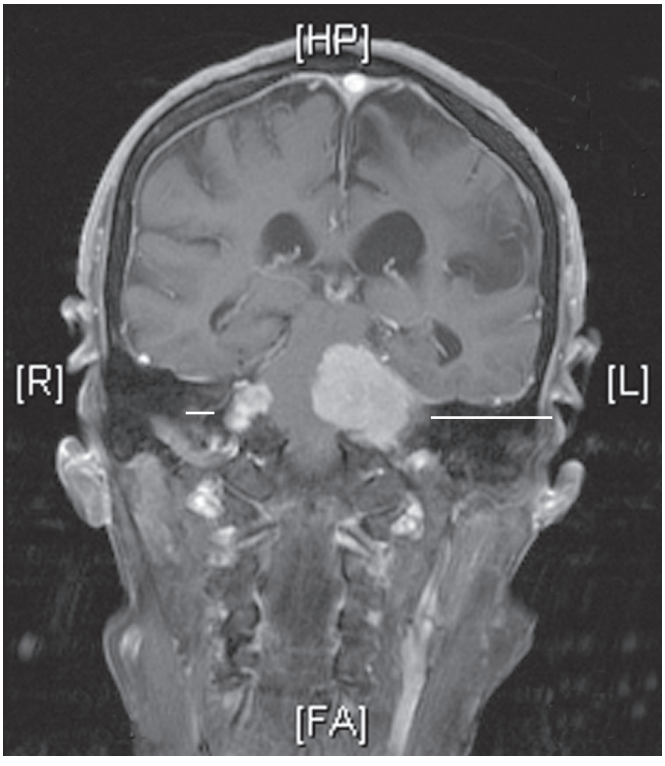

Figure 48.27 The appearances of a meningioma in the left cerebellopontine angle (CPA) (long arrow), with a coexisting vestibular schwannoma in the right CPA (short arrow).

diagnosis includes meningioma, metastasis and epidermoid cyst.

Small intracanalicular tumours (within the internal auditory canal) may be managed with surveillance. For intermediate size tumours, radiosurgery is an alternative to operation. Large lesions (>4 cm), especially with brainstem compression, will require excision and consideration of ventriculoperitoneal shunt to relieve hydrocephalus. Translabyrinthine, retrosigmoid and middle fossa approaches are possible, the latter options offering potential preservation of hearing in smaller tumours with some intact function at presentation. Patients with larger tumours will typically have no serviceable hearing in the affected ear and the focus is then on preserving facial nerve function.

Summary box 48.11

Skull base and paediatric tumours

- Pituitary tumours typically present with endocrinological disturbance (microadenomas) or visual deficits due to compression (macroadenomas). Some of these tumours are managed surgically, in close cooperation with endocrinologists
- Vestibular schwannomas (acoustic neuromas) are benign nerve sheath tumours, usually presenting with hearing loss, tinnitus and balance problems. Their proximity to the brainstem allows them to cause significant morbidity and mortality and can present a major surgical challenge

PAEDIATRIC NEUROSURGERY

Paediatric neurosurgery incorporates the management of tumours and developmental abnormalities, for example cysts, neural tube defects and posterior fossa malformations. In general these present with combinations of developmental delay, seizures and macrocephaly or hydrocephalus. Early fusion of one or more cranial sutures, craniosynostosis, is also a common neonatal presentation.

Brain tumours in children

Brain tumours are the most common solid tumours in children but are nonetheless seen only infrequently outside specialist units. They typically present with developmental regression and enlarging head circumference in the youngest, with headache, seizure and focal deficits prominent in older children.

Posterior fossa tumours are relatively more common in children, in particular:

- medulloblastoma;
- ependymoma;
- pilocytic astrocytoma.

Treatment will typically combine surgical resection or biopsy, CSF diversion, chemotherapy and/or radiotherapy.

Cysts

These benign fluid-filled intracranial lesions typically present incidentally or with mass effect or hydrocephalus. Treatment of symptomatic or enlarging lesions is usually surgical, involving excision, endoscopic fenestration into a cistern or ventricle or shunting for hydrocephalus. Cyst types include:

- arachnoid cyst: typically middle fossa, CSF enclosed in an envelope of arachnoid mater;
- colloid cyst: occur in the roof of the third ventricle, believed to represent embryonic endoderm remnants;
- dermoid and epidermoid cysts: epithelium-lined structures arising from displaced ectodermal remnants, typically in the posterior fossa (midline) and cerebellopontine angle, respectively;
- porencephalic cysts: brain cavities lined with gliotic white matter, containing CSF in communication with the ventricles or subarachnoid space.

Neural tube defects

Failure of closure of the neural tube is associated with folate deficiency, family history and some anticonvulsants. Prenatal screening, using serum α-fetoprotein levels and ultrasound, and diagnostic testing, using amniocentesis, are possible. The spectrum of conditions associated with failed closure of the posterior neuropore includes the conditions described below.

Spina bifida occulta

A congenital absence of a spinous process, without exposure of meninges or neural tissue, but presenting a characteristic shallow hair-covered hollow at the base of the spine. This is common and rarely clinically significant.

Sometimes it may be associated with tethered cord syndrome, which involves thickening of the filum terminale, resulting in traction on the cord. Presentation is with progressive deficits, spasticity, bladder dysfunction or scoliosis, and treatment involves surgical exploration and untethering of the cord.

Meningocele

A sac of meninges, covered by skin and containing CSF alone, herniates through an anterior or posterior bony defect.

Myelomeningocele

A herniating sac of meninges without covering skin contains spinal cord, nerves or both. This is always associated with Chiari II malformation (see ***Posterior fossa malformations***). Open myelomeningocele presents a high infection risk and requires early surgical repair.

Lipomyelomeningocele

Adipose tissue adherent to the spinal cord herniates through a bony defect to the sacrolumbar soft tissue. This may be associated with bladder dysfunction and require surgical relief of the resultant cord tethering.

Failure of closure of the anterior neuropore produces anencephaly, which is uniformly fatal; the spectrum of spinal dysraphisms, however, is replicated in the skull. Cranium bifidum is a failure of fusion, often in the occipital region. This may be associated with herniation of meninges and CSF (meningocele) and potentially also brain substance (encephalocele) (***Figure 48.28***).

Posterior fossa malformations

Chiari malformations involve cerebellar herniation through the foramen magnum:

- Normal: up to 5 mm of cerebellar tonsillar descent through the foramen magnum.
- Chiari I: >5 mm of tonsillar descent; presents typically in young adults with cough headaches and neurological disturbance reflecting brainstem/cerebellar compression and/or formation of a fluid-filled syrinx in the spinal cord as a result of disordered CSF flow. Shunting and foramen magnum decompression are the mainstay of treatment.
- Chiari II: descent of the tonsils and vermis associated with myelomeningocele and hydrocephalus, so clinically apparent in infancy.

Dandy–Walker malformations present in infancy with macrocephaly, developmental delay and hydrocephalus; most patients have associated abnormalities in the CNS and other organ systems. Imaging demonstrates a hypoplastic cerebellar vermis, with the posterior fossa occupied by a large thin-walled cyst. Treatment usually involves shunt placement.

Figure 48.28 An occipital encephalocele.

Craniosynostosis

Normal fusion of the coronal, lambdoidal, squamosal and sagittal sutures occurs between 6 and 12 months of age; others such as the frontal suture fuse later. Craniosynostosis is the premature fusion of one (simple craniosynostosis) or more (complex craniosynostosis) cranial sutures, preventing growth perpendicular to the suture. This results in a range of skull deformities (***Table 48.8*** and ***Figures 48.29 and 48.30***) and hydrocephalus. Syndromic craniosynostosis, often associated with abnormalities of the fibroblast growth factor receptor genes, is accompanied by developmental delay and other abnormalities. The surgical treatment aims to correct deformity and prevent development of raised ICP.

TABLE 48.8 Types of craniosynostosis.

Type	Suture involved	Clinical features
Scaphocephaly	Sagittal suture	Narrow boat-shaped head
Brachycephaly	Coronal suture	Shortened/broad forehead
Microcephaly	All sutures involved	Small head
Plagiocephaly	Unilateral coronal/ lambdoid suture	Asymmetric skull
Trigonocephaly	Metopic suture	Pointed narrow forehead

FUNCTIONAL NEUROSURGERY

Functional neurosurgery aims to relieve epilepsy, movement disorders or pain by ablation or stimulation of brain tissue and nerves.

Hans Chiari, 1851–1916, Professor of Pathological Anatomy, Strasbourg, Germany (Strasbourg was returned to France in 1918 after the end of the First World War), gave his account of this condition in 1891.
Walter Edward Dandy, 1886–1946, American neurosurgeon and scientist, considered one of the founding fathers of neurosurgery.
Arthur Earl Walker, 1907–1995, Canadian-born neurosurgeon, neuroscientist and epileptologist.

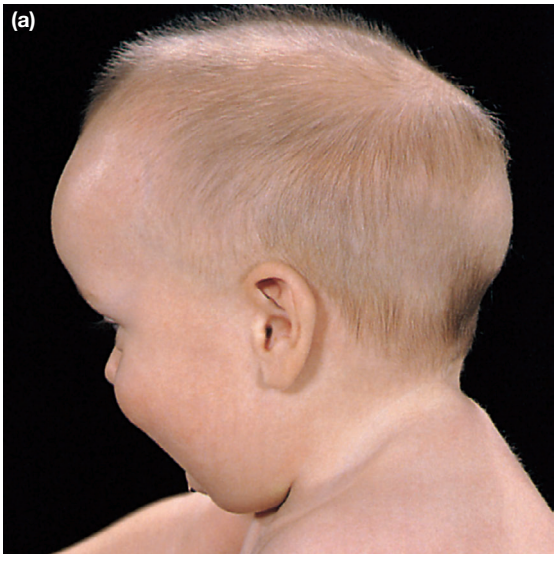

Figure 48.29 (a–c) Characteristic appearance of scaphocephaly due to sagittal suture synostosis.

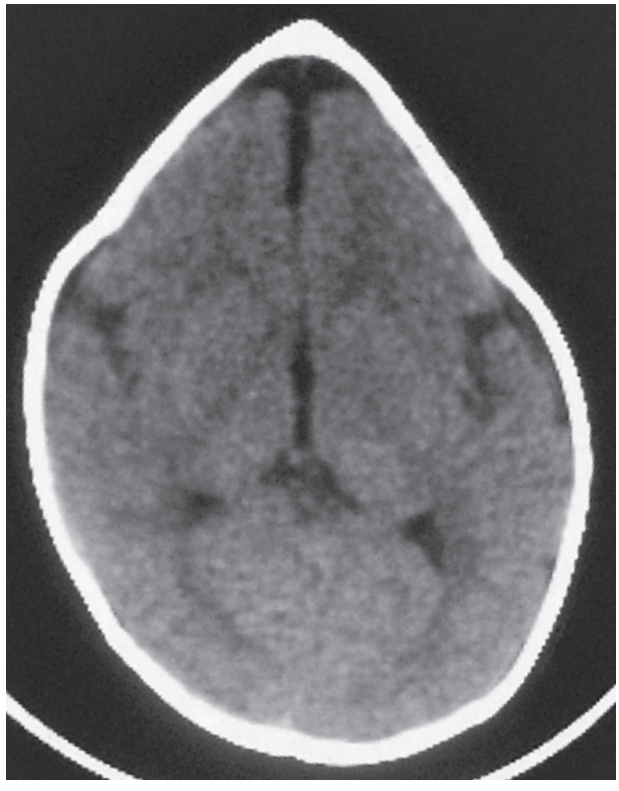

Figure 48.30 Axial computed tomography scan showing severe trigonocephaly due to premature fusion of the metopic suture.

Summary box 48.12

Paediatric neurosurgery

- A large variety of mostly neuroectodermal brain tumours represent the most common solid organ tumours in children
- Children manifest a range of developmental pathologies requiring neurosurgical management, including:
  - Cysts
  - Neural tube defects
  - Posterior fossa abnormalities
  - Craniosynostosis
- Generic features of intracranial pathology include developmental delay, seizures, macrocephaly and hydrocephalus

Epilepsy

Up to 10% of the population will suffer a seizure at some point in their lives, and epilepsy, a syndrome of recurrent unprovoked seizures, represents the most common neurological disorder. About 20–30% of patients fail to achieve adequate seizure control with drugs, and many of these focal epilepsies may benefit from surgery. Where a primary lesion such as a tumour, AVM or cavernoma is present, lesionectomy alone may be appropriate. Over time, however, repeated seizures can trigger hippocampal atrophy, which can then present a second seizure focus. This dual pathology is clinically important because seizure control may require removal of the atrophic hippocampus as well as the primary pathology.

Investigation

MRI is a mainstay, demonstrating, for example, reduced hippocampal volume and distorted architecture in mesial temporal sclerosis. Nuclear medicine modalities, including single-photon emission CT (SPECT) and positron emission tomography (PET), are sometimes used to demonstrate ictal and interictal metabolic abnormalities.

Electroencephalography (EEG) entails recording from an array of scalp electrodes and comparison between ictal and interictal recordings. This is especially helpful in lateralising the focus of complex partial seizures in temporal lobe epilepsy and is combined with video monitoring of the seizure in a videotelemetry suite. A more detailed localisation may be achieved invasively by the preoperative placement of subdural or depth electrodes, preoperatively or by intraoperative electrocorticography (ECoG).

Neuropsychological evaluation is used to evaluate the patient's preoperative function, looking for concordant focal impairments and, using the Wada test (***Table 48.9***), assessing the risk of postoperative language and memory deficits in temporal lobe epilepsy surgery.

TABLE 48.9 Wada test.

- Sodium amytal is injected into each internal carotid artery in turn, with simultaneous speech and memory testing to localise function
- The aim is to confirm language laterality, and hence that resection on the side of the lesion will not significantly impair verbal memory functions

Surgical management

The seizure focus may be resected, generally where it is in non-eloquent brain, or otherwise a disconnection can be performed. Awake craniotomy, allowing mapping particularly of speech centres, is increasingly employed.

Mesial temporal epilepsy is commonly medically refractory and can be addressed surgically by amygdalohippocampectomy or resection of the temporal lobe including the mesial structures. With careful patient selection, cure rates of up to 70% or greater can be achieved.

Functional, or rarely anatomical, hemispherectomy (***Figure 48.31***) may be performed for specific epilepsy syndromes associated with hemiplegia, such as infantile hemiplegia syndrome. This is usually considered in the early years of life when plasticity and potential for functional recovery is greatest.

Disconnection procedures include corpus callosotomy, which is used for patients suffering drop attacks, and subpial transections to isolate a seizure focus in eloquent brain from the surrounding cortex.

Vagal nerve stimulators can be implanted in severe drug-refractory epilepsy, with electrodes applied to the vagus nerve in the carotid sheath in the neck. This option can achieve

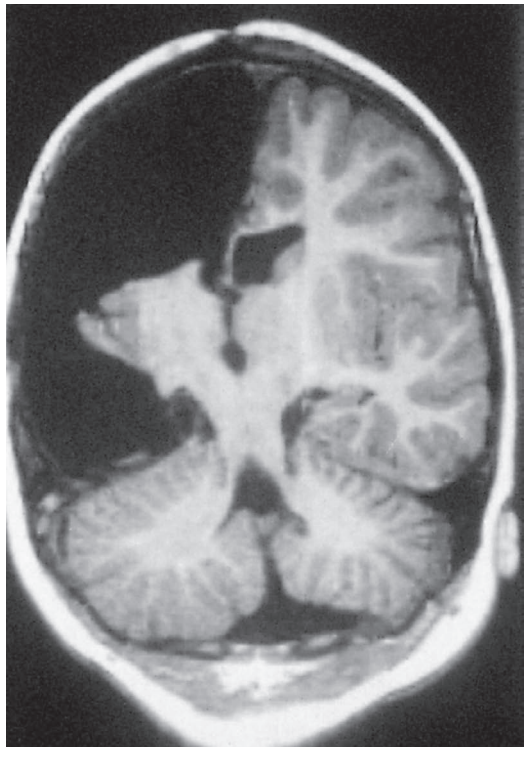

Figure 48.31 Coronal T2-weighted magnetic resonance image following anatomical hemispherectomy.

significant reductions in seizure frequency, especially in children, although the mechanism is not clear.

Movement disorders

Prior to the development of levodopa drug therapy, surgical ablation of the subthalamic nucleus (STN) or globus pallidus interna (GPi) was a mainstay of management for Parkinson's disease. Inhibition of the action of these centres remains a valuable tool later in the course of the disease as the therapeutic window using levodopa narrows, but this is now achieved using deep brain stimulation with electrodes. This offers the advantage of an adjustable and reversible effect and can be performed bilaterally where equivalent lesioning surgery would probably result in deficits.

Deep brain stimulation is also an option for other movement disorders where less invasive approaches are ineffective. These include dystonias, which may be amenable to bilateral GPi stimulation, and essential tremor, where the ventralis intermediate nucleus (Vim) of the thalamus is a preferred target.

Pain syndromes

Neurosurgical approaches to the relief of pain may address the underlying aetiology directly or may seek to interrupt or modulate the transmission responsible for the pain. The contrasting

Juhn Atsushi Wada, b. 1924, Japanese–Canadian neurologist known for research into epilepsy and human brain asymmetry, including his description of the Wada test for cerebral hemispheric dominance of language function.
James Parkinson, 1755–1824, general practitioner of Shoreditch, London, UK, published *An essay on the shaking palsy* in 1817.

approaches are demonstrated in the management of trigeminal neuralgia. This manifests, generally in middle age or later, with paroxysmal lancinating pain in the distribution of one or more divisions of the trigeminal nerve. The pain occurs without other neurological disturbance and may be triggered by trivial stimuli such as eating or brushing the teeth. The pain is often attributable to impingement on the nerve by the superior cerebellar artery or other vessels, as first postulated by Walter Dandy. Occasionally another primary lesion is responsible; for example demyelination due to multiple sclerosis can result in nerve impulses 'jumping' from adjacent sensory nerves to pain fibres, a process termed ephaptic transmission. When medications such as gabapentin and carbamazepine cannot achieve control, surgical options include the following.

- **Craniotomy and microvascular decompression** (MVD): this is designed to address the proposed origin of the neuropathic pain by applying material between the nerve and adjacent vessel to prevent direct contact and stimulation. It achieves long-lasting relief of symptoms in over 90% of patients with evidence of neurovascular compression on MRI. In other patients success rates are lower, and for older patients the risks associated with craniotomy may be hard to justify.
- **Stereotactic radiosurgery** is non-invasive but symptom improvement can take weeks or months; overall efficacy is lower than for MVD.
- **Percutaneous Gasserian rhizolysis** involves needle placement under radiographic guidance at the Gasserian ganglion in Meckel's cave. This permits lesioning of the ganglion by glycerol injection, radiofrequency thermocoagulation or balloon compression, with the aim of disrupting aberrant pain transmission. Facial numbness and recurrence of pain within 2 years are common after these procedures, and overall efficacy is lower than for MVD.

Treatment of pain elsewhere may also be based on lesioning of nerve tracts. For example pain related to brachial plexus infiltration or injury may be treated by sectioning the spinothalamic tract (cordotomy) or the dorsal root entry zone (DREZ operation). These approaches are limited by the potential for producing deficits, and especially by the occurrence of deafferentation ('phantom limb') pain syndromes, which are particularly unpleasant and difficult to treat.

Electrical stimulation is used to modulate pain transmission: for example, spinal cord stimulators can be applied to a range of pain syndromes, especially those associated with failed spinal surgery. Deep brain stimulation targeting the periaqueductal grey and sensory thalamic nuclei has a role in chronic pain arising in the context of thalamic stroke. Implanted devices may also be used for intrathecal delivery of opiates for pain control or baclofen to alleviate spasticity.

Summary box 48.13

Functional neurosurgery

- Intractable epilepsy can be treated surgically by implantation of a vagal nerve stimulator or by resection of one or more seizure foci
- Deep brain stimulation using implanted electrodes has largely replaced lesioning of these structures for management of drug-refractory Parkinson's disease
- Microvascular decompression is offered for trigeminal neuralgia, and other neuropathic pain syndromes may respond to lesioning of nerve tracts

PRACTICAL AND ETHICAL ISSUES

Creutzfeldt–Jakob disease

Creutzfeldt–Jakob disease (CJD) is a rare transmissible spongiform encephalopathy producing a rapidly progressive dementia; it is uniformly fatal. The causative agent seems to be a misfolded protein – a prion – that is not destroyed by conventional sterilisation techniques. UK practice involves undertaking preoperative checks to exclude any risk factors for CJD infection. These include family history, receipt of pituitary-derived human growth hormone, receipt of cadaveric dura mater grafts and previous brain or spinal surgery prior to 1997. Where risk factors are present, instruments must be quarantined or destroyed postoperatively.

Risks of craniotomy

The risks associated with craniotomy are important to appreciate in discussing operations with patients and family, and in evaluating patients who deteriorate postoperatively. Specific risks depend on the anatomy of each approach. The following figures quoted in brackets will vary significantly between individual procedures and even between centres:

- infection (5%) and wound breakdown;
- intracerebral haemorrhage;
- seizures;
- CSF leak;
- permanent neurological deficit;
- death (1%).

Brainstem death

This is defined as the irreversible loss of cerebral and brainstem function. Brainstem death is legally equivalent to death, and is a precondition for the harvesting of organs for transplant from heart-beating donors.

Johann Lorenz Gasser, 1723–1765, Professor of Anatomy, Vienna, Austria.
Johann Friedrich Meckel (the elder), 1724–1774, German anatomist, has 'the elder' appended to his name to avoid confusion with his famous grandson, Johann Friedrich Meckel (1781–1833), who was also an anatomist.
Hans Gerhard Creutzfeldt, 1885–1946, neurologist, Kiel, Germany.
Alfons Maria Jakob, 1884–1931, neurologist, Hamburg, Germany.

Diagnosis requires:

- identification of the cause of irreversible coma;
- exclusion of reversible causes of coma;
- clinical demonstration of the absence of brainstem function.

In the UK, this entails testing twice, by two clinicians, to demonstrate the absence of:

- response to pain;
- respiratory drive (apnoea despite a PCO_2 >6.7 kPa);
- pupillary light reflex;
- corneal reflex;
- vestibulo-ocular reflex;
- oculocephalic reflex;
- gag reflex.

PART 7 | Head and neck

CHAPTER 49

The eye and orbit

Learning objectives

To understand and appreciate:

- The anatomy of the eye and orbit
- The common ocular disorders and their symptoms and specific signs
- The value of special investigations
- When specialist referral is appropriate
- Recent advances in ocular surgery

OCULAR ANATOMY

Adnexae

The lids comprise skin, connective tissue, the orbicularis oculi (cranial nerve VII) and the tarsal plate, with multiple meibomian glands opening posterior to the lashes and lined with conjunctiva, which is reflected onto the sclera. The upper lid is elevated by the levator muscle (cranial nerve III) and has a horizontal strip of sympathetically innervated Müller's muscle, giving rise to 2 mm of ptosis in Horner's syndrome. The frontalis muscle may also contribute to eyelid elevation, particularly when the levator muscle is weak. Both lids are attached to the orbital rim by the medial and lateral canthal tendons. Both have a rich vascular supply and are innervated by the V1 division of the trigeminal nerve (cranial nerve V) above and the V2 division below.

Lacrimal system

The almond-shaped lacrimal gland lies under the upper outer orbital rim and opens into the upper conjunctival fornix through 10–15 ducts. Tears are swept across the globe by the lids and evaporate or pass into the upper and lower lid puncta, and then into the canaliculi to join the common canaliculus, which passes into the lacrimal sac under the medial canthal tendon. The sac is drained by the nasolacrimal duct into the nose, opening in the inferior meatus under the inferior turbinate.

The globe

The cornea is the 12-mm-diameter window of the eye, 550 μm thick centrally on average; its clarity is due to the regular arrangement of collagen bundles and relative dehydration. It merges into the sclera at the corneoscleral junction (the limbus), the insertion of the bulbar conjunctiva. The sclera, which is 1 mm thick, constitutes four-fifths of the wall of the eye and gives attachment to the extraocular muscles (***Figure 49.1***). It is perforated by the long and short posterior ciliary arteries and the vortex veins and is contiguous with the optic nerve sheath.

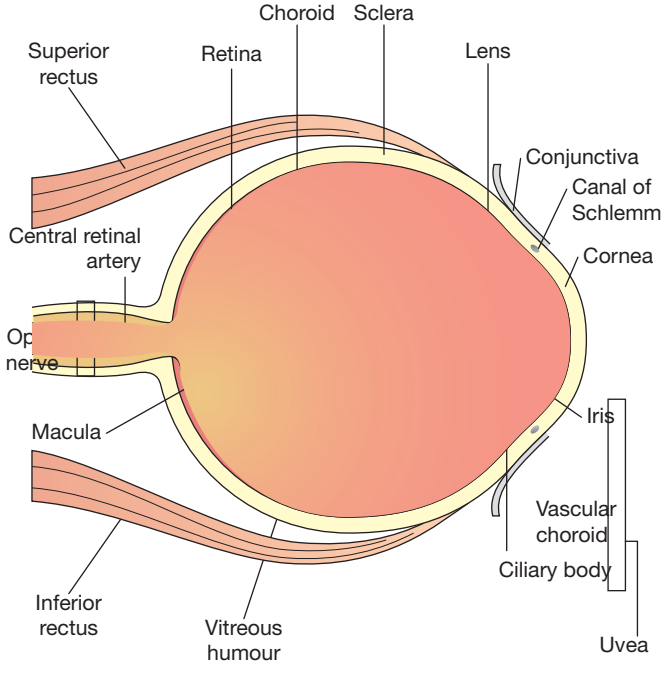

Figure 49.1 Anatomy of the eye.

Heinrich Meibom (Meibomius), 1638–1700, Professor of Medicine, History and Poetry, Helmstadt, Germany, described these glands in 1666.
Johannes Peter Müller, 1801–1858, Professor of Anatomy and Physiology, Berlin, Germany.
Johan Friedrich Horner, 1831–1886, Professor of Ophthalmology, Zurich, Switzerland, described this syndrome in 1869.

The uvea comprises the iris, ciliary body and vascular choroid. Photoreceptor cells in the outer retina sense light and send impulses to retinal ganglion cells in the inner retina via bipolar cells. The retinal pigment epithelium underlies the photoreceptors and is responsible for reprocessing of photopigments. The optic nerve conveys the axons of retinal ganglion cells from the eye to the brain. The most high-resolution part of the retina – the macula – lies at the posterior pole within the vascular arcade. The biconvex lens and capsule are suspended by the lens zonules, over 300 tiny fibres attached to the ciliary muscle. Aqueous humour arises from the ciliary processes, hydrates the vitreous gel, passes through the pupil into the anterior chamber between the iris and the cornea and then drains out through the trabecular meshwork into Schlemm's canal in the drainage angle and from there to the episcleral venous circulation. The balance between production and drainage of aqueous humour determines the intraocular pressure, which in most normal eyes is regulated at a level of 10–21 mmHg. The inner retina is supplied by the central retinal artery and drained by the central retinal vein.

Orbit

The orbit is four-sided and pyramidal in structure, housing the globe, optic nerve, the four rectus and two oblique muscles, the lacrimal gland, orbital fat, the cranial nerves III–VI, the ophthalmic artery with its tributaries and the ophthalmic veins, which anastomose anteriorly with the face and posteriorly with the cranial cavity. Above is the frontal lobe of the brain, temporally the temporal fossa, inferiorly the maxillary sinus and nasally the lacrimal sac and ethmoidal and sphenoidal air sinuses. The optic nerve passes through the optic canal to the chiasm, with other nerves and vessels passing through the superior ophthalmic fissure.

PERIORBITAL AND ORBITAL SWELLINGS

Swellings related to the supraorbital margin

Dermoid cysts

Dermoid cysts are benign congenital choristomas of the orbit that originate from fetal bone suture lines during development, most commonly the frontozygomatic suture (***Figure 49.2***), although they may also occur more medially. Dermoid cysts account for about half of childhood orbital neoplasms and consist of keratinised epithelium and adnexal structures such as sweat glands and hair follicles. They often cause a bony depression and they may have a dumbbell extension into the orbit, which is of particular importance should they need to be excised. Dermoid cysts can also erode the orbital plate of the frontal bone to become attached to dura; for this reason it is important to image the area by computed tomography (CT) before excision.

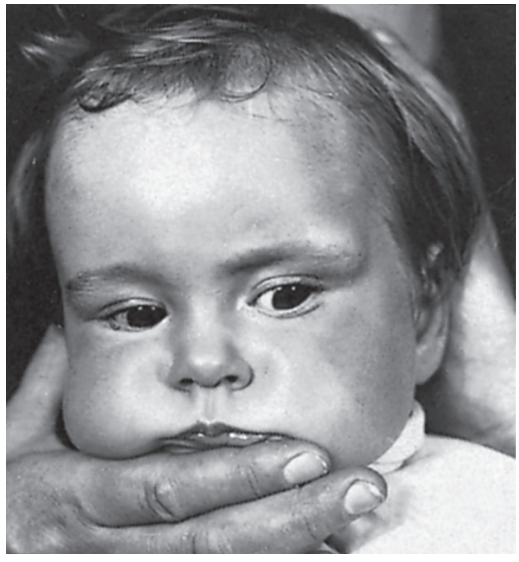

Figure 49.2 External angular dermoid.

Neurofibromatosis

Neurofibromatosis may also produce swellings above the eye. The diagnosis can usually be confirmed by an examination of the whole body, as there are often multiple lesions. Proptosis can also result (***Figure 49.3***). Other ophthalmic features may be present.

Figure 49.3 Neurofibroma in the orbit with proptosis, and also similar lesions in the forehead.

Swellings of the lids

Meibomian cysts (chalazion)

These are the most common lid swellings (***Figure 49.4***). A meibomian cyst is a chronic granulomatous inflammation of a meibomian gland. It may occur on either upper or lower lids and presents as a smooth, painless swelling. It can be felt by rolling the cyst on the tarsal plate. It can be distinguished from

Friedrich Schlemm, 1795–1858, Professor of Anatomy, Berlin, Germany.

Figure 49.4 Meibomian cyst (courtesy of Mr D Spalton, FRCS).

a stye (hordeolum), which is an infection of a hair follicle and is usually painful. Persistent meibomian cysts that do not resolve with conservative treatment (hot compresses) are treated by incision and curettage from the conjunctival surface. Styes are treated by antibiotics and local heat.

Basal cell carcinoma (rodent ulcer)

This is the most common malignant tumour of the eyelids (***Figure 49.5***). Basal cell carcinomas may be locally invasive but do not tend to metastasise. They are more common on the lower lids, often start as a small pimple that ulcerates and has raised edges ('rodent ulcer') and are usually easily excised in the early stages. Histological confirmation that the excision is complete is required. More extensive lesions may require specialist techniques such as Mohs' micrographic surgical excision controlled by frozen section. Local radiotherapy or cryotherapy can be carried out; however, recurrence is more common, more aggressive and more difficult to detect.

Figure 49.5 Rodent ulcers (courtesy of Mr J Beare, FRCS).

Summary box 49.1

Basal cell carcinomas

- Basal cell carcinomas are the most common malignant eyelid tumour
- Treatment is by wide local excision with careful histopathological margin control
- All unusual eyelid lesions (especially in the elderly) should be biopsied

Other lid swellings

Other types of lid swelling are less common. They include squamous cell carcinoma and malignant melanoma, sebaceous cyst, papilloma, keratoacanthoma, cyst of Moll (sweat glands) (***Figure 49.6***) or Zeis (sebaceous glands) and molluscum contagiosum. When molluscum contagiosum occurs on the lid margin, it can give rise to a mild viral chronic keratoconjunctivitis and should be curetted or excised.

Carcinoma of the meibomian glands and rhabdomyosarcomas are rare lesions; they need to be treated by radical excision. Atypical or meibomian cysts that recur should be biopsied to exclude sebaceous gland carcinoma.

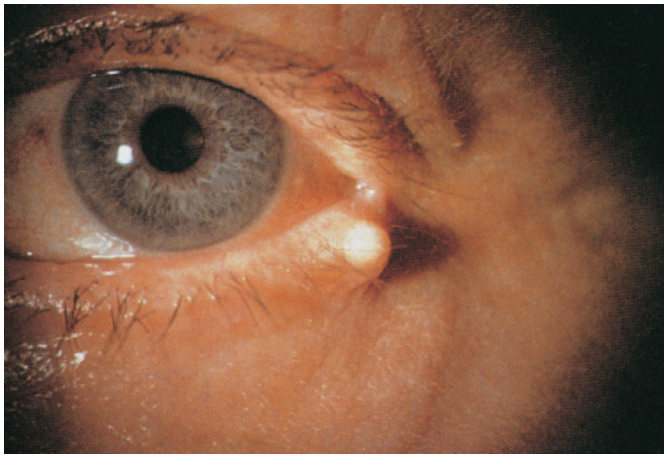

Figure 49.6 Cyst of Moll.

Swellings of the lacrimal system

Lacrimal sac mucocele

This occurs from obstruction of the lacrimal duct beyond the sac and results in a fluctuant swelling that bulges out just below the medial canthus. It can become infected to give rise to a painful tense swelling (acute dacryocystitis). If untreated, it may give rise to a fistula. Treatment is by performing a bypass operation between the lacrimal sac and the nose (a dacryocystorhinostomy). Watering of the eye can also occur as a result of eversion of the lower lid (ectropion), which causes loss of contact between the lower punctum and the tear film, or from

Frederic E Mohs, 1910–2002, developed the technique of micrographic surgical excision while a medical student at University of Wisconsin, USA.
Jacob Antonius Moll, 1832–1913, ophthalmologist of The Hague, The Netherlands.
Eduard Zeis, 1807–1868, Professor of Surgery, Marburg (1844–1850), who later worked at Dresden, Germany, described these glands in 1835.

reflex hypersecretion as a result of irritation, for example by inturning lashes in entropion, and these must be distinguished from a mucocele.

Lacrimal gland tumours

These are swellings of the lacrimal glands, which lie in the upper lateral aspect of the orbit. Eventually they lead to impairment of ocular movements and displacement of the globe forwards, downwards and inwards. Pathologically the tumours resemble parotid tumours and they can be pleomorphic adenomas with or without malignant change, carcinomas or mucoepidermoid tumours.

Orbital swellings

Orbital swellings result in displacement of the globe and limitation of movement. A full description of orbital swellings is outside the realm of this text, but some of the most common causes include the following.

- **Pseudoproptosis**. This results from a large eyeball, as seen in congenital glaucoma or high myopia.
- **Orbital inflammatory conditions** that result in orbital cellulitis (***Figure 49.7***).
- **Haemorrhage** after trauma or retrobulbar injection.
- **Neoplasia** affecting the lacrimal gland, the optic nerve, the orbital walls or the nasal sinuses (e.g. glioma [neurofibromatosis, ***Figure 49.3***], meningioma and osteoma [***Figure 49.8***]).
- **Thyroid eye disease** (***Figures 49.9–49.11***). This is the most common cause of unilateral and bilateral proptosis in adults and may occur in the absence of active thyroid disease or after thyroidectomy. Management of severe thyroid eye disease may require large doses of systemic steroids, radiotherapy or even orbital lateral wall decompression if the eyeball is threatened by exposure or optic nerve compression. The disease is often more severe in smokers and those with poorly controlled thyroid function. CT and

Figure 49.9 Computed tomogram of the orbit in dysthyroid exophthalmos, showing swollen muscles (courtesy of Dr Glyn Lloyd).

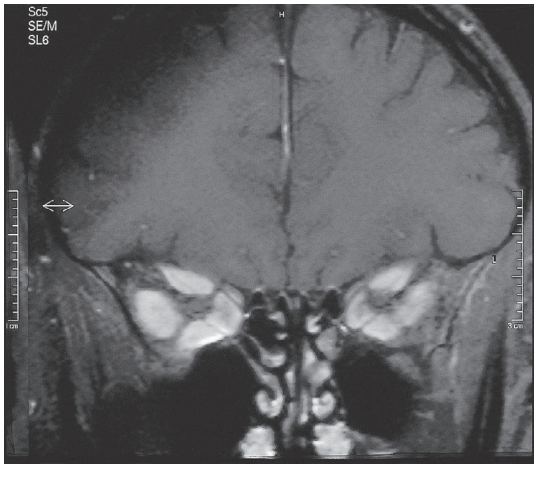

Figure 49.10 Magnetic resonance imaging scan of a coronal view of the orbit, showing enlarged muscles in thyroid disease (courtesy of Dr Juliette Britton).

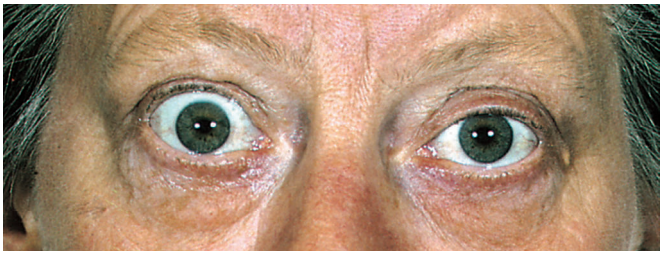

Figure 49.11 Exophthalmos in dysthyroid eye disease.

magnetic resonance imaging (MRI) scans are useful in diagnosis. MRI with short tau inversion recovery (STIR) sequences is particularly useful for identification of active inflammation within the orbital tissues.

- **Pseudotumour**, or malignant lymphoma.
- **Haemangiomas** of the orbit (***Figure 49.12***).
- **Tumour metastases**. These are rare. In children they usually arise from neuroblastomas of the adrenal gland, whereas in adults the oesophagus, stomach, breast and prostate can be sites of primary lesions.

Diagnostic aids

Diagnostic aids include radiography, CT, MRI, ultrasonography and, less commonly, tomography and orbital venography.

Treatment

Treatment is directed to the cause of the lesion, taking care to prevent exposure of the eye, diplopia or visual impairment from optic nerve compression.

INTRAOCULAR TUMOURS

Children

Retinoblastoma, the most common ocular malignancy of childhood, is a malignant tumour of the retina that can be bilateral in around one-third of cases. Half of cases are hereditary (autosomal dominant) and are due to mutation of the *RB1* gene on chromosome 13; children with a family history should

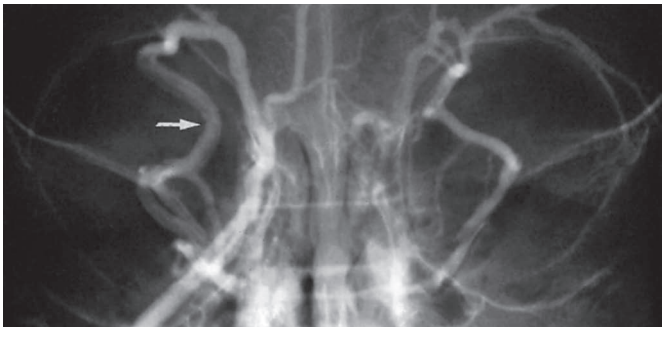

Figure 49.12 Capillary haemangioma in a child. An orbital venogram demonstrates displacement of the second part of the superior ophthalmic vein (arrow) (courtesy of Dr Glyn Lloyd).

Figure 49.13 Retinoblastoma giving rise to a white pupillary reflex. This child was first seen with a convergent squint and discharged without a fundus examination. He was next seen many years later with a 'white reflex' and died soon after diagnosis (courtesy of MA Bedford, FRCS).

be carefully monitored from birth. Remaining cases occur sporadically. Inherited retinoblastoma is more likely to be bilateral. Retinoblastoma is often not spotted until the tumour fills the globe and presents as a white reflex in the pupil or as a squint (***Figure 49.13***). The differential diagnosis includes retinopathy of prematurity, persistent fetal vasculature (PFV) and intraocular infections. If the tumour is large, enucleation may be required, but radiotherapy, cryotherapy, chemotherapy or laser treatment can cure small lesions. Liaison with a paediatric oncologist is essential.

Summary box 49.2

Intraocular tumours

- Any child with a white pupil (leukokoria) should be referred to an ophthalmologist to exclude retinoblastoma, although congenital cataracts may also cause this sign
- A blind painful eye may hide a melanoma or other ocular tumour

Adults

Malignant melanoma is the most common primary malignant tumour of the eye and originates in the pigmented cells of the choroid (***Figure 49.14***), ciliary body or iris. It can present with a reduction in vision, a vitreous haemorrhage or by the chance finding of an elevated pigmented lesion in the eye. Tumour growth is variable but, as a general rule, the more posterior the lesion, the more rapidly progressive it is likely to be. Spread may be delayed for many years; however, the liver is frequently involved, hence the advice 'beware of the patient with a glass eye and an enlarged liver'. Treatment options vary by size and location of the tumour but include laser photocoagulation, radioactive plaque, radiotherapy/proton beam therapy, enucleation and, in selected cases, local excision. Diagnosis is made by direct observation and/or ultrasonography, which shows a solid tumour, often with low internal reflectivity on ultrasound (***Figure 49.15***).

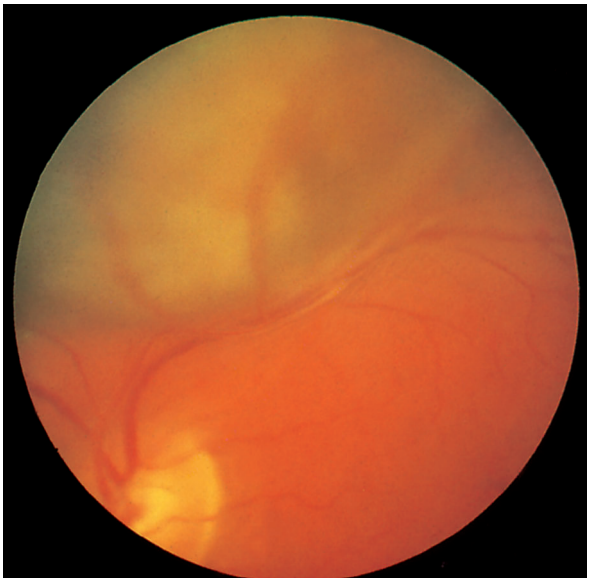

Figure 49.14 Choroidal melanoma.

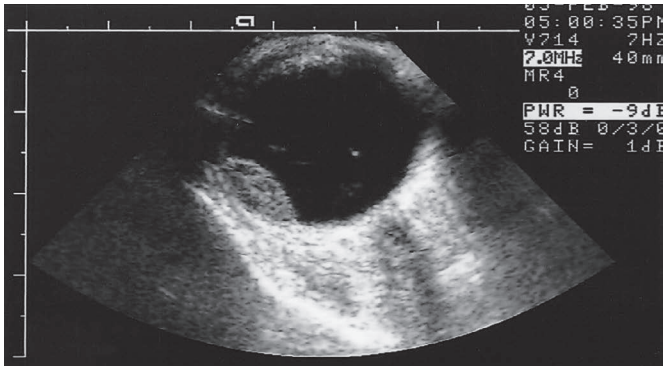

Figure 49.15 B-scan showing choroidal melanoma (courtesy of Dr Marie Reston).

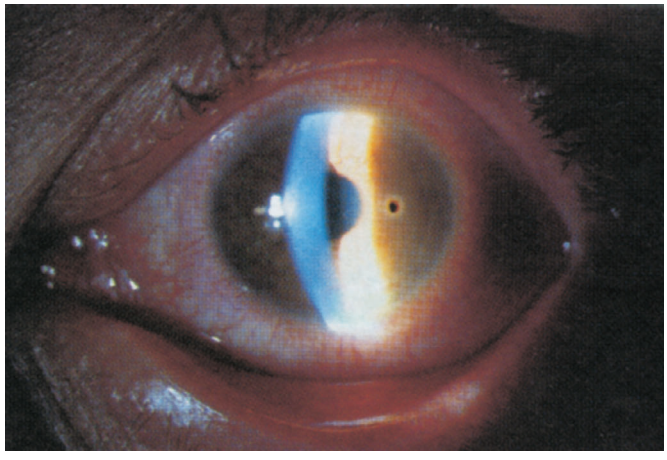

Figure 49.16 Corneal foreign body.

INJURIES INVOLVING THE EYE AND ADJACENT STRUCTURES

Corneal abrasions and ulceration

The cornea is frequently damaged by direct trauma or by foreign bodies (***Figure 49.16***). Ulceration can occur with infection, exposure (for example in severely ill patients with incomplete eye closure) or after damage to the facial nerve. Postherpetic ulceration is common and serious if not treated. Fluorescein instillation illuminated by blue light shows up corneal ulceration at an early stage, with areas of epithelial loss fluorescing green.

Treatment of sterile corneal abrasions or exposure is by topical lubrication or padding of the eye. If bacterial infection is suspected, a swab or scrape may be performed for microbiological diagnosis and topical antibiotics such as 0.5% chloramphenicol or ofloxacin eye drops are commonly used. The eye is made more comfortable by the use of mydriatics such as cyclopentolate to reduce photophobia. Herpes simplex dendritic ulcers are treated with aciclovir ointment. In countries in the Far and Middle East, chronic infection with trachoma can cause corneal opacification and blindness, although the worldwide incidence of this condition is falling. Corneal grafting is the only cure for an opaque cornea. Until recently, full-thickness penetrating keratoplasty was the only corneal graft technique. For some conditions this has largely been replaced by lamellar or partial-thickness graft surgery, in a technique termed DSEK or 'Descemet's stripping endothelial keratoplasty'. However, penetrating keratoplasty remains the treatment of choice for severe corneal damage due to infection or injury. Rarely, osteo-odonto-keratoprosthesis can be attempted in very severe cases of opaque corneas that are not suitable for grafting. Artificial corneal prostheses have also been developed. Acanthamoeba is a rare serious cause of corneal infection. This infection usually follows the use of contact lenses. Specialist management and treatment is recommended.

Summary box 49.3

Corneal abrasions

- A drop of fluorescein dye illuminated by a blue light reveals even the smallest corneal abrasion
- Corneal ulcers are often more serious in contact lens wearers and require prompt assessment and treatment
- Development of white infiltrate in/around a corneal abrasion is a sign of infection

Blunt injuries to the eye and orbit

The floor of the orbit is its weakest wall and in blunt trauma, such as a blow from a fist, it is often fractured without fractures of the other walls. This is called a blow-out fracture. Clinical signs are enophthalmos, bruising around the orbit, maxillary hypoaesthesia and limitation of upward gaze owing to entrapment of the inferior rectus muscle leading to vertical diplopia.

Jean Descemet, 1732–1810, French physician and botanist.

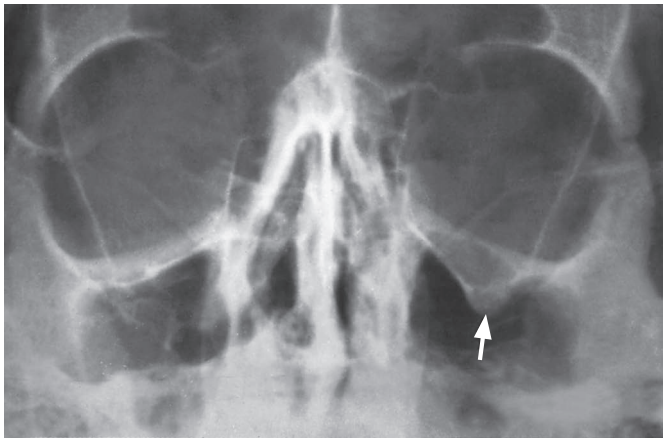

Figure 49.17 Radiograph showing a blow-out fracture of the orbit (left) with soft tissue in the antrum (arrow) (courtesy of Dr Glyn Lloyd).

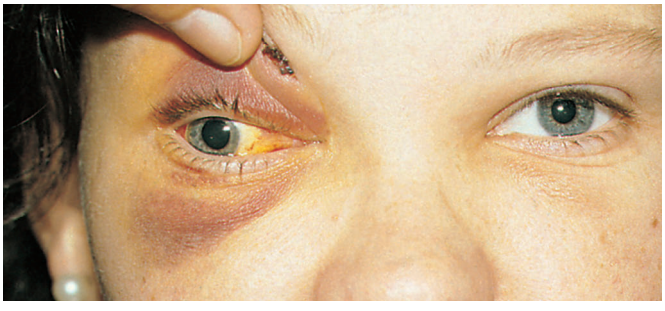

Figure 49.18 Injury from a ski pole into the right brow. Vision reduced to 'no perception of light' (courtesy of J Beare, FRCS).

This occurs when the extraocular muscles or orbital septa become trapped in the fracture and can be identified as a soft-tissue mass in the antrum on a radiograph (***Figure 49.17***), although CT scans or tomograms may be necessary. Surgical repair of the orbital floor with freeing of the trapped contents may be necessary if troublesome diplopia persists or enophthalmos is marked. A child with an orbital floor fracture requires urgent assessment, particularly if upgaze is restricted, as trapping of the inferior rectus muscle may cause ischaemia and require urgent surgery. If an orbital haemorrhage is too extensive to examine the eye, it may be necessary to examine the eye under anaesthesia because there may be a hidden perforation of the globe. Injuries to the lids and lid margins must be repaired; if the lacrimal canaliculi are damaged, they should be repaired if possible, especially the lower canaliculus, as 75% of tear drainage goes through it.

Blunt injuries can also cause damage to the optic nerve, which can result in blindness and a total afferent nerve defect (***Figures 49.18 and 49.19***).

Blunt ocular injuries

Blunt injuries to the eye can give rise to several problems, which include the following:

- **Iritis**. Inflammation; treated with topical steroids.
- **Hyphaema** (blood in the anterior chamber) (***Figure 49.20***). Rest and sedation, particularly in children, are advised because the main danger in this condition is secondary bleeding, resulting in an acute rise in intraocular pressure and blood staining of the cornea. The use of antifibrinolytic agents (ε-aminocaproic acid) has been advocated; if the pressure rises, surgery to wash out the blood may be necessary.
- **Subluxation of the lens**. This is suspected if the iris, or part of the iris, 'wobbles' on movement (iridodonesis).
- **Secondary glaucoma**. This is often associated with recession of the iridocorneal drainage angle.
- **Retinal and macular haemorrhages and choroidal tears** (***Figure 49.21***).
- **Retinal dialysis**. This may lead to a retinal detachment and permanent damage to vision (***Figure 49.22***).

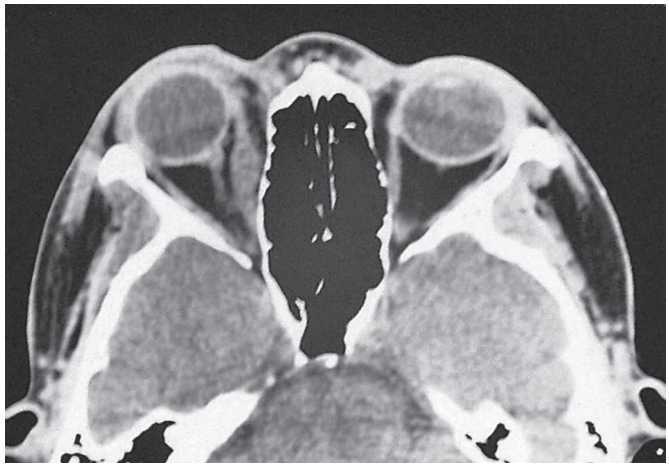

Figure 49.19 Scan of orbit from ***Figure 49.18*** showing a massive swelling of the medial rectus (courtesy of J Beare, FRCS).

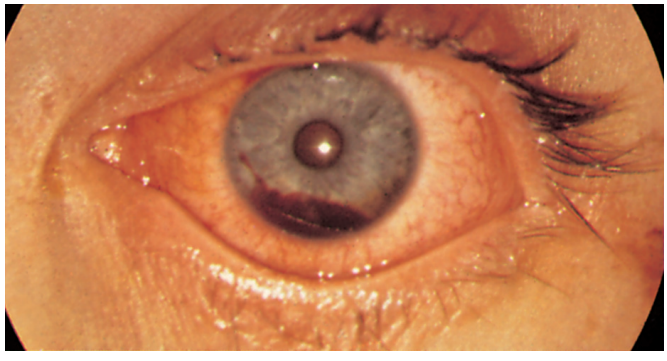

Figure 49.20 Hyphaema. Blood in the vitreous chamber after a concussional injury.

Penetrating eye injuries

These occur when the globe is penetrated, often in road traffic and other major accidents (***Figure 49.23***) and also in injuries from sharp instruments. The compulsory wearing of seat belts in motor vehicles has substantially reduced the incidence of this type of eye injury, by up to 73% in the UK. The presence of an irregular pupil suggests prolapse of the iris and should arouse suspicion of a penetrating injury. Treatment is prompt primary repair to restore the integrity of the globe.

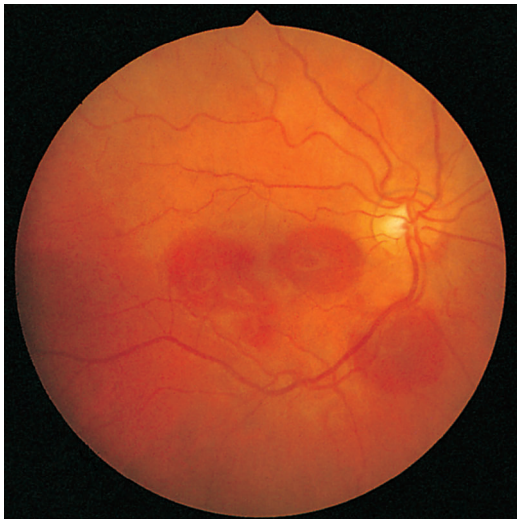

Figure 49.21 Retinal haemorrhage from a cricket bat injury (courtesy of J Beare, FRCS).

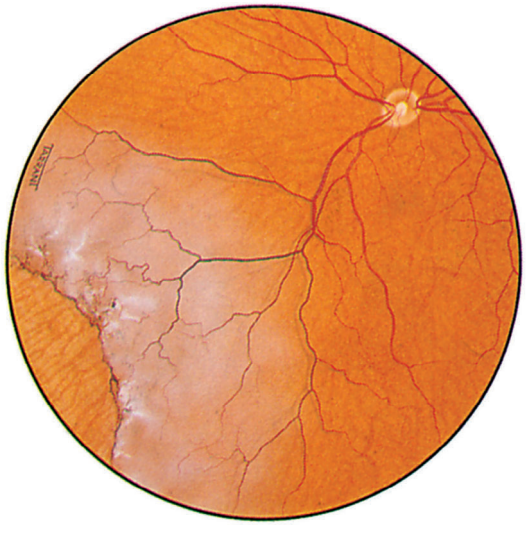

Figure 49.22 Retinal dialysis after blunt ocular injury.

Figure 49.23 Facial lacerations from a windscreen injury. Beware of a perforating eye injury.

If a perforation is suspected, extensive eye examination should not be attempted before anaesthesia because this may lead to further extrusion of the intraocular contents. If the fundal view is poor, ultrasonography and orbital imaging are indicated. Secondary corneal grafting, lensectomy and vitrectomy have considerably improved the visual prognosis; these must be done by an experienced eye surgeon. Injuries to the optic nerves must also be excluded in severe accidents.

Intraocular foreign bodies

Intraocular foreign bodies must always be excluded when patients attend the accident and emergency department with an eye injury and a history of working with a hammer and chisel or a history of a potentially high-velocity injury. Radiography of the orbits must be performed. Ferrous and copper foreign bodies should always be removed, sometimes requiring the use of a magnet. B-scan ultrasonography can also assist in localising foreign bodies when a vitreous haemorrhage or cataract is present. CT can be used, but MRI is contraindicated if a ferrous intraocular foreign body is suspected.

Summary box 49.4

Penetrating eye injuries

- A distorted and irregular pupil warrants the careful exclusion of a penetrating eye injury
- Avoid extensive eye examination if globe rupture is suspected to avoid worsening the injury prior to surgical repair

Burns

Radiation burns

Corneal injury may occur after exposure to ultraviolet radiation, for example after arc welding or excessive sunlight (snow blindness) and sun lamps. Such burns cause intense gritty burning pain and photophobia as a result of keratitis (corneal inflammation), which starts some hours after exposure. Mydriatic and local steroids with antibiotic drops ease the condition, and healing usually occurs after 24 hours.

Thermal burns

If these involve the full thickness of the lids, corneal scarring may occur from exposure and immediate corneal protection is necessary. A splash of molten metal may cause marked local necrosis and may lead to permanent corneal scarring. Treatment is to remove any debris by irrigation and to instil local atropine, antibiotics and steroids to prevent superadded infection and scarring. Lid reconstruction may be necessary.

Chemical burns

Chemical burns, and especially alkali burns, can be serious because ocular penetration occurs quickly and ischaemic necrosis can result (***Figure 49.24***). Immediate copious irrigation until the pH is neutral will ensure that the chemical is diluted as much as possible, and all particles should be removed from the fornices. Treatment can then be continued as with thermal burns. Well-fitting goggles should prevent such injuries.

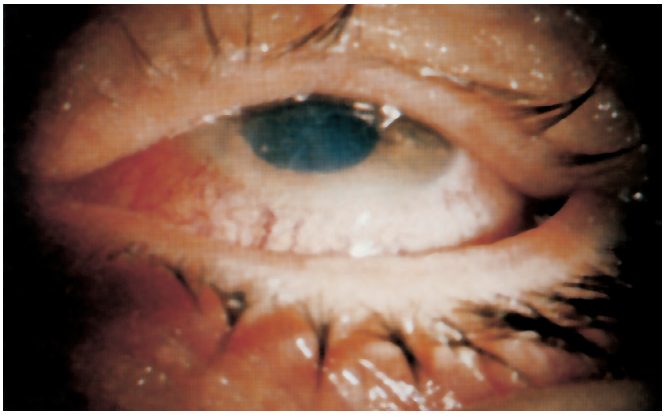

Figure 49.24 Chemical burn showing conjunctival necrosis.

DIFFERENTIAL DIAGNOSIS OF THE ACUTE RED EYE

This is important in the management of minor ocular complaints and the recognition of conditions that require expert attention. Possible causes of the acute red eye include:

- subconjunctival haemorrhage;
- conjunctivitis;
- keratitis;
- uveitis;
- episcleritis and scleritis;
- acute glaucoma.

Any condition with pain, visual impairment or a pupil abnormality suggests a more serious diagnosis.

Subconjunctival haemorrhage

This presents as a bright red eye, often noticed incidentally with only minimal discomfort and normal vision. Causes include coughing, sneezing, minor trauma, hypertension and, rarely, a bleeding disorder. Subconjunctival haemorrhages are more common in those receiving antiplatelet or anticoagulation therapy. Reassurance and treatment of the underlying cause are required. Most settle within a week, but can recur.

Conjunctivitis

Symptoms are grittiness, redness and discharge. Causes are infective, chemical, allergic or traumatic. In the newborn it can be serious; gonococcal and chlamydial infection must be excluded. Bacterial conjunctivitis is purulent, usually self-limiting and treated with topical broad-spectrum antibiotics. Chlamydial and adenovirus infections must be considered. Adenoviral infections are common and usually affect one eye much more in severity and onset, tending to be more watery than sticky, and are often associated with a palpable preauricular gland.

Vernal conjunctivitis (***Figure 49.25***) is a form of allergic conjunctivitis that is characterised by itchy eyes, usually worse in the spring and early summer and often associated with other allergic problems such as hay fever. Clinically, most signs are under the upper lid, which may have a cobblestone appearance instead of a smooth surface.

Giant papillary conjunctivitis with large papillae under the upper lid may be seen in soft contact lens wearers. This is usually caused by an allergy to the sterilising solutions and lens protein and may be helped by either using a preservative-free solution or using daily-wear disposable lenses.

Kaposi's sarcoma, often associated with human immunodeficiency virus (HIV) infection, can rarely present like a subconjunctival haemorrhage (***Figure 49.26***).

Considerable conjunctival and corneal irritation can be caused by the lids turning in (entropion) (***Figure 49.27***) or turning out (ectropion) (***Figures 49.28 and 49.29***), and by ingrowing lashes. The lids should be repaired surgically to their normal position.

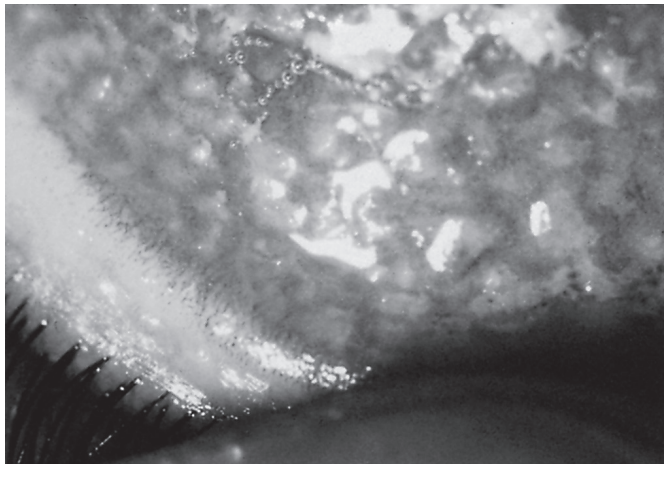

Figure 49.25 Vernal conjunctivitis (spring catarrh) showing cobblestone appearance under the upper lid.

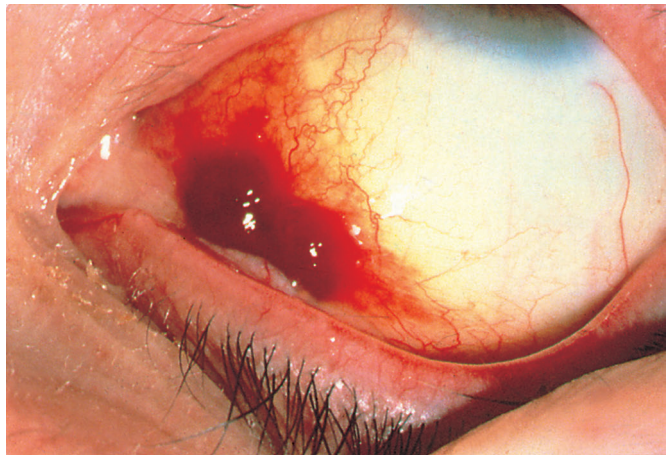

Figure 49.26 Kaposi's sarcoma of conjunctiva.

Moritz Kaposi, 1837–1902, Professor of Dermatology, Vienna, Austria, described pigmented sarcoma of the skin in 1872.

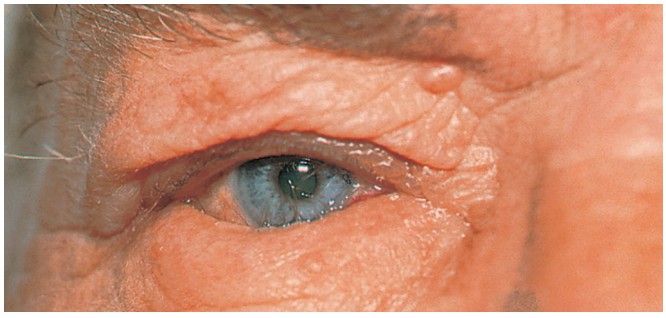

Figure 49.27 Entropion (courtesy of J Beare, FRCS).

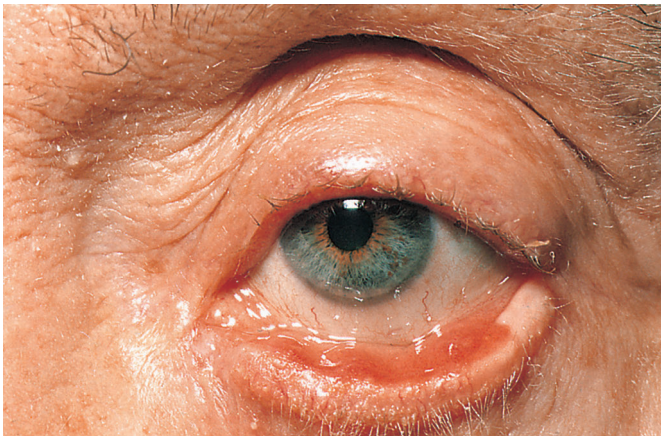

Figure 49.28 Ectropion, lower lid (courtesy of J Beare, FRCS).

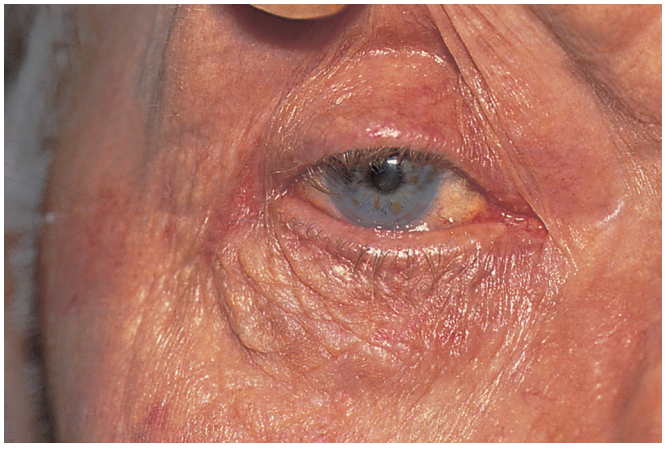

Figure 49.29 Ectropion, upper lid – chronic staphylococcal infection (courtesy of J Beare, FRCS).

Vision is not commonly affected in conjunctivitis but, with some viral infections, a keratitis may be present and result in visual impairment and pain. All of the other conditions below are painful and usually affect vision.

Keratitis (inflammation of the cornea)

Herpes simplex infection presents as a dendritic (branching) ulcer, shown easily by staining with fluorescein or Rose Bengal. It is treated with aciclovir ointment five times per day. The use of steroid drops must be avoided as this can make the condition much worse (***Figure 49.30***).

Corneal ulceration may occur as a result of ingrowing lashes or corneal foreign bodies, marginal ulceration and infected abrasions. Infected ulcers can occur in patients wearing soft contact lenses or elderly immunocompromised individuals. Herpes zoster (shingles) may affect the ophthalmic division of cranial nerve V and can give rise to a keratitis and uveitis. It is important to avoid the use of steroid drops until a diagnosis has been made. Local anaesthetic drops should also not be given on a regular basis.

Uveitis

This can be anterior (iritis) or, more rarely, posterior. In anterior uveitis, the pupil is sometimes small and/or irregular owing to formation of posterior synechiae (adhesions between the iris and the lens). There is often circumcorneal injection and there may be keratic precipitates present on the posterior surface of the cornea. Pain, photophobia and some visual loss are usually present. Posterior uveitis can present with a white eye and blurred vision. It usually takes a chronic course. Granulomatous diseases, Behçet's disease, Reiter's syndrome, toxoplasmosis and cytomegalovirus infection should be excluded. Topical systemic steroids and, sometimes, immunosuppressive drugs are useful in treating these conditions; management should be under the care of an ophthalmologist.

Figure 49.30 Dendritic staining caused by herpes keratitis.

Rose Bengal (or Bengal Rose) is dichlorotetraiodofluorescein.
Hulusi Behçet, 1889–1948, Professor of Dermatology, Istanbul, Turkey, described this disease in 1937.
Hans Conrad Julius Reiter, 1881–1968, President of the Health Service and Honorary Professor of Hygiene at the University of Berlin, Germany, described this disease in 1916.

Episcleritis and scleritis

Episcleritis or inflammation of the episcleral tissue often occurs as an idiopathic condition (***Figure 49.31***). Scleritis is a less common, more serious, condition in which the deeper sclera is involved. There is often an associated uveitis and severe pain. Thinning of the sclera may result. Systemic non-steroidal anti-inflammatory drugs or steroids/other immunomodulatory agents may be required to treat the condition adequately. Approximately half of patients with scleritis have an underlying systemic disorder.

Scleritis is often associated with severe rheumatoid conditions. The presence of scleritis suggests that there is active systemic disease and this requires systemic work-up, including renal function tests.

Acute angle closure

This usually occurs in older, often hypermetropic, patients. The prevalence is much higher in some Asian populations. The cornea becomes hazy, the pupil oval, dilated and non-reacting, the vision poor and the eye feels hard. In severe cases pain may be accompanied by vomiting and the condition can be mistaken for an acute abdominal problem. Tonometry (intraocular measurement) and examination of the iridocorneal angle by gonioscopy (using a prism placed on the cornea) is diagnostic. Urgent treatment to reduce the pressure with pilocarpine eyedrops, oral acetazolamide and, if refractory, mannitol should be started, followed by yttrium aluminium garnet (YAG) laser iridotomy, laser iridoplasty, anterior chamber paracentesis or surgical iridectomy. The condition is usually bilateral and the second eye usually needs a prophylactic iridotomy at the same time.

Except for a simple conjunctivitis and subconjunctival haemorrhage, which are self-limiting, the management of an acute red eye requires expert treatment and a specialist opinion should be sought. A painful eye with a cranial nerve III palsy (ptosis, dilated pupil, globe down and out) often signifies an intracranial aneurysm and should be investigated immediately.

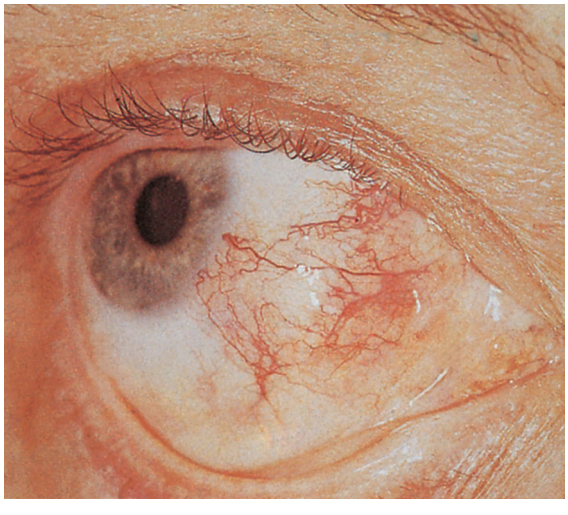

Figure 49.31 Episcleritis.

PAINLESS LOSS OF VISION

This may occur in one or both eyes, and the visual loss may be transient or permanent. Possible causes are:

- **Acute**:
  - obstruction of the central retinal artery (***Figure 49.32***);
  - obstruction of the central retinal vein (***Figure 49.33***);
  - ischaemic optic neuropathy;
  - migraine and other vascular causes;
  - vitreous and retinal haemorrhages;
  - retinal detachment (***Figure 49.34***);
  - macular hole, cyst or haemorrhage;
  - cystoid macular oedema, often after surgery;
  - hysterical blindness.
- **Chronic**:
  - cataract;
  - glaucoma;
  - macular degeneration.
  - diabetic retinopathy.

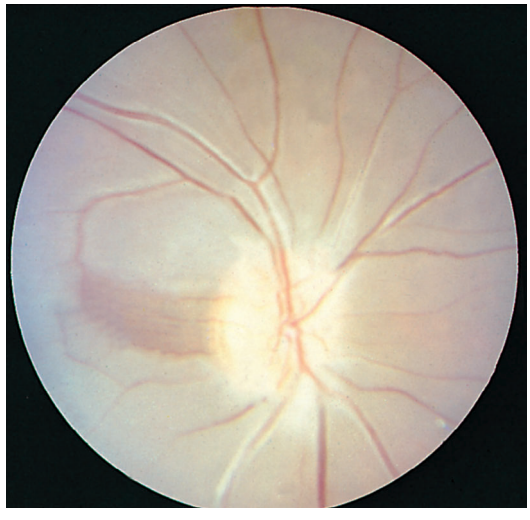

Figure 49.32 Retinal artery occlusion.

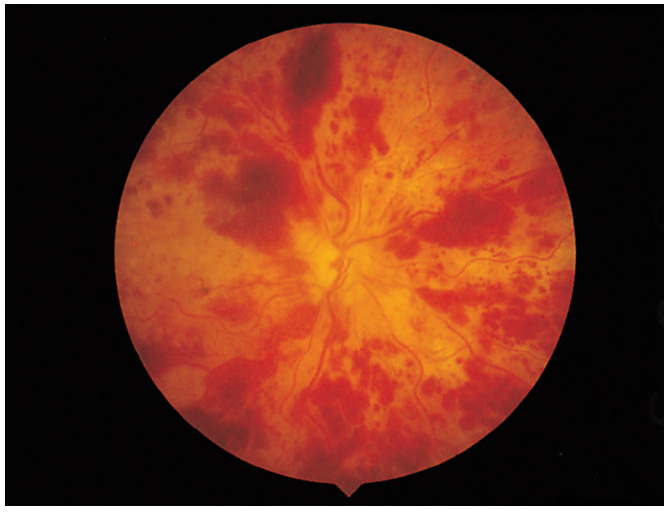

Figure 49.33 Central retinal vein occlusion.

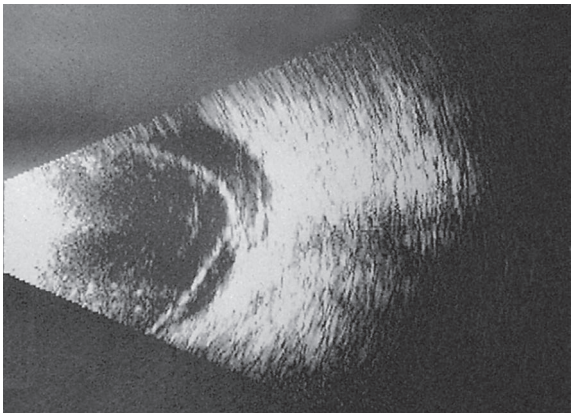

Figure 49.34 B-scan of a retinal detachment.

Specialist help should be sought in any case of loss of vision. The possibility of temporal arteritis should always be considered in the differential diagnosis of sudden visual loss, as prompt treatment of this condition is extremely important. Elderly patients with sudden visual loss should be specifically asked for symptoms of scalp tenderness and jaw claudication and temporal arteries should be palpated for pulsation and tenderness. The erythrocyte sedimentation rate and C-reactive protein should be measured immediately if temporal arteritis is suspected, and the carotid system should be examined for bruits and other signs of arteriosclerosis in cases of ischaemic optic neuropathy and central retinal artery occlusion. Glaucoma, hypertension, hyperviscosity syndromes and diabetes should be looked for in cases of central vein thrombosis.

RECENT DEVELOPMENTS IN EYE SURGERY

In the last three decades, eye surgery has become a microsurgical specialty. Cataract surgery has been transformed by changes in local anaesthesia, implants, phacoemulsification and small-incision surgery, which allows compressible/foldable silicone or acrylic implants to be inserted through a 2-mm incision. The implant power can be more accurately measured by new formulae and the use of A-scan ultrasonography or laser wavefront biometry, and multifocal and accommodative lenses are now available. An even more recent advance in cataract surgery is the development of femtosecond laser technology, which allows extremely controlled corneal incisions, lens capsule opening and lens fragmentation to be achieved automatically together with the facility to adjust the shape of the cornea at the time of surgery to improve visual outcome for some patients. The extent to which this technology improves long-term visual outcomes remains to be seen.

There are new treatments for eye disorders that involve abnormal growth of blood vessels in the back of the eye, such as the wet form of age-related macular degeneration. Anti-vascular endothelial growth factor (VEGF) antibodies, such as the drug ranibizumab, may be injected directly into the vitreous cavity to reduce new vessel proliferation. Intravitreal steroid injections or anti-VEGF agents are now also being used to treat patients with macular oedema caused, for example, by diabetic retinopathy or retinal vein occlusion.

Developments in vitreous surgery have enabled membranes to be peeled off the retina and macular holes to be repaired, and have also increased success rates in retinal detachment surgery with the additional use of gases and silicone oil or heavy liquid inserted into the vitreous cavity to tamponade the retina. Advances in technology have also led to the development of photosensitive chips and camera systems that can be implanted into the eye to restore some vision in patients with severe and otherwise untreatable macular diseases.

Some paralytic squints can be helped by the use of adjustable sutures or injections of botulinum toxin into the overacting muscles.

Refractive errors can be treated by the excimer laser. These can be combined with *laser in situ* keratomileusis (LASIK) surgery, which involves cutting a corneal flap (by femtosecond laser or surgery) and performing the laser surgery at a deeper level. There have been some concerns about defective contrast sensitivity and problems with night vision after laser correction of myopia. Phakic implants have also been used to correct high refractive errors. Corneal topography aids the accuracy of corneal and refractive surgery and the increased use and quality of CT and MRI scans has revolutionised the diagnosis of orbital and intracranial lesions involving the optic pathways (***Figures 49.35–49.37***).

Fluorescein angiography and ocular coherence tomography (OCT) are invaluable in the diagnosis and treatment of macular conditions. OCT angiography has recently been developed; this allows assessment of the retinal microvasculature without the need for systemically administered agents. This technology may reduce the need for fluorescein angiography in the future. OCT as well as scanning laser polarimetry of the retinal nerve fibre layer and Heidelberg retinal tomography (HRT) are widely used in the diagnosis and management of glaucoma. Surgical glaucoma management is also developing rapidly. Trabeculectomy surgery, where eye pressure is reduced by creating a fistula between the anterior chamber

Figure 49.35 Magnetic resonance imaging scan, sagittal view. Craniopharyngioma. The mass in the suprasellar cistern is of high signal intensity because of the proteinaceous fluid that the cyst contains (courtesy of Dr Juliette Britton).

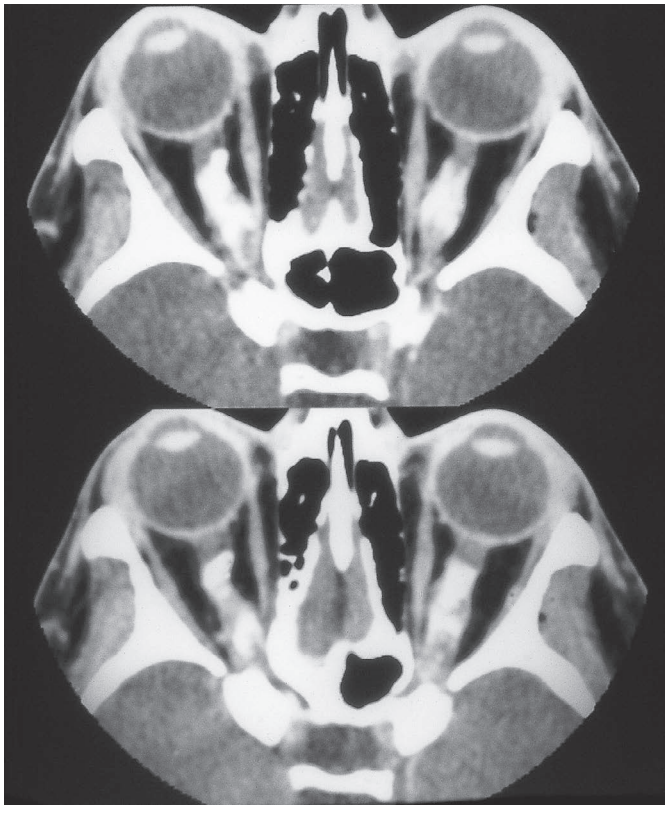

Figure 49.36 High-resolution computed tomography through the orbits showing dense calcification of the optic nerve sheaths typical of optic nerve meningioma (courtesy of Dr Juliette Britton).

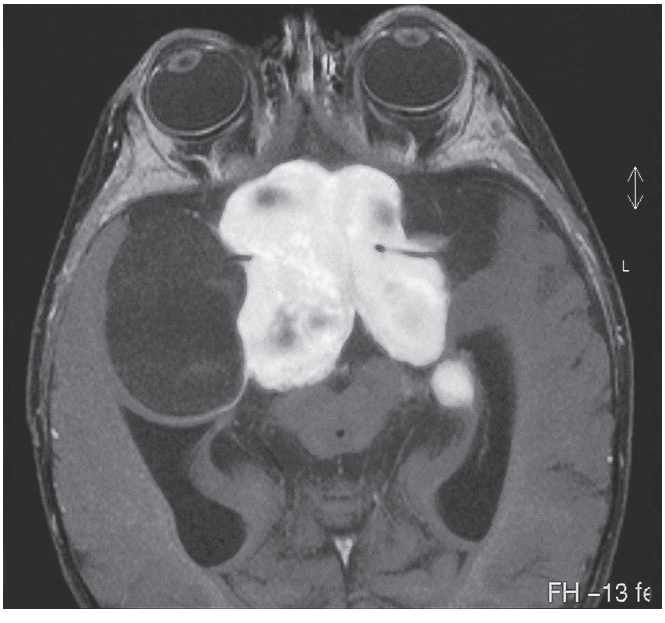

Figure 49.37 Axial enhanced magnetic resonance imaging scan showing a mass involving the optic chiasma and extending down the optic nerves and tracts.

and the subconjunctival space, remains widely used and has become more refined in recent years, with better control of wound healing using topical application of antiscarring drugs such as mitomycin C. Alternatives to trabeculectomy have been developed using devices such as Baerveldt and Ahmed shunts that drain aqueous from the eye to lower the pressure. A new revolution is also under way using minimally invasive glaucoma surgical techniques, with a variety of tiny devices now available to shunt aqueous and reduce eye pressure.

LASERS IN OPHTHALMOLOGY

Blue-green lasers (argon or frequency-doubled YAG) or diode lasers are used to treat the retina in diabetic retinopathy (pan-retinal photocoagulation for proliferative disease or focal treatment for leaky microaneurysms) and may also be used to close retinal tears or breaks that might lead to retinal detachment.

Argon laser or selective laser trabeculoplasty can be used to open the drainage angle to control elevated intraocular pressure in open angle glaucoma. Trans-scleral diode photocoagulation of the ciliary body is used to treat refractory secondary glaucoma with uncontrolled ocular pressure.

Laser iridotomy with the neodymium-doped YAG (Nd:YAG) laser is used to treat both the affected and fellow eye in acute angle closure glaucoma. The Nd:YAG laser is also used to photodisrupt and clean an opaque posterior capsule, which occurs in 5–10% of cases following cataract surgery.

SURGICAL PROCEDURES

Excision of an eyeball/enucleation

Indications include a blind, painful eye, a blind, cosmetically poor eye/intraocular neoplasm and, in cadavers, for use in corneal grafting.

The operation

The speculum is introduced between the lids and opened. The conjunctiva is picked up with toothed forceps and divided completely all round as near as possible to the cornea. Tenon's capsule is entered and each of the four rectus and two oblique muscle tendons is hooked up on a strabismus hook and divided close to the sclera. The speculum is now pressed backwards and the eyeball projects forwards. Blunt scissors, curved on the flat, are insinuated on the inner side of the globe, and these are used to sever the optic nerve. The eyeball can now be drawn forwards with the forceps, and the oblique muscles, together with any other strands of tissue that are still attaching the globe to the orbit, are divided. A swab, moistened with hot water and pressed into the orbit, will control the haemorrhage. If an orbital implant is inserted to give better eye movement, the muscles are sutured to the implant at the appropriate sites. The subconjunctival tissues and conjunctiva are closed in layers.

George G Baerveldt, 1945–2021, ophthalmologist, Emeritus Professor of Ophthalmology, UC Irvine, CA, USA.
A Mateen Ahmed, contemporary, Nigerian ophthalmologist, based in California, USA, developed the shunt that was approved by the US Food and Drug Administration in 1993.
Jacques Rene Tenon, 1724–1816, surgeon, La Salpêtrière, Paris, France.

Evisceration of an eyeball

Evisceration is preferred to excision in endo-ophthalmitis, minimising the risk of orbital and intracranial spread with meningitis. The sclera is transfixed with a pointed knife a little behind the corneosclerotic junction, and the cornea is removed entirely by completing the encircling incision in the sclera. The contents of the globe are then removed with a curette, care being exercised to remove all of the uveal tract. At the end of the operation the interior must appear perfectly white. A ball orbital implant made of acrylic or hydroxyapatite may be placed within the orbit behind the sclera to improve the appearance when the artificial eye is fitted.

Incision and curettage of chalazion (meibomian cyst)

The lid margin is everted to allow the application of a meibomian clamp. The ring of the clamp is placed on the palpebral conjunctiva with the granuloma in the centre. An incision is made with a small blade in the axis of the gland. The herniating granulomatous tissue is removed with a curette and the cavity is scraped clean. Recurrent cysts may have to have the cyst wall dissected away with scissors. A biopsy may be necessary in atypical or recurrent cysts to exclude malignant change.

PART 7 | Head and neck

CHAPTER 50

Developmental abnormalities of the face, mouth and jaws: cleft lip and palate

Learning objectives

To understand:

- The range and complexity of craniofacial anomalies
- The principles driving interventions for the developing child with a craniofacial anomaly
- In more depth the epidemiology, pathogenesis and management of cleft lip and palate

INTRODUCTION

Congenital abnormalities of the head and neck are complex and often confusing. For these reasons it is helpful to have a classification system that helps to understand the variety of conditions. For any classification system to be useful it should ideally help to explain the aetiology and pathogenesis of the abnormality and to determine treatment. For these multifaceted and multifactorial conditions an ideal classification system is not available. Consequently, there are a number of different systems available: some are purely descriptive (e.g. Tessier's classification of clefts), while others apply only to single conditions, such as the OMENS (O, orbital abnormalities; M, mandibular deformity; E, ear deformity; N, nerve involvement; and S, soft-tissue abnormalities) classification of hemifacial (craniofacial) microsomia, which has utility in instituting treatment protocols.

CLASSIFICATION OF CRANIOFACIAL ABNORMALITIES

van der Meulen and his colleagues proposed a classification system that has significant utility in helping to understand the variety and complexity of craniofacial malformations. This classification considers the embryological development of the craniofacial region. First, in terms of the formation and fusion of the processes (branchial arches): the failure of the fusion

TABLE 50.1 Types of developmental abnormalities of the face, mouth and jaws.

Type	Examples
Cerebrocranial dysplasias	Anencephaly, microcephaly
Cerebrofacial dysplasias	Rhinencephalic and oculo-orbital dysplasias
Craniofacial dysplasias with clefting	Lateronasomaxillary, medionasomaxillary, intermaxillary, maxillomandibular clefting
Craniofacial dysplasias with dysostosis	Sphenoidal, sphenoidal frontal, frontal, frontofrontal, frontonasoethmoidal, internasal, nasal, premaxillomaxillary, nasomaxillary, maxillozygomatic, zygomatic, zygoauromandibular, temporoauromandibular, mandibular, intermandibular
Craniofacial dysplasias with synostosis	• Craniosynostosis: lambdoid and sagittal • Craniofaciosynostosis: metopic, coronal, bicoronal • Faciosynostosis: vomeropremaxillary (Binder syndrome)
Craniofacial dysplasias with dysostosis and synostosis	Crouzon, Apert and Pfeiffer syndromes
Craniofacial dysplasias with dyschondrosis	Achondroplasia

After van der Meulen JC, Mazzola R, Vermey-Keers C *et al.* A morphogenetic classification of craniofacial malformations. *Plast Reconstr Surg* 1983; **71**(4): 560–72.

Paul Tessier, 1917–2008, French maxillofacial surgeon, considered the 'father of modern craniofacial surgery'.
Jacques C H van der Meulen, 1929–2017, Professor in Plastic and Reconstructive Surgery, Erasmus University, Rotterdam, The Netherlands.
Karl Heinz Binder, 1923–2016, German dentist, documented the facial features of three children with the condition that now bears his name.
Louis Edouard Octave Crouzon, 1874–1938, neurologist, Paris, France, described this syndrome in 1912.
Eugene Apert, 1868–1940, physician, L'Hôpital des Infants Malades, Paris, France, described this syndrome in 1906.
Rudolf Arthur Pfeiffer, 1931–2012, geneticist, Münster, Germany, described this syndrome in 1964.

of these processes leads to clefting disorders, for example the failure of fusion between the frontonasal process and the maxillary process results in a cleft lip, either unilaterally or bilaterally. Second, in the formation of bone and cartilage; if this is abnormal it is termed dysostosis or dyschondrosis. Third, the formation and growth at the sutures between the various bones of the craniofacial skeleton: premature fusion leads to synostosis. Superimposed on this concept is the consideration of the development of the central nervous system; this leads to a number of types of abnormality, as outlined in ***Table 50.1***.

In addition, and in common with all classification systems, there is another large group of conditions that do not sit within the system outlined above and also listed in ***Table 50.1***.

EPIDEMIOLOGY

The incidence of congenital craniofacial anomalies varies in different parts of the world and is often not easy to quantify. ***Table 50.2*** outlines the various incidences of the more common craniofacial abnormalities.

TABLE 50.2 Approximate incidence data from multiple sources.

Condition	Incidence
Apert syndrome	1 in 100 000
Pfeiffer syndrome	1 in 100 000
Crouzon syndrome	1 in 62 500
Treacher Collins syndrome	1 in 50 000
Unicoronal synostosis	1 in 10 000
Metopic synostosis	1 in 7000
Sagittal synostosis	1 in 5000
Hemifacial microsomia	1 in 3500
Neurofibromatosis	1 in 2600
Cleft lip and palate	1 in 600

DIAGNOSIS

The diagnosis of the craniofacial anomalies has, in recent years, undergone a massive change on two fronts: first, advances in ultrasonography have increased the rate of prenatal diagnosis and impacted management significantly; second, the rapid expansion in genetic understanding has led to many more mutations being linked to particular phenotypes. Despite these advances the diagnosis of the majority of these conditions remains clinical.

MANAGEMENT

In considering the management of this vast range of heterogeneous congenital abnormalities it is very difficult to generalise about management protocols. The vast majority of management is delivered by multidisciplinary teams (MDTs) within specialist centres.

Prenatal management

There have been a few reported cases of prenatal surgery when a diagnosis was made or suspected prenatally. However, these procedures remain at present experimental; in general, the options open are for termination or best supportive care in preparation for the birth. This can often provide the parents with a period of time to adjust to the impending birth of a child with additional demands and needs. The opportunity to meet parents, adults and children who have experienced the same condition is often very valuable. Termination and its therapeutic uses is obviously a contentious and very personal issue. However, some parents may request this for very treatable conditions (e.g. isolated cleft lip); in these circumstances, the local ethics board must be involved and ultimately on occasions the advice of the courts must also be sought.

Neonatal management

In the neonatal period management is aimed at addressing the urgent issues relating to the airway, breathing, eye protection and establishing feeding.

In many of the craniofacial conditions the airway can be affected and may be fully or partially obstructed. This may be because of a retropositioned hypoplastic maxilla – the tongue falling back to close off the upper airway; this is often compounded by a hypoplastic mandible. The trachea itself may also be abnormal and tracheomalacia can lead to respiratory problems. Neonates are obligate nasal breathers and some forms of nasal obstruction can precipitate airway symptoms. In the most severe cases intubation is not possible as a result of the abnormal anatomy and a tracheostomy may be necessary. In emergency situations it may be helpful to nurse the baby prone, allowing the tongue to fall forwards.

In some cases, particularly the syndromic craniosynostoses such as Apert syndrome, Pfeiffer syndrome or Crouzon syndrome, the combination of midface retrusion and brachycephalic forehead shape can lead to severe exorbitism. In the worst cases this can cause ocular dislocation with the eyelids closing behind the globe. In severe exorbitism the eyelids do not close adequately to moisturise and protect the cornea; without intervention this may lead to irreversible corneal damage.

In neonates with airway embarrassment, even without anatomical abnormalities, the effort of breathing can be exhausting and this can significantly compromise the ability to feed. Structural anomalies can also affect the ability to feed; expert input from a specialist feeding nurse is often helpful. The use of specialised teats may be helpful but in some cases naso- or orogastric feeding may be necessary.

Management in infancy (0–12 months)

At this age treatment falls into two categories: that directed at major functional issues as for neonatal care and that directed at skull surgery in cases of craniosynostosis.

Edward Treacher Collins, 1862–1932, ophthalmic surgeon, Royal London Ophthalmic Hospital and Charing Cross Hospital, London, UK, described this syndrome in 1900.

In the older child the indications for surgery remain the same; however, there is the possibility of surgery to advance the mandible in the severely retrognathic patient. This can be used to obviate the need for a tracheostomy or to allow for early decannulation. The most effective technique is distraction osteogenesis (or distraction histogenesis), which utilises the same basic principles as in limb lengthening. The bone is cut and a device placed across the osteotomy site; after a short latent period the bone ends are gradually separated, distracting the callus. In the mandible, unlike the long bones, it is not necessary to limit the bone cut to the cortex (corticotomy) and a complete osteotomy is used. The technique allows for a lengthening of approximately 1 mm/day, after which there is a retention period to allow for consolidation of the callus.

Craniosynostosis results in premature fusion of one or more of the skull sutures. The conditions may be isolated or part of a syndrome. This can result in abnormalities of both the skull and, particularly in syndromic cases, the facial skeleton. In 10–20% of single-suture cases and a higher proportion of syndromic multisuture cases the infants develop raised intracranial pressure, which presents as episodes of distress, listlessness and disturbed sleep. This may be associated with papilloedema and, untreated, can lead to visual failure. The diagnosis is confirmed with intracranial pressure monitoring.

Some congenital lesions may obstruct the vision of one or both eyes and this type of problem needs to be addressed to minimise the chances of amblyopia developing. An example of this would be the development of a large true haemangioma of the eyelids threatening to obscure the child's vision out of one eye.

Management in early childhood (1–12 years)

In early childhood management should be aimed at dealing with functional problems – airway obstruction, speech and feeding issues – but there is an increasing imperative for surgery to address the appearance of the child. There is no doubt that visible differences can affect a child's development, both socially and emotionally; however, there is a significant role for psychological and emotional support for the whole family and in some cases for the school community to help the child, family and school understand and deal with the additional pressures that visible difference makes. Surgery can make a significant difference for some patients, but for many surgery should be delayed as long as possible for an optimal outcome in the long term.

In the older child airway issues can become a problem and their identification is more difficult. The usual presentation is of sleep apnoea, which often has an insidious onset; the history should be actively sought as parents may be accustomed to noisy snoring and daytime tiredness in the child and may not consider it abnormal. Initial investigation is with a home overnight oxygen saturation monitor, which, if abnormal, should trigger a comprehensive sleep study. The management of obstructive sleep apnoea includes the use of tonsillectomy/adenoidectomy, midface advancement and mandibular distraction as well as a variety of ventilator support devices.

Management in late childhood to maturity

Airway and other functional issues are usually stabilised by this time and interventions are aimed at optimising the overall appearance. The transition from primary school to secondary school is often a period of distress for patients with visible differences and their families. If there are pressing psychological reasons corrective surgery can be offered, although this is usually best postponed until growth is complete. In general, a comprehensive integrated corrective plan should be developed within the MDT. This would usually address the skeletal and dental abnormalities first and then address the soft tissues. The majority of the major craniofacial abnormalities should be managed by a formal MDT.

CLEFT LIP AND PALATE

Introduction

Cleft lip and/or palate is the most common congenital abnormality affecting the orofacial region. These conditions most commonly occur as isolated deformities but can also be associated with other medical conditions, e.g. congenital heart disease. They are also an associated feature in over 300 recognised syndromes. All children born with a cleft are screened for other congenital abnormalities. Where the cleft is thought to be associated with a syndrome any appropriate further investigations, including genetic counselling, will be organised.

Incidence

The incidence of cleft lip and/or palate is around 1:600 live births. There are geographical and ethnic variations, with a higher incidence among the South East Asian and Native American populations than elsewhere in the world. The accuracy of these figures may be questionable owing to a variance in reporting and healthcare infrastructure.

The typical distribution of cleft types is:

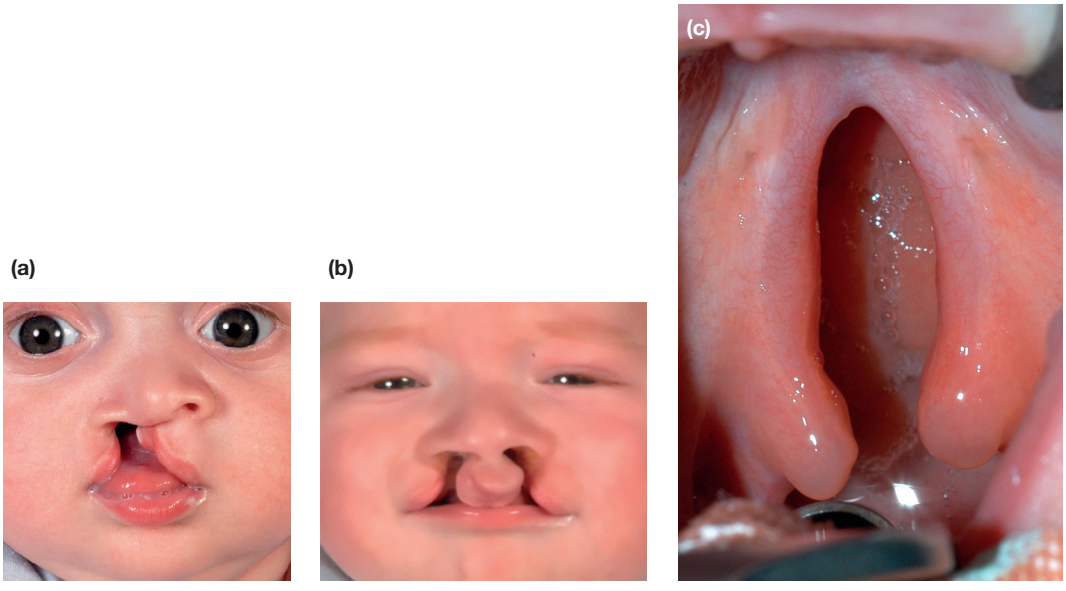
- cleft lip alone: 15% (***Figure 50.1a,b***);
- cleft lip and palate: 45%;
- isolated cleft palate: 40% (***Figure 50.1c***).

Classification of cleft

Cleft lip and/or palate presents in a heterogeneous manner. In simple terms these conditions can be divided into two clinical types (phenotypes):

1. isolated cleft palate;
2. cleft lip with or without involvement of the alveolus (tooth-bearing portion of the jaw) or palate.

Within these broad classifications a variety of combinations of cleft type can exist. These all aim to define the extent and laterality of the cleft (left/right/bilateral) (***Figure 50.2***). This information is both diagnostic and, increasingly, of prognostic value. Many have argued for a single classification system to be



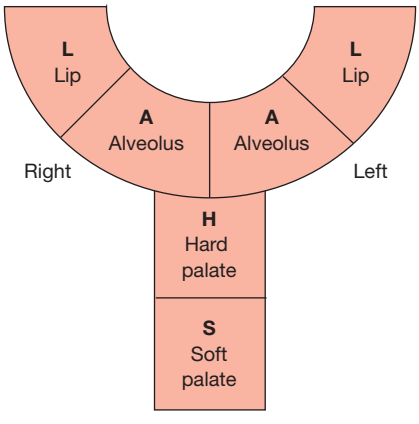


Figure 50.1 **(a)** Unilateral cleft lip. **(b)** Bilateral cleft lip. **(c)** Isolated cleft palate.

(a)

(b)

Class	Description
I	Soft palate only
II	Hard and soft palate to the incisive foramen
III	Complete unilateral of soft, hard, lip and alveolar ridge
IV	Complete bilateral of soft, hard and/or lip and alveolar ridge

Figure 50.2 **(a)** The LAHSHAL code. **(b)** The Veau classification system.

adopted: even when the same system is being used, clinicians may interpret the findings inconsistently.

In the UK, national audit data are collected for outcomes in unilateral cleft lip and palate (UCLP), thus allowing intercentre comparison. Cleft lip and/or palate is more common in males, whereas isolated cleft palate is more common in females. In UCLP the condition affects the left side in 60% of cases.

Summary box 50.1

Overview of cleft lip and palate

- Cleft lip and/or palate has two main phenotypes
- Cleft palate is more common in females and cleft lip and/or palate is more common in males
- The incidence/prevalence demonstrates geographical variation
- There are simple classification systems that describe phenotype

Aetiology

Non-syndromic cleft lip and/or palate may present as new diagnosis within a family or with a clear family history. A family history of cleft lip and palate in which a first-degree relative is affected increases the risk of subsequent cleft cases in the family, supporting the theory that there are underlying genetic mutations contributing to the aetiology. Isolated cleft palate is more commonly associated with a syndrome than cleft lip and palate and isolated cleft lip. Over 150 named syndromes are associated with cleft lip and palate, although Stickler (ophthalmic and musculoskeletal abnormalities), DiGeorge (cardiac/thymic anomalies), Down, Apert and Treacher Collins syndromes are most frequently encountered.

Victor Veau, 1871–1949, French surgeon and author of several books on cleft lip and cleft palate surgery.
Gunnar B Stickler, 1925–2010, born in Germany, Chair of Section of Paediatrics and later Paediatric Cardiology, The Mayo Clinic, Rochester, MN, USA.
Angelo Mario DiGeorge, 1921–2009, Italian American physician and pediatric endocrinologist.
John Langdon Haydon Down (sometimes given as Haydon-Down), 1828–1896, physician, The London Hospital, London, and Superintendent, Earlswood Asylum for Idiots, Surrey, UK, described this syndrome in 1866.

Various environmental factors have been implicated in the aetiology of cleft lip and/or palate, including maternal epilepsy (and associated medication) and drugs (e.g. steroids, diazepam, sodium valproate and phenytoin). The role of antenatal folic acid supplements in preventing cleft lip and/or palate remains equivocal.

Pierre Robin sequence is a condition worth considering in specific terms. This sequence comprises isolated cleft palate, retrognathia and a posteriorly displaced tongue (glossoptosis), which is associated with early airway and feeding difficulties.

Although airway obstruction does not commonly occur in babies with a non-syndromic cleft lip and/or palate, in babies with an airway obstruction, e.g. Pierre Robin sequence, hypoxic episodes during sleep and feeding can be life-threatening. Intermittent airway obstruction is more frequent and is managed conservatively. In more severe cases the children will often require adjunctive support for their airway compromise such as supplemental oxygen, nasopharyngeal airway and even tracheostomy. More controversially, surgical adhesion of the tongue to the lower lip (labioglossopexy) in the first few days after birth is an alternative but less commonly practised method of management. Mandibular distraction surgery has advocates but numerous attempts at developing a consensus view in support of this procedure for airway compromise in cleft have been unsuccessful.

Summary box 50.2

Aetiology of cleft lip and palate

- The cause of cleft lip and/or palate is multifactorial
- Most cases occur without a clear family history or known risk factors
- Clefts can be associated with many craniofacial/medical syndromes

Cleft lip and/or palate: embryology and pathogenesis

Embryologically, the lip and palate are derived from facial prominences/processes.

1. The lip/nose complex is derived from a mixture of the median nasal process and the maxillary processes.
2. The primary palate is derived from the median nasal process and consists of all anatomical structures anterior to the incisive foramen, namely the alveolus and philtral portion of the upper lip. The remainder of the lip is derived from the maxillary processes.
3. The secondary palate is derived from the maxillary processes and is defined as the remainder of the palate behind the incisive foramen, which is divided into the hard palate and, more posteriorly, the soft palate. Cleft palate results in failure of fusion or descent of the two palatal shelves. This failure to descend, fuse or remain fused can result in a cleft affecting any part of the palate.

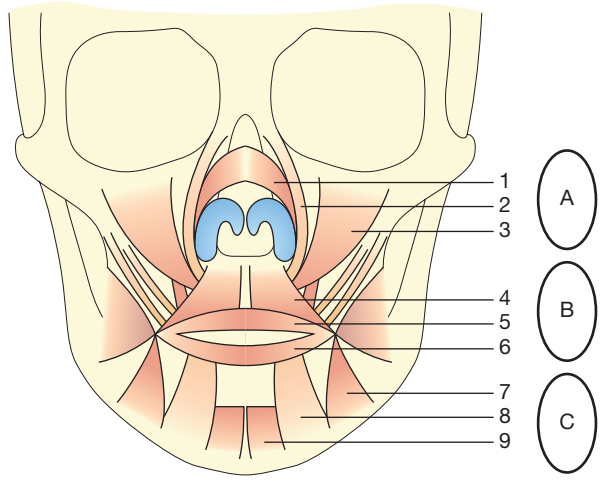

Figure 50.3 The muscle chains of the face: frontal view. The nasal cartilages are represented in blue. A, nasolabial (muscles 1–3); B, bilabial (muscles 4–6); C, labiomental (muscles 7–9); 1, transverse nasalis; 2, levator labii superioris alaeque nasi; 3, levator labii superioris; 4, orbicularis oris (oblique head) – upper lip; 5, orbicularis oris (horizontal head) – upper lip; 6, orbicularis oris – lower lip; 7, depressor anguli oris; 8, depressor labii inferioris; 9, mentalis.

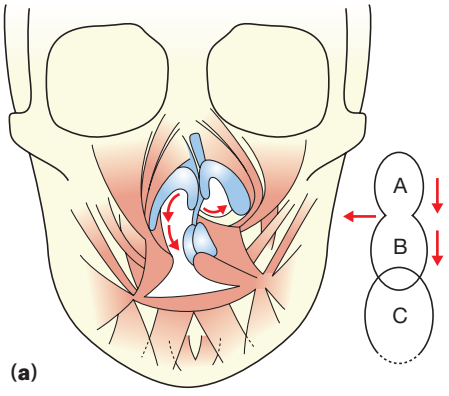
Clinical anatomy

The muscle chains of the face are shown in ***Figure 50.3***. Their disruption in unilateral cleft lip is shown in ***Figure 50.4***.

Summary box 50.3

Embryology and pathogenesis of cleft lip and/or palate

- Clefts occur at the points of fusion of facial processes
- Normal anatomical structures are displaced and disrupted
- Abnormal muscle insertion results in aesthetic and functional sequelae



Cleft lip

The abnormalities in cleft lip are the direct consequence of disruption of the muscles of the upper lip and nasolabial region. The muscle continuity is disrupted, leading to the cleft lip and also abnormal insertions of the muscle at the cleft edge. The effect of this can be seen on the nasal septum and the nose itself.

Unilateral cleft lip

In the unilateral cleft lip, the muscle rings are disrupted on one side, resulting in an asymmetric upper lip and/or nose. This involves the external nasal cartilages, nasal septum and anterior maxilla (premaxilla). This influences the mucocutaneous tissues, causing a displacement of nasal skin onto the lip and a retraction of labial skin, as well as changes to the vermilion and lip mucosa. All these changes need to be considered in planning the surgical repair of the unilateral cleft lip.

Pierre Robin, 1867–1950, Professor, The French School of Dentistry, Paris, France, described this syndrome in 1929.

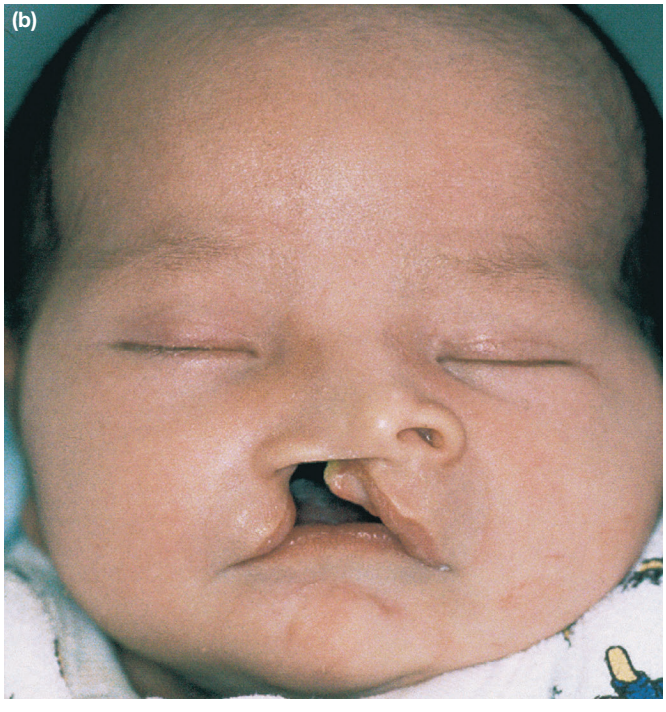


Figure 50.4 (a) Schematic representation of disruption of the nasolabial and bilabial muscle chains in unilateral (right) cleft lip. A, nasolabial; B, bilabial; C, labiomental. **(b)** Unilateral cleft lip before muscular reconstruction (courtesy of William P Smith).

Bilateral cleft lip

In the bilateral cleft lip the disruption is greater but often symmetrical. Muscular continuity is disrupted bilaterally, producing a flaring of the nose (caused by a lack of nasolabial muscle continuity), a protrusive premaxilla and an area of skin in front of the premaxilla devoid of muscle, known as the prolabium. As in the unilateral cleft lip, the muscular, cartilaginous and skeletal deformities influence the mucocutaneous tissues, which must be respected in planning the repair of the bilateral cleft lip.

Cleft palate

Embryologically, the primary palate consists of all anatomical structures anterior to the incisive foramen, namely the alveolus and upper lip. The secondary palate is defined as the remainder

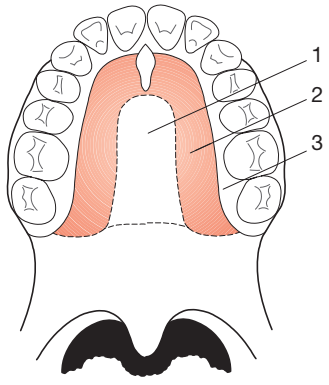

Figure 50.5 The three mucosal zones of the hard palate. 1, palatal fibromucosa; 2, maxillary fibromucosa; 3, gingival fibromucosa.

of the palate behind the incisive foramen, divided into the hard palate and, more posteriorly, the soft palate.

Cleft palate results in failure of fusion of the two palatine shelves. This failure may be confined to the soft palate alone or involve both hard and soft palate. When the cleft of the hard palate remains attached to the nasal septum and vomer, the cleft is termed incomplete. When the nasal septum and vomer are completely separated from the palatine processes, the cleft palate is termed complete.

Soft palate

In the non-cleft soft palate, closure of the velopharynx, which is essential for normal speech development, is achieved by elevation of the soft palate. Although this is achieved by coordinated muscular activity, it is the levator veli palatini that is the key muscle in achieving this. In general, the muscle fibres of the soft palate are orientated transversely with no significant attachment to the hard palate. In a cleft palate the muscle fibres are orientated in an anteroposterior direction, inserting into the posterior edge of the hard palate.

Hard palate

The hard palate can be divided into three anatomical and physiological zones (***Figure 50.5***). The central palatal fibromucosa is very thin and lies directly below the floor of nose. The maxillary fibromucosa is thick and contains the greater palatine neurovascular bundle. The gingival fibromucosa lies more lateral and adjacent to the teeth.

In performing surgical closure of a cleft palate, the changes associated with the cleft must be understood to obtain an anatomical and functional repair. In complete cleft palate the median part of the palatal vault is absent and the palatal fibromucosa is reduced in size. The maxillary and gingival fibromucosa are not modified in thickness, width or position.

The cleft multidisciplinary team and primary management

The cleft team

Modern cleft services rely on well-coordinated patient pathways. The pathways and protocols may vary from country to country but the aims of treatment are consistent. Care is

provided from diagnosis onwards to ensure that every patient with cleft lip and/or palate has appropriate access to the correct clinician and care at the optimal time. In the UK, most children with a cleft involving the lip are diagnosed antenatally. Scanning protocols now include an 'anomaly scan' at around 20 weeks. Isolated cleft palate cannot be diagnosed antenatally using routine scanning techniques. Some researchers have suggested that Doppler studies may help in diagnosing isolated cleft palate. When an antenatal diagnosis is confirmed, referral to a cleft team is appropriate. Clinical nurse specialist involvement would commence from this point onwards.

The cleft MDT therefore has a range of clinical expertise and specialisms within it. These are:

- **Cleft coordinator/administrator**. This is vital to ensure that patients and families have clinical episodes organised as per the protocol of the service. Responsive administrative support is vital for patients, families and clinicians.
- **Clinical nurse specialist** (CNS). The role of the CNS is central to the safe and effective delivery of cleft care. These clinicians will, in most cases, be the first clinical contact with the team. The CNS will assess the child and provide initial support to the family. Assessment of feeding, airway and general well-being is carried out. The role of the CNS is vital in ensuring that each child is optimally prepared for surgery.
- **Paediatrician**. Most children who have a cleft will be otherwise well. In some cases there may be associated or coexisting medical problems, e.g. cardiac or respiratory. These will require appropriate specialist input and perhaps coordination of care by a paediatrician.
- **Speech and language therapist** (SLT). The input of an SLT is vital where palatal involvement exists in the cleft type. Assessment and therapy are provided where required. Outcome measurements and diagnosis of palatal dysfunction are key elements of the SLT's role in cleft care.
- **Ear–nose–throat (ENT)/audiology**. Regular hearing tests and effective intervention for hearing loss are vital in ensuring speech development. This is a key part of early cleft care.
- **Paediatric dentist**. Traditionally dental/oral health has been poor for this patient group. A greater emphasis on disease prevention has resulted in much improved dental outcomes. A key part of early health care would involve a paediatric dentist.
- **Orthodontist**. The role of the orthodontist varies in different services. Some services will have early orthodontic intervention to mould the anterior cleft presurgically. This is not undertaken in many countries, e.g. the UK. The orthodontist, therefore, becomes a key figure at around 7 years of age as the child enters the early 'mixed dentition' phase. Assessment and preparation for alveolar bone grafting (ABG) as well as definitive orthodontic alignment are undertaken where required. The orthodontist is a key member of the team delivering orthognathic (jaw alignment) surgery at the point of skeletal maturity if required.
- **Clinical psychologist**. These clinicians are involved throughout the clinical pathway, providing support to patients, families and team members. Key outcomes in relation to quality of life are assessed by these clinicians.
- **Cleft surgeon**. The cleft surgeon's role is to provide assessment and intervention to patients. The main aim of cleft surgery is to correct the underlying anatomical abnormalities that can lead to issues with appearance and function. Optimal clinical outcomes can be achieved for most patients with limited surgical intervention. One to three operative interventions (depending on the type of cleft) in childhood are all that would be planned as part of a cleft pathway/protocol. Outcomes of surgery/cleft care are audited annually in most countries.

Immediate/neonatal care

Feeding

Babies born with a cleft involving the palate will feed well and thrive, provided that they receive the appropriate CNS input. The feeding aids for a child with a cleft palate aim to improve the efficiency of delivery of milk, reducing the effort of feeding. Expressed breast milk is best. A range of modified bottles and teats are available. Soft bottles allow the parents to do much of the work of milk delivery for the child by synchronising their 'squeeze' to the baby's 'suck'. Feeding plates, constructed from a dental impression of the upper jaw, were used in the past in the UK and may still be used in other parts of the world.

In some units, babies are provided with an active plate that aims not only to improve feeding but also to reduce the width of the cleft and improve the shape of the nose prior to surgery – nasoalveolar moulding (NAM). The evidence in the literature of long-term benefit using such a regime is conflicting.

Summary box 50.4

Immediate/neonatal care for a patient with a cleft and/or palate

- Babies born with a cleft may have issues with feeding and airway
- A team of clinicians is required to meet all the needs of a child with a cleft
- Most of the care delivered to a child with a cleft lip and/or palate is non-surgical in the initial phase

PRINCIPLES OF CLEFT SURGERY

The ultimate aim in cleft lip and palate management is to facilitate normal development and well-being. In seeking this, surgical repair is aimed at producing normal anatomy in the lip, nose and palate. Essentially, oral and dental health should also be optimised in the management. Key outcomes measured include speech, facial growth, general well-being and dental health.

With the exception of rare conditions such as holoprosencephaly, there is no true hypoplasia of the tissues involved

Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the 'Doppler principle' in 1842.

Figure 50.6 Postoperative unilateral cleft lip repair.

Figure 50.7 Postoperative bilateral cleft lip repair.

on either side of the cleft. There is, however, displacement, deformation and underdevelopment of the muscles and facial skeleton. Emphasis is placed on muscular reconstruction of the lip, nose and face as well as muscles of the soft palate.

Normal or near-normal anatomy promotes normal function, thereby encouraging normal growth and development of lip, nose, palate and facial skeleton. An in-depth understanding of the anatomy of the cleft is invaluable if the surgeon is to achieve normal, or near-normal, anatomical reconstruction.

Surgical techniques

Much debate and variation exist across the world in the timing and techniques employed in cleft repair. All have the common aims stated above. Restoration of form and function can be achieved using many of these protocols, but the following protocol is that which is used in the UK and was popularised in Norway.

- Cleft lip/nose and anterior palate repair is performed between 3 and 6 months of age (***Figures 50.6 and 50.7***).
- The anterior palate closure is achieved by using a single-layer mucosal flap from the vomer. The lip is closed using a variety of described techniques but most surgeons believe that the muscle repair is more important than the skin incision, hence the variation.

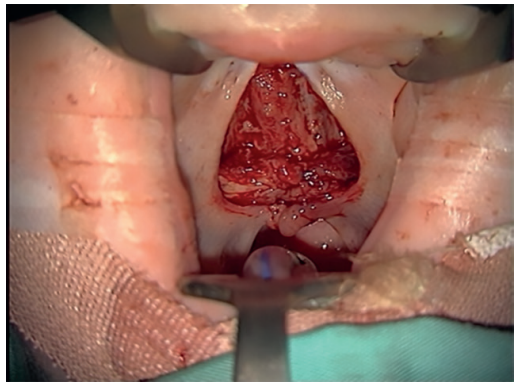

Figure 50.8 Dissection of the levator muscles.

- Definitive cleft palate repair is carried out between 6 and 12 months. There is conflicting evidence within the published literature relating to optimal timing of palate repair. The principle applied in the UK is that of closure during the early stages of speech development.
- The most common surgical approach in cleft palate repair is the intravelar veloplasty (IVVP), in which incisions along the cleft edge provide access to the soft palate muscle. The levator muscles are dissected free (***Figure 50.8***) and sutured together in the midline to recreate a muscular sling.

Summary box 50.5

Primary surgery for cleft lip and/or palate

- Treatment staged from anterior (lip) to posterior (soft palate) in the UK
- Multiple eponymous skin incisions for lip repair but muscle reconstruction is key
- Management of the levator sling is key in cleft palate repair

Age 1–7 years: early years care/ follow-up

Following primary surgery, regular review by an MDT is essential. Many aspects of cleft care require review during the early years of childhood:

- hearing;
- speech;
- dental development;
- wound healing and aesthetics.

Hearing

Eustachian tube dysfunction plays a central role in the pathogenesis of otitis media with effusion (OME) in babies and children born with a cleft palate. Children with a cleft lip alone exhibit the same frequency of otitis media as their age-matched counterparts, whereas those children with palatal involvement may have an increased incidence of OME. Regardless of the

Bartolomeu Eustachio (Eustachius), 1513–1574, Professor of Anatomy, appointed physician to the Pope in 1547.

incidence it is important for normal speech development that hearing is within normal limits.

All children are screened at birth, but those who have a cleft palate are monitored regularly with audiological screening.

Speech

In the UK, specialist SLTs involved in cleft care engage at an early stage with families and children. Some teams will run group sessions to encourage speech development. Speech is constantly monitored during development and early intervention is advisable if speech pathology is suspected or diagnosed.

The problems that may present can be considered in two broad groups:

1. **Velopharyngeal incompetence** (VPI). Where the soft palate fails to achieve adequate velopharyngeal closure, which is required for certain sounds in speech, air escape occurs, leading to the resonance issue of hypernasality. This can lead to unintelligible speech because of either the hypernasality itself or the adaptations made by the child in an attempt to achieve velopharyngeal closure.
2. **Articulation errors**. These either arise as a compensatory mechanism, as stated above to overcome VPI, or, less commonly, are caused by jaw/dental and occlusal abnormalities.

To investigate these problems, the cleft team relies upon the specialist SLT assessment and investigations such as lateral videofluoroscopy and nasendoscopy. These investigations are used to visualise the palate as it moves in real time during speech.

Secondary speech surgery may be offered when there are structural issues to overcome such as VPI. Cleft palate repair is carried out when the palatal function is assessed to be suboptimal but other procedures that alter the dynamics of airflow during speech to reduce nasal escape may also be employed. These interventions are broadly termed pharyngoplasty procedures.

Dental

Dental anomalies are common findings in children with cleft lip and/or palate. Various phenomena, including delayed tooth development, delayed eruption of teeth and morphological abnormalities, are well documented. The number of teeth may be reduced (hypodontia) or increased (hyperdontia), occurring most commonly in the region of the cleft alveolus and involving the maxillary lateral incisor tooth. These abnormalities can occur in both primary and secondary dentition. All children with cleft lip and palate should undergo regular dental examination. Dental management should also include preventive measures such as dietary advice, fluoride supplements and fissure sealants. A well-maintained and disease-free dentition in childhood provides the optimal situation for successful orthodontic treatment.

Wound healing/aesthetics

Wound infections are rare but if they occur may lead to revision surgery. If this is a lip wound infection then revision can be timed to be pre-school or, if the problem is subtle, the lip can be revised opportunistically at the time of, for example, ABG.

Palatal dysfunction may require cleft palate repair or pharyngoplasty as described earlier in ***Speech***.

Age 7–12 years: late childhood care/ follow-up

Alveolar bone grafting

ABG is a key surgical intervention for patients with alveolar involvement. The procedure can be carried out at the same time as primary cleft lip surgery and is defined as primary bone grafting. More commonly the procedure is a separate surgical intervention later in development. In this case the term secondary bone grafting is used. Secondary bone grafting is timed in relation to the development of the underlying adult dentition in the region of the cleft. Dental development can be assessed radiographically and the optimal window for bone grafting is thus easily defined. The lateral incisor tooth is commonly absent or diminutive but, if present and of normal morphology, the bone graft can be timed around the root development of this tooth (often described as early secondary grafting at age 5–7 years).

The canine tooth is most commonly used in assessment and timing. The optimal timing for intervention is at the point when the canine root is one-half to two-thirds formed (often described as late secondary grafting at age 8–11 years). As there is wide variation in the rate of dental development it is better to assess each patient and their dentition on an individual basis and tailor the treatment to this.

Patients may undergo a short period of orthodontic treatment prior to bone grafting. Less than 50% of patients with UCLP will require this. When carried out, the aim is to expand the alveolar cleft to improve surgical access. Occasionally the adjacent teeth may be aligned in advance of surgery if they are interfering with access. It is vital in a bilateral cleft to be able to stabilise the mobile anterior (premaxillary) segment to facilitate bone healing. Adjunctive secondary procedures can be carried out simultaneously, e.g. cleft lip revision.

The success rate of ABG is high. There are a variety of scoring systems used to measure outcome. Close teamwork between the cleft surgeon and the orthodontist is vital. In the situation where there is significant hypodontia in the region of the cleft a decision may be taken **not** to perform ABG. In this case the missing teeth can be replaced with a variety of restorative options, including a denture, an adhesive bridge or an implant-retained prosthesis. Bone grafting will be required for implant placement but this is better carried out when the patient is skeletally mature.

The primary objectives when performing ABG are to:

- provide adequate bony support for the adult teeth to enable subsequent orthodontic alignment;
- enable the eruption of adult teeth into the line of the dental arch;
- stabilise the premaxilla in bilateral clefts;
- definitively close the residual alveolar cleft.

The secondary objectives or associated benefits may include aesthetic improvements to the nasolabial region.

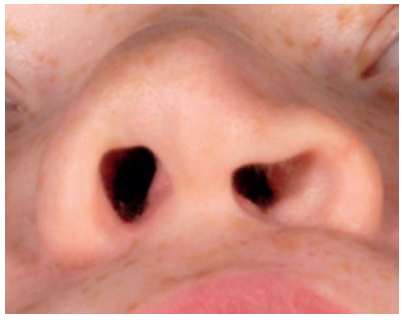

Figure 50.9 Nasal asymmetry.

Figure 50.10 Nasal asymmetry addressed by open surgical revision.

Orthodontic treatment

Children with cleft lip and alveolar involvement will often benefit from orthodontic treatment. Orthodontic treatment is commonly carried out in two phases:

1. Mixed dentition (8–10 years): to prepare the alveolar cleft for ABG (see ***Alveolar bone grafting***).
2. Permanent dentition (12–18 years): to definitively align the dental arches, aiming for a normal functioning occlusion. This phase of treatment may be linked to preparation for orthognathic surgery (jaw alignment surgery).

SECONDARY/REVISION SURGERY

These procedures are undertaken to improve aesthetics and/or function. They may be considered as procedures that were unplanned at the time of primary surgery. Specific examples are as follows.

Cleft lip/nose revision

Indications for revisional surgery to a previously repaired cleft lip are dependent on the site and severity of the residual deformity.

Relative indications for lip revision include:

- misaligned vermilion;
- lip asymmetry.

Relative indications for residual nasal deformity include:

- incorrect alar base position;
- poor nasal tip projection;
- deviation of cartilaginous nasal septum into the non-cleft nostril.

Residual nasal deformity is an external manifestation of incomplete reconstruction of the nasolabial muscle ring (see ***Clinical anatomy***). It is thought less than ideal to surgically interfere with the nasal septum in the growing child. Minor adjustments are possible before the age of 14–15 years (***Figures 50.9 and 50.10***), but more major nasal surgery is usually delayed until after this age.

Open septorhinoplasty may be considered for definitive surgical nasal correction. In patients with cleft lip and palate, open surgery is preferred to gain access to the external cartilaginous framework, which is frequently affected by the primary issues of muscle attachment related to the cleft. One common feature is collapse of the lower lateral cartilage on the cleft side together with a dislocation of the cartilaginous septum into the non-cleft nostril. The open method ensures adequate access and repositioning of the cartilaginous framework as a tertiary procedure to improve nasal tip projection, correct septal deformity and relocate alar cartilages. Grafting techniques are often employed using harvested septal (nasal) cartilage or conchal (ear) cartilage.

Orthognathic surgery

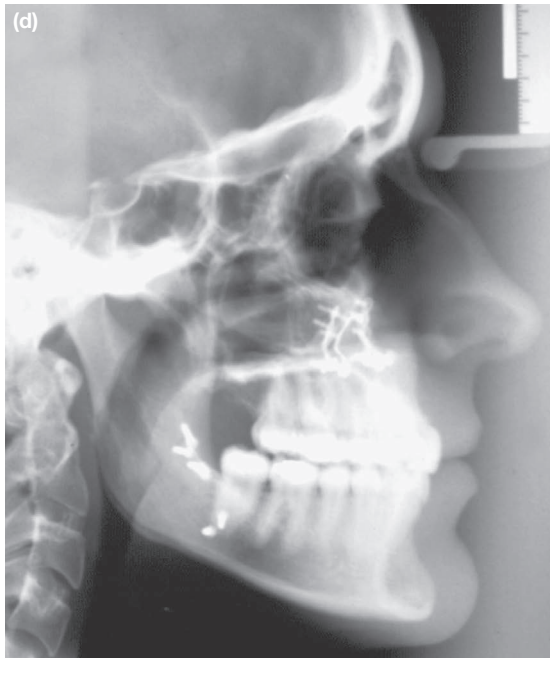
Impaired growth of the midface (maxilla) is a consequence of a number of factors, which are poorly understood. Genetic factors as well as local factors following primary surgery may be involved. Elective maxillary advancement or bimaxillary surgery may be indicated to restore aesthetics and dental occlusal harmony. Orthognathic surgery is usually performed when facial growth is complete (16–17 years in female patients, 17–19 years in male patients).

The principal dentofacial deformity associated with cleft lip and palate is underdevelopment in both the horizontal and vertical direction of the maxilla. This jaw size discrepancy can be corrected with orthognathic surgery (***Figure 50.11***).

SUMMARY

Cleft care has been the subject of significant reorganisation in recent years. Coordinated care is provided in most countries by MDTs. Specific training pathways exist in many countries for cleft surgery. Better collection and collation of outcome data will drive evidence-based improvements in care and service development.

Summary box 50.6



Summary of care for patients with cleft lip and/or palate

- Cleft surgery in infants is time sensitive
- Aesthetic and functional outcomes are important and are measured
- Surgery involves restoration of muscle position to as close to normal as possible
- Planned surgery includes bone grafting in children with alveolar involvement
- Revision/secondary surgery optimises aesthetic and functional outcomes

PART 7 | Head and neck

CHAPTER 51

The ear, nose and sinuses

Learning objectives

To be familiar with:
- The anatomy of the ear
- The conditions of the outer, middle and inner ear
- The examination of the ear, including hearing tests
- The basic anatomy of the nose and paranasal sinuses
- The principles of managing post-traumatic nasal and septal deformity
- The causes and management of epistaxis

To understand:
- The outer layer of the tympanic membrane migrates outwards
- The facial nerve can be damaged by trauma and ear disease
- Chronic ear disease can lead to intracranial sepsis
- There are two types of hearing loss: conductive and sensorineural
- The clinical features of sinus infection, its treatment and potential complications
- The diagnosis and management of chronic rhinosinusitis with and without nasal polyposis
- The common sinonasal tumours, their presentation, investigation and principles of treatment

INTRODUCTION

Disorders affecting the ear, nose and sinus are common reasons for primary care attendance; however, few surgeons will encounter such diseases in day-to-day practice. Nonetheless, traumatic, infective and neoplastic processes can impact on these organs and their anatomical proximity to critical anatomical structures demands a basic understanding in order to efficiently diagnose, refer and treat conditions. A full and detailed review of the management of ear and nose conditions is beyond the scope of this text. Instead, the aim of this chapter is to familiarise the reader with the basic anatomy and pathology relevant to patients who present with conditions affecting the ear, nose and sinuses.

THE EAR

The mammalian ear is an evolutionary masterpiece. Its highly complex 'three-dimensional anatomy' is best learnt by dissecting cadaver temporal bones.

The external ear

The external and middle ear develop from the first two branchial arches. The external ear canal is 3 cm in length; the outer two-thirds is cartilage and the inner third is bony. The skin on the lateral surface of the tympanic membrane is highly specialised and migrates outwards along the ear canal. As a result of this migration most people's ears are self-cleaning. The external canal is richly innervated and the skin is tightly bound down to the perichondrium so that swelling in this region results in severe pain.

The lymphatics of the external ear drain to the retroauricular, parotid, retropharyngeal and deep upper cervical lymph nodes.

The tympanic membrane and middle ear

The anatomy of the tympanic membrane and ossicles is shown in ***Figure 51.1***. The relations of the middle ear are important (***Figure 51.2***). The tympanic membrane and ossicles act as a transformer of vibrations in the air to vibrations within the fluid-filled inner ear.

The inner ear

The inner ear comprises the cochlea and vestibular labyrinth (saccule, utricle and semicircular canals). These structures are embedded in dense bone called the otic capsule.

The cochlea is a coiled shell of two and three-quarter turns. Within the cochlea is a spiral structure called the cochlear duct (***Figure 51.3***), which contains endolymph that is partitioned by Reissner's membrane from the perilymph of the scala vestibuli and the basilar membrane from the perilymph of the scala tympani. The perilymph sits uninterrupted from the oval window and stapes footplate at the start of the scala vestibuli in continuity with the round window membrane at the end of the scala tympani (***Figure 51.4***). The endolymph has a high concentration of potassium, similar to intracellular fluid, and

Ernst Reissner, 1824–1878, Professor of Anatomy at Dorpat and later at Breslau, Germany (now Wrocław, Poland), described the vestibular membrane of the cochlea in 1851.

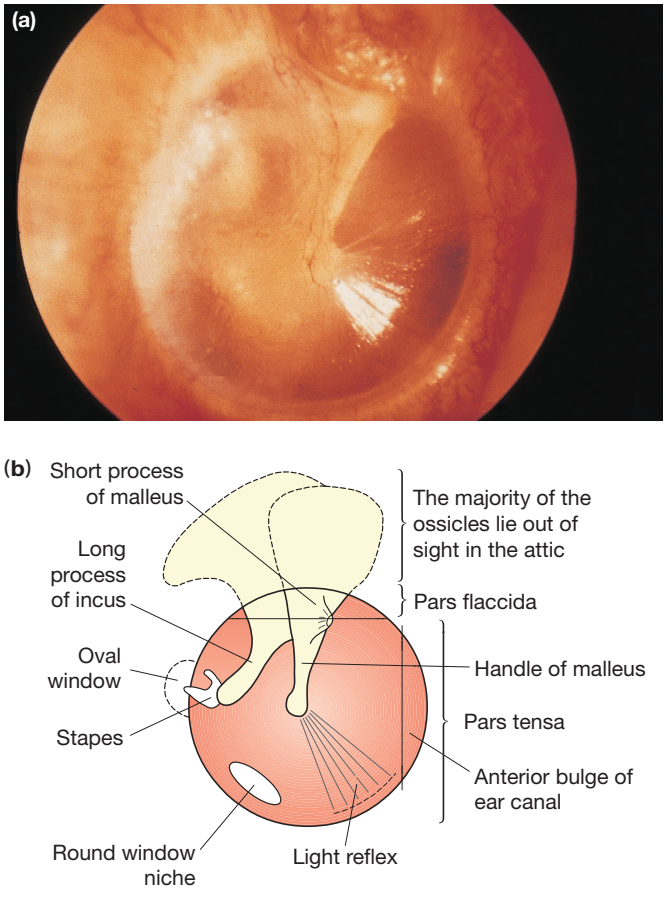

Figure 51.1 (a) Right tympanic membrane and **(b)** diagram to illustrate the anatomy of the tympanic membrane and ossicles (courtesy of Dr Christian Deguine).

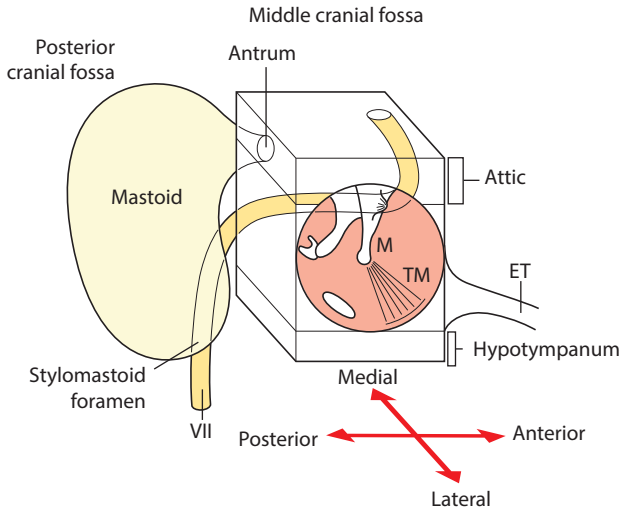

Figure 51.2 Diagram of the right ear to show the relationships of the middle ear. ET, Eustachian tube; M, malleus; TM, tympanic membrane; VII, facial nerve (courtesy of Dr Christian Deguine).

the perilymph has a high sodium concentration and communicates with the cerebrospinal fluid (CSF). Maintenance of the ionic gradients is an active process and is essential for neuronal activity.

There are approximately 15 500 hair cells in the human cochlea. They are arranged in rows of 3500 inner and 12 000 outer hair cells. Movement of the stapes footplate causes a pressure wave through the perilymph, resulting in vibration of the basilar membrane and a shearing motion between the tops of the hair cells and the tectorial membrane. The inner hair cells act as mechanicoelectric transducers, converting the acoustic signal into an electric impulse. The outer hair cells contain contractile proteins and serve to tune the basilar membrane on which they are positioned. Each inner hair cell responds to a particular frequency of vibration. When stimulated, it depolarises and passes an impulse to the cochlear nuclei in the brainstem.

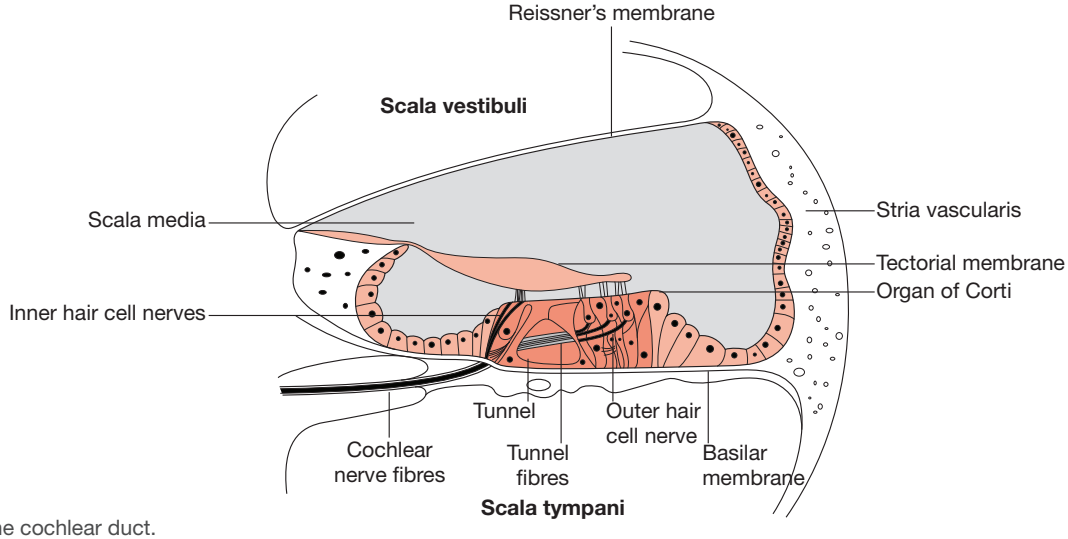

Figure 51.3 The cochlear duct.

Bartolomeu Eustachio (Eustachius), 1513–1574, Professor of Anatomy, appointed physician to the Pope in 1547.
Alfonso Giacomo Gaspare Corti, 1822–1876, Italian anatomist.

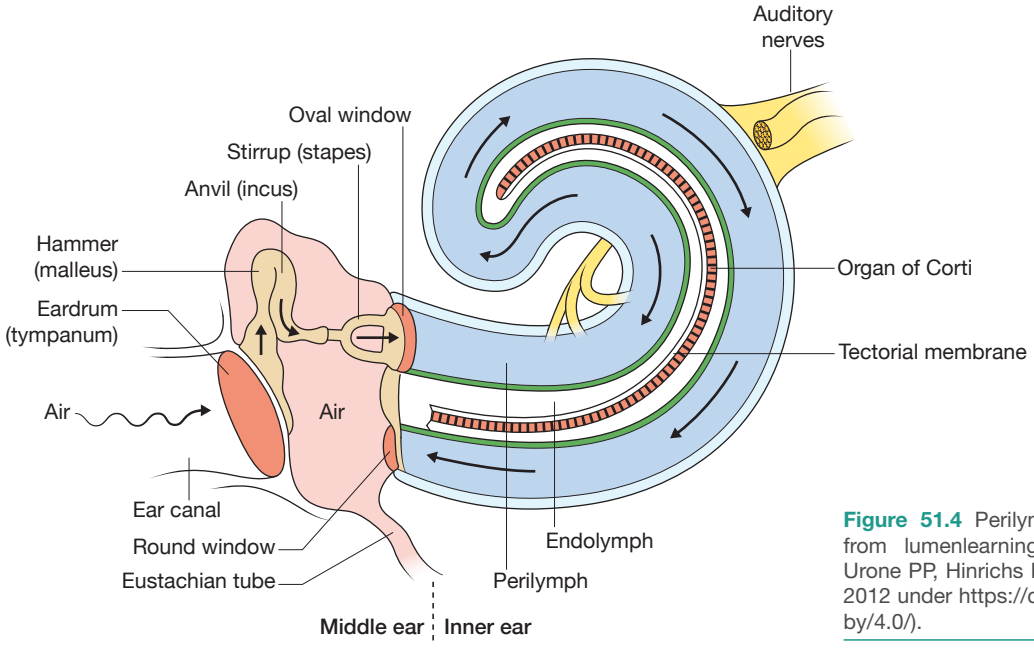

Figure 51.4 Perilymph pressure wave (adapted from lumenlearning.com; originally taken from Urone PP, Hinrichs R. *College Physics*, OpenStax, 2012 under https://creativecommons.org/licenses/by/4.0/).

The vestibular labyrinth consists of the semicircular canals, utricle and saccule and their central connections. The three semicircular canals are arranged in the three planes of space at right angles to each other. Like the auditory system, hair cells are present. In the lateral canals, the hair cells are embedded in a gelatinous cupula. Shearing forces, caused by angular movements of the head, produce hair cell movements and generate action potentials. In the utricle and saccule the hair cells are embedded in an otoconial membrane, which contains particles of calcium carbonate. These respond to changes in linear acceleration and the pull of gravity.

Impulses are carried centrally by the vestibular nerve and connections are made to the spinal cord, cerebellum and external ocular muscles. Its function is to record the position and movements of the head.

The sensory nerve supply

The external ear is supplied by the auriculotemporal branch of the trigeminal nerve (cranial nerve [CN] V) and the greater auricular nerve (C2/3), together with branches of the lesser occipital nerve (C2). CNs VII, IX and X also supply small sensory branches to the external ear. The middle ear is supplied by the glossopharyngeal nerve (CN IX).

This complicated and rich sensory innervation means that referred otalgia is common and may originate from the normal area of distribution of any of the above nerves. A classic example is the referred otalgia caused by cancer of the larynx or hypopharynx.

Taking a thorough history is the most important part of the assessment; the symptoms that need to be enquired after are listed in ***Table 51.1***.

Summary box 51.1

Applied anatomy

- The skin on the outer surface of the eardrum migrates outwards so that the ear canal is 'self-cleaning'
- Infection of the middle ear and mastoid can easily spread to the cranial cavity
- The facial nerve pursues a tortuous course through the middle ear
- The ear has a rich sensory innervation so that 'referred otalgia' is common
- Cancer of the larynx or lower pharynx can present with otalgia

TABLE 51.1 History taking.

Ask about:

- Earache, pain and itch
- Hearing loss
- Discharge: type, quantity and smell
- Tinnitus
- Vertigo
- Facial weakness
- Speech and development (in children)
- Past history: head injury, baro- or noise trauma, ototoxics, family history and previous ear surgery

EXAMINATION OF THE EAR

The instruments required for examination are shown in ***Figure 51.5***. Examination of the ear is part of the general ear, nose and throat (ENT) examination. Rinne and Weber tuning fork tests are used to distinguish between a conductive

Friedrich Heinrich Adolf Rinne, 1819–1868, otologist, Göttingen, Germany, described this test in 1855.
Friedrich Eugen Weber-Liel, 1832–1891, otologist, University of Berlin and Jena, Germany, described the operation of tenotomy of the tensor tympani used for certain forms of partial deafness.

Figure 51.5 Tools of the trade: a fibreoptic otoscope, with pneumatic attachment and a selection of specula. Also a 512-Hz tuning fork.

Figure 51.6 The correct method of holding the otoscope. Note the pinna is retracted to straighten the ear canal. Hold the barrel of the otoscope so that the examiner's little finger is balanced on the patient's cheek; this prevents the speculum impinging on the tympanic membrane in case of sudden movement.

and a sensorineural hearing loss. The correct way to hold an otoscope is shown in ***Figure 51.6***.

The CNs and especially the function of the facial nerve should be examined. Although conversational testing can give a useful guide to the level of hearing, pure tone audiometry in a soundproof booth is the best way of establishing the air and bone hearing levels (***Figure 51.7***). Other common audiological tests include speech audiometry, tympanometry, stapedial reflexes, electric response audiometry, otoacoustic emissions, caloric testing and electronystagmography (see ***Further reading***).

Radiological investigation

Computed tomography (CT) scanning of the temporal bones is commonly performed before mastoid surgery to show detailed individual anatomy, as well as alerting the surgeon to anatomical variants. Pus, bone and air are shown well on high-resolution CT (***Figure 51.8***).

Figure 51.7 Audiometry. The patient sits in a soundproof room and the audiologist presents sounds at different thresholds and records the responses.

Figure 51.8 Computed tomography scan showing a normal left ear. The air-filled middle ear and the incus and stapes, the semicircular canals and internal acoustic meatus can be seen. In the right ear the entire middle ear and mastoid are opaque and filled with soft tissue. This is the typical appearance of a cholesteatoma.

Magnetic resonance imaging (MRI) is better than CT at imaging soft tissue (e.g. facial and auditory nerve) and is the best method for imaging tumours of the acoustic nerves (***Figure 51.9***). Diffusion-weighted MRI is also commonly used to detect recurrent cholesteatoma.

CONDITIONS OF THE EXTERNAL EAR

Congenital anomalies

The external and middle ear originate from the first and second branchial arches, but the cochlea is neuroectodermal in origin. An individual can have a congenital abnormality of the pinna and middle ear with a normal cochlea and therefore the potential for normal hearing.

Trauma

A haematoma of the pinna occurs when blood collects under the perichondrium. The cartilage receives its blood supply

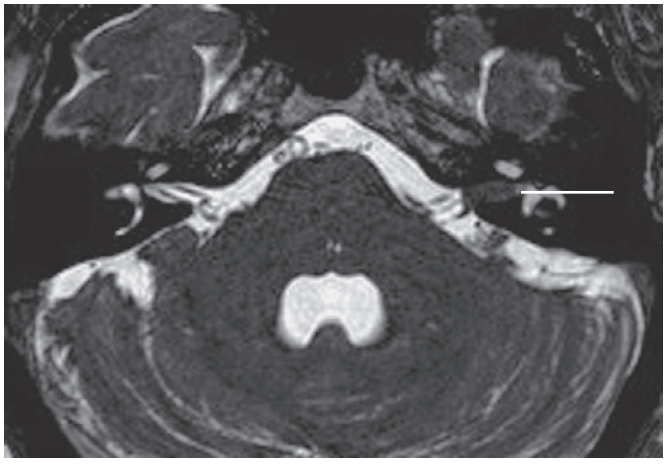

Figure 51.9 Computed tomography scan showing a vestibular schwannoma occluding the left internal acoustic meatus (arrow).

from the perichondrial layer and will die if the haematoma is not evacuated, resulting in a so-called cauliflower ear. A generous incision under anaesthetic, with a pressure dressing or compressive sutures and antibiotic cover, is recommended (***Figure 51.10***).

Foreign bodies in the ear canal are most easily removed at the first attempt by an experienced practitioner with the aid of a microscope. General anaesthesia may be required in children and those with learning difficulties. Batteries need to be removed within the hour (***Figure 51.11***).

Summary box 51.2

Trauma of the external ear

- A haematoma of the pinna requires thorough drainage, antibiotics and a compressive dressing or sutures
- Foreign bodies in the ear canal are most easily removed at the first attempt with the aid of a microscope
- Batteries need to be removed urgently

Inflammation and infection

Otitis externa is very common and consists of generalised inflammation of the skin of the external auditory meatus. The cause is often cotton bud use, a moist environment, immunocompromise, allergies or skin disorders, such as psoriasis and eczema. Common pathogens are *Pseudomonas* and *Staphylococcus* bacteria, *Candida* and *Aspergillus*. Once the skin of the ear canal becomes oedematous, skin migration stops and debris collects in the ear canal. This acts as a substrate for the pathogens. Movement of the pinna elicits pain, which distinguishes it from otitis media.

The initial treatment is with a topical antibiotic and steroid ear drops together with analgesia. If this fails, meticulous removal of the debris with the aid of an operating microscope is required. Fungal infection can be recognised by the presence

Figure 51.10 Haematoma of the pinna.

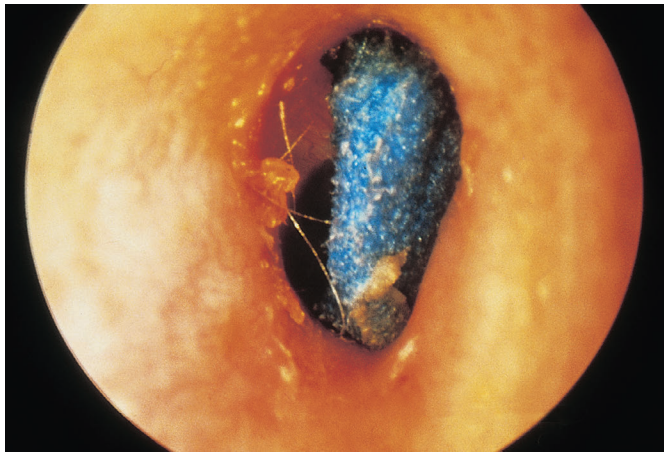

Figure 51.11 Removal of a foreign body from the ear canal can be a challenge (courtesy of Dr Christian Deguine).

of hyphae within the canal (***Figure 51.12***). Fungal infection causes irritation and itch. The treatment is meticulous removal of the fungus and any debris, as well as stopping any concurrent antibiotics. Systemic antibiotics are rarely required for otitis externa but should be used if cellulitis of the pinna occurs (***Figure 51.13***).

Necrotising otitis externa is a rare but important condition because, if left untreated, it has a high mortality. It presents as a severe, persistent, unilateral otitis externa possibly with facial weakness in an immunocompromised individual (e.g. elderly patient with diabetes). Usually the infecting organism is *Pseudomonas aeruginosa*. Osteomyelitis of the skull base may result in lower CN palsy (VII–XII). A multidisciplinary approach

Friedrich Theodor Schwann, 1810–1882, Professor of Anatomy and Physiology, successively at Louvain (1839–1848) and Liège (1848–1880), Belgium, described the neurilemma in 1839.

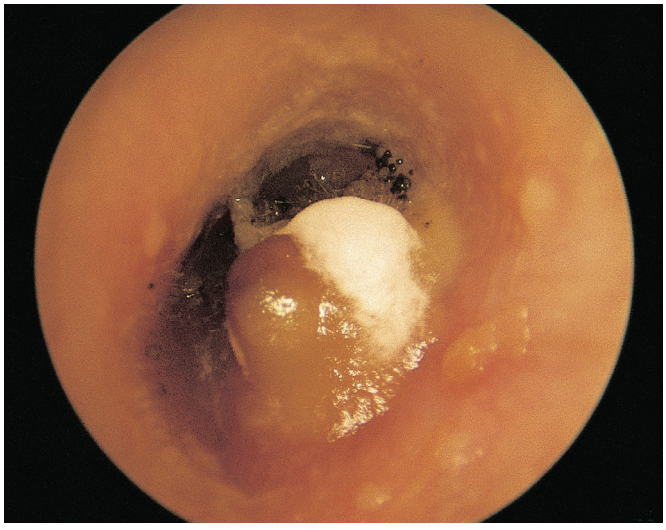

Figure 51.12 Fungal otitis externa. Note the spores.

Figure 51.13 Cellulitis of the pinna.

involving microbiology and radiology is required with long-term systemic antibiotic treatment.

Neoplasms

Exostosis is an area of hyperostosis rather than a neoplasm that arises from the bone of the ear canal in individuals who swim in cold water (synonym 'surfer's ear') (***Figure 51.14***). No treatment is required unless the exostosis obstructs the canal. Osteomas are true neoplasms, often singular and more lateral than exostosis. Other benign tumours include papillomas and adenomas.

Malignant primary tumours of the external ear are either basal cell or squamous cell carcinomas (***Figure 51.15***).

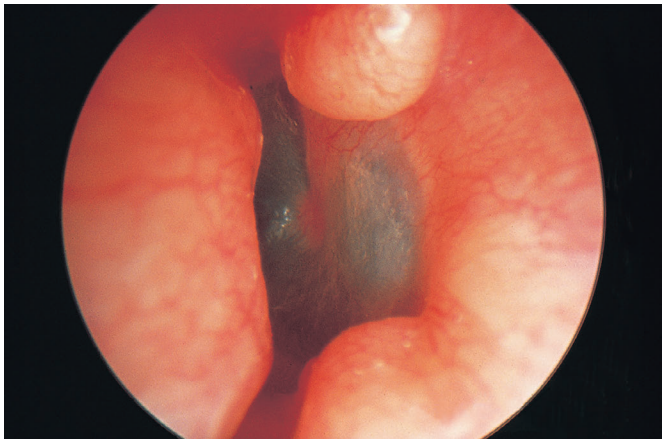

Figure 51.14 Exostoses grow from the bony part of the ear canal in response to cold and so are found in swimmers, surfers and divers. Treatment is only required if the exostoses occlude the ear canal.

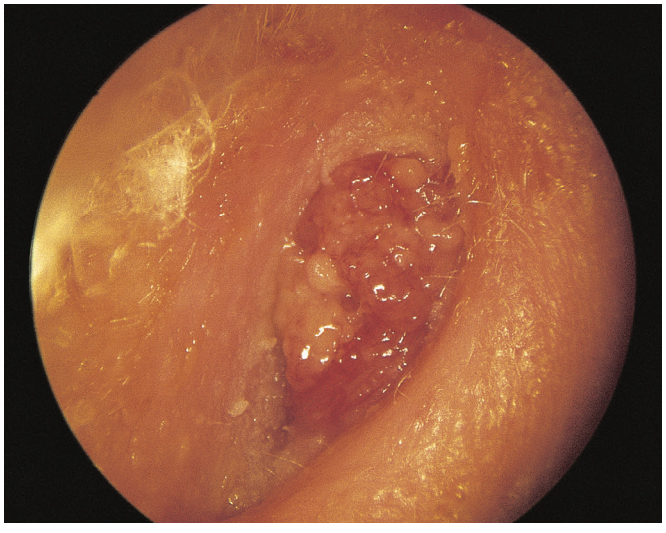

Figure 51.15 Squamous cell carcinomas of the external ear usually originate from the pinna. In this case the tumour is growing from the canal (courtesy of Mr P Beasley).

Summary box 51.3

Types of otitis externa

- Acute bacterial otitis externa is very common and painful; treat with topical steroid and antibiotic drops
- Systemic antibiotics should be reserved for cellulitis of the pinna
- Chronic otitis externa needs the underlying dermatitis to be treated
- Fungal otitis externa itches and can be diagnosed by the presence of hyphae and spores; treat with meticulous cleaning and stop antibiotics
- Necrotising otitis externa is a progressive skull base infection that occurs in immunocompromised individuals and can be life-threatening; intensive long-term antibiotic treatment is required

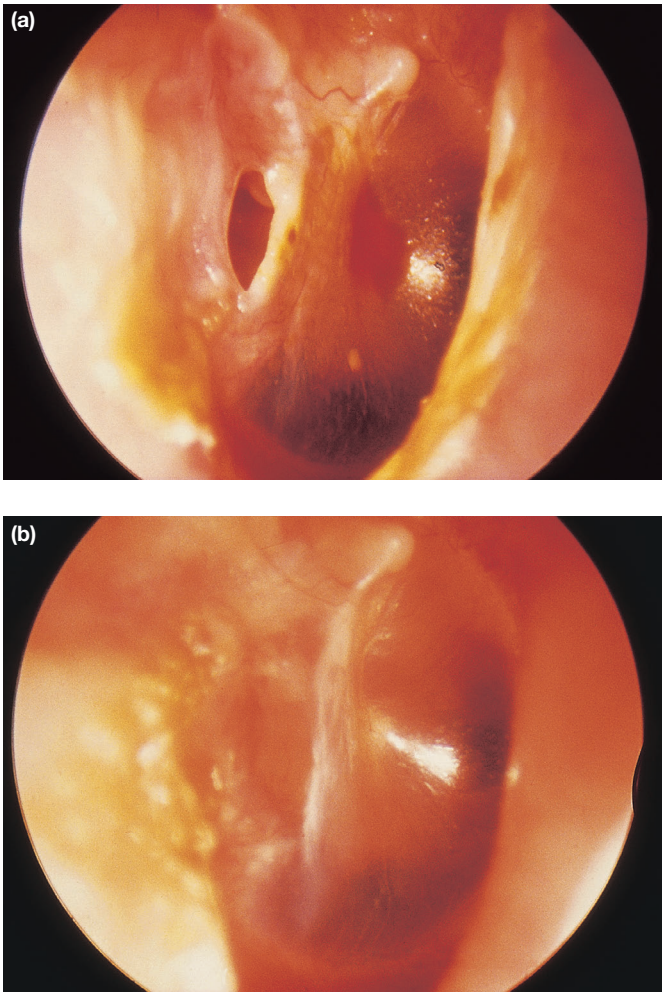

Figure 51.16 (a) Traumatically perforated tympanic membrane. **(b)** The same tympanic membrane 2 days later (courtesy of Dr Christian Deguine). (Reproduced with permission from O'Donoghue GM, Bates GJ, Narula A. *Clinical ENT*: an illustrated textbook. Oxford: Oxford University Press, 1991.)

Both may present as ulcerating or crusting lesions that grow slowly and may be ignored by elderly patients. Squamous cell carcinomas metastasise to the parotid and/or neck nodes. The ear canal may be invaded by tumours from the parotid gland and postnasal space carcinomas, which 'creep' up the Eustachian tube. All resectable malignant tumours of the ear are treated primarily with surgery, with or without the addition of radiation therapy.

CONDITIONS OF THE MIDDLE EAR

Congenital anomalies

Aural atresia and congenital anomalies of the middle ear occur in 1/10 000 to 1/20 000 births and are typically unilateral and non-syndromal but may be associated with other branchial arch syndromes (e.g. Pierre Robin, craniofacial dysostosis, Down and Treacher Collins syndromes).

Trauma

Trauma to the middle ear can result in a perforated tympanic membrane (***Figure 51.16a***); 90% of such perforations heal spontaneously within 6 weeks (***Figure 51.16b***). Trauma can also result in ossicular discontinuity and it is usually the incus that is displaced. A damaged ossicular chain and tympanic membrane are repaired by ossiculoplasty or tympanoplasty, respectively.

Summary box 51.4

Congenital anomalies and trauma of the middle ear

- Congenital anomalies may be isolated or associated with general congenital deformities
- Traumatic perforations of the tympanic membrane usually heal spontaneously but explosive and welding injuries do not
- A myringoplasty is an operation that repairs the tympanic membrane
- With severe head trauma the incus can be displaced, which leads to a conductive hearing loss

Acute otitis media

Acute otitis media (AOM) is one of the most common childhood illnesses with a peak incidence between 6 and 18 months of age. It has occurred in 70% of children by the age of 2 and in 90% by the age of 6. It is characterised by purulent fluid in the middle ear. The tympanic membrane bulges because of pressure from the pus in the middle ear (***Figure 51.17***). The child suffers pain, fever and lethargy. The most common infecting organisms are *Streptococcus pneumoniae* and *Haemophilus influenzae*. Treatment is with analgesics and antipyretics. Systemic antibiotics should be reserved for children under 2 years with bilateral disease or those with other risk factors for complications.The most common complication is mastoiditis because the mastoid air cells connect freely with the middle ear space. Mastoiditis (***Figure 51.18***) requires hospital admission for intravenous antibiotics, for consideration of CT scanning and to monitor for complications such as facial nerve palsy, lateral sinus thrombosis and meningitis. If infection does not resolve quickly abscess aspiration and myringotomy (with/without grommet insertion) is performed. A cortical mastoidectomy is carried out if complications arise.

Otitis media with effusion (glue ear)

Otitis media with effusion (OME) is a middle ear effusion with no evidence of infection. It has a bimodal incidence affecting

Pierre Robin, 1867–1950, Professor, The French School of Dentistry, Paris, France, described this syndrome in 1929.
John Langdon Haydon Down (sometimes given as Langdon-Brown), 1828–1896, physician, The London Hospital, London, UK, published the classification of ailments in 1866.
Edward Treacher Collins, 1862–1932, ophthalmic surgeon, The Royal London Ophthalmic Hospital and Charing Cross Hospital, London, UK, described this syndrome in 1900.

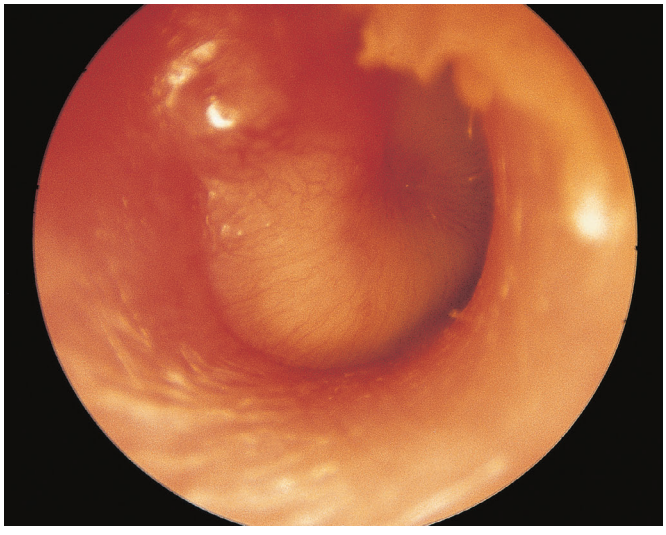

Figure 51.17 Acute otitis media of the left ear. Note the bulging tympanic membrane.

Figure 51.18 Child with acute mastoiditis whose tympanic membrane is shown in ***Figure 51.16***.

40% of 2-year-olds (age of starting nursery) and 20% of 5-year-olds (age of starting school). It arises mainly in the winter months, suggesting an infective aetiology. Infection and inflammation of the immature Eustachian tube results in poor middle ear ventilation, negative pressure and the transudation of fluid.

The following symptoms may be associated with glue ear:

- hearing impairment, which often fluctuates;
- delayed speech;
- behavioural problems;
- recurrent ear infections (the exudate is an ideal culture medium for microorganisms);
- reading and learning difficulties at school.

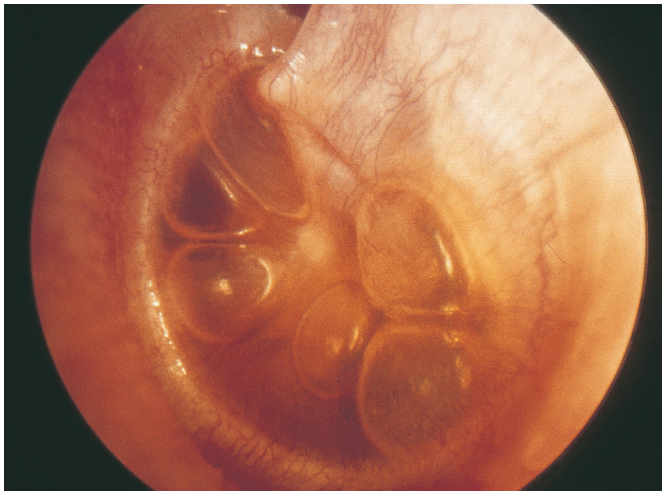

Figure 51.19 The initial serous transudate of glue ear, left ear (courtesy of Dr Christian Deguine). (Reproduced with permission from O'Donoghue GM, Bates GJ, Narula A. *Clinical ENT: an illustrated textbook*. Oxford: Oxford University Press, 1991.)

Figure 51.20 Otovent® device.

Otoscopic findings with glue ear

The otoscopic findings of exudative glue ear are of a dull drum that is immobile on pneumatic otoscopy. The tympanic membrane is retracted and radial blood vessels may be present (***Figure 51.19***).

In children first presenting with bilateral glue ear, 50% will be better within 12 weeks, therefore a 'wait and watch' policy is appropriate. If a bilateral conductive hearing loss persists, there is some evidence of reduced IQ and behaviour changes. However, speech delays are reversed by age 8.

Medical treatment is of limited value. Valsalva manoeuvres and the Otovent® device (***Figure 51.20***) are worth trying for patients old enough to comply in an attempt to improve Eustachian tube function. Surgical insertion of ventilation tubes (grommets) (***Figure 51.21***) and adenoidectomy are effective and should be discussed if there is no resolution after a period of watchful waiting. A middle ear effusion in adults is often associated with an upper respiratory tract infection.

Antonio Maria Valsalva, 1666–1723, Italian physician and anatomist.

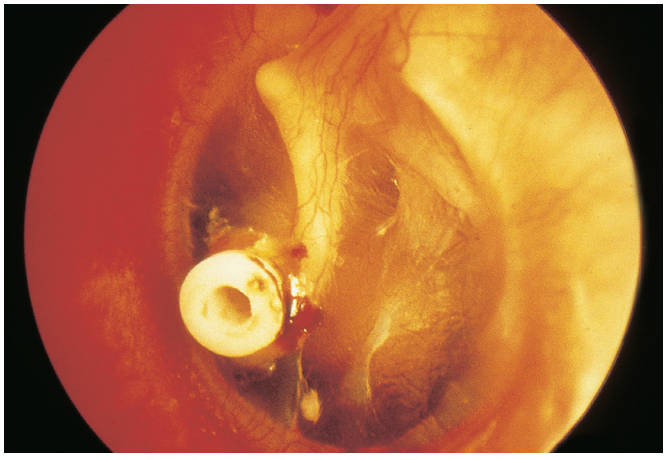

Figure 51.21 Ventilation tube in the tympanic membrane, left ear (courtesy of Dr Christian Deguine).

A persistent unilateral effusion in an adult requires examination of the postnasal space to exclude obstructive nasopharyngeal carcinoma, which is the most common carcinoma in men in southern China.

Summary box 51.5

AOM and OME

- AOM is very common but rarely associated with severe complications such as mastoiditis
- OME is very common in children and usually resolves without treatment
- Persistent OME and/or recurrent AOM are best treated with grommets and/or adenoidectomy
- A persistent middle ear effusion in an adult may be caused by a nasopharyngeal carcinoma; this is commonest in people from southern China

Chronic otitis media

Chronic otitis media (COM) is a persisting (at least 2 weeks to 3 months) abnormality of the tympanic membrane from previous recurrent AOM and/or OME. It is classified as active (i.e. inflammation and pus present), inactive (potential to become active) or healed (no potential to become active). Active and passive are then further subclassified as mucosal or squamous (***Figure 51.22***).

Active mucosal COM implies a perforation with otorrhoea (ear discharge) due to inflamed middle ear mucosa with or without granulation tissue. Inactive mucosal COM implies a dry perforation without inflammation. Surgery in the form of tympanoplasty (repair of the perforation) is indicated in patients with recurrent infection (to reduce symptoms of otorrhoea and prevent further deterioration of the hearing due to the ototoxic effects of infection) and where there is a likelihood that it will restore hearing in the operated ear to 30 dB or better or to within 15 dB of the contralateral ear (this is known as the Belfast rule of thumb).

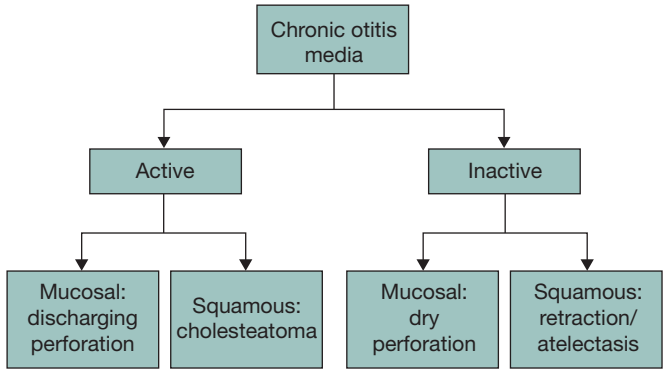

Figure 51.22 Classification of chronic otitis media.

Active squamous COM is otherwise known as acquired cholesteatoma. This represents a quarter of all active COM with an incidence of 1/10 000. It usually presents with persistent otorrhoea and hearing loss as a result of keratinising squamous epithelium within the middle ear. The cholesteatoma matrix destroys the structures in its path through the release of lytic enzymes, inflammatory mediators and pressure necrosis. If left, there is a risk of all the complications attributable to AOM. The lifetime risk of intracerebral abscess is 1/200 in a 30-year-old patient. The recommended treatment is mastoid surgery using a drill under microscopic or endoscopic guidance to access and remove the cholesteatoma. Often the ossicles are involved or eroded so an ossiculoplasty (to restore hearing by reconstructing the ossicular chain) may be performed at the same time.

Otosclerosis

This is an autosomal dominant condition of variable penetrance in which excess bone is laid down around the footplate of the stapes, impeding mobility of the stapes and resulting in a conductive hearing loss (***Figure 51.23***). A diagnosis should be suspected in any patient with a conductive hearing loss and a normal tympanic membrane.

The treatment options are simple reassurance, a conventional hearing aid, a stapedotomy operation or bone conduction hearing aid (***Figure 51.24***).

Neoplasms

Middle ear tumours are rare, with the most common being a glomus tumour (***Figure 51.25***). Glomus tumours are paragangliomas arising from non-chromaffin paraganglionic tissue (the carotid body tumour arising in the neck is an example of this type of tumour). In the temporal bone, two types of glomus tumour are recognised and classification depends on the location: glomus tympanicum (arising in the middle ear) and glomus jugulare (arising next to the jugular bulb).

Symptoms include pulse synchronous tinnitus and conductive and sensorineural hearing loss. Palsies of CNs VII, IX, X, XI and/or XII may occur. The classic sign is a cherry-red mass lying behind the tympanic membrane. The treatment of

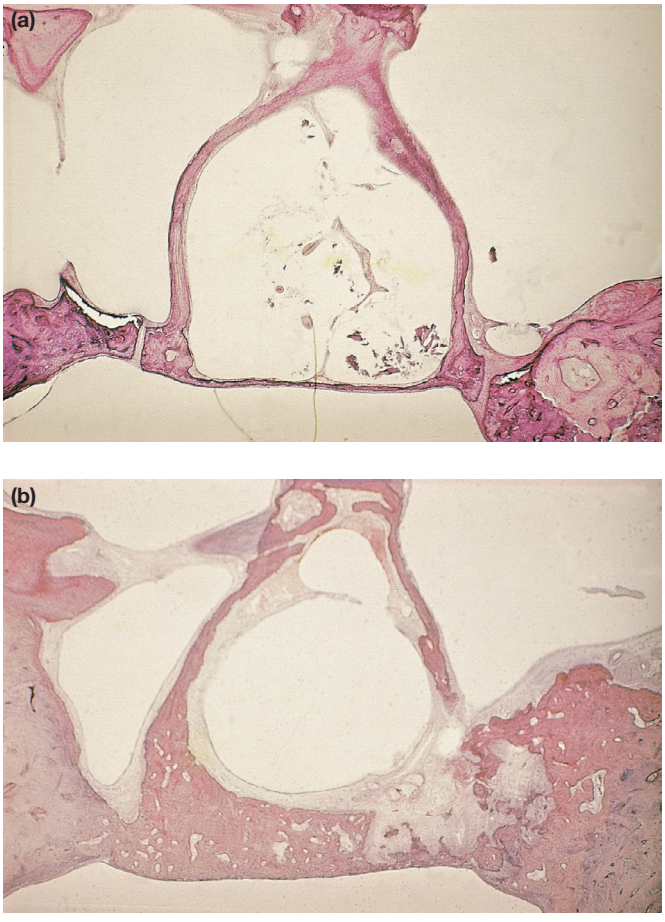

Figure 51.23 Section of normal stapes **(a)** and section of stapes affected by otosclerosis **(b)**.

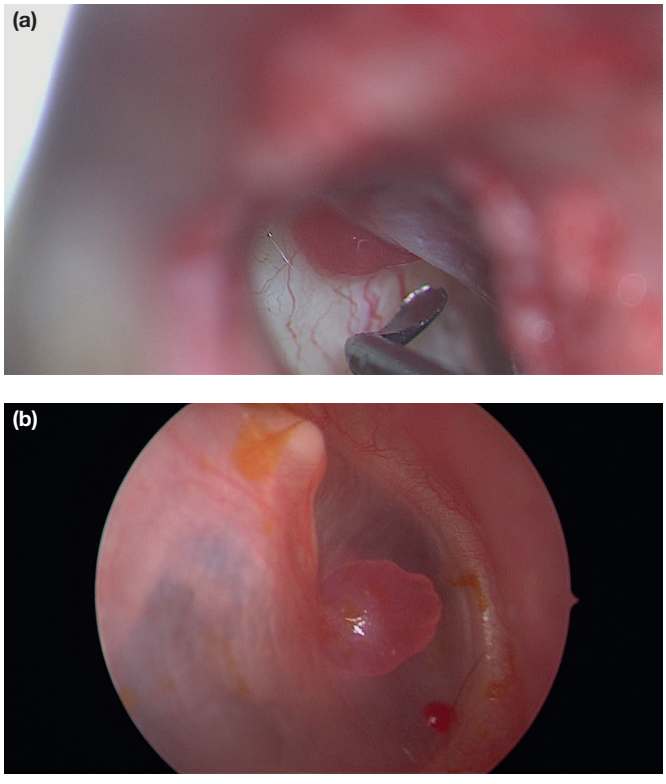

Figure 51.25 (a, b) Glomus tumour in the middle ear, left ear (courtesy of Professor Peter Rea, Leicester).

choice is preoperative embolisation followed by surgical excision. Radiotherapy is also effective.

Squamous cell carcinoma may also occur within the middle ear. It usually presents with deep-seated pain and a blood-stained discharge. Facial paralysis often occurs. Squamous carcinomas usually arise in a chronically discharging ear and can arise in a chronically infected mastoid cavity. Radical surgical excision with or without radiotherapy provides the only chance of cure.

Summary box 51.6

Neoplasms of the middle ear

- Highly vascular glomus tumours are rare and may present with pulsatile tinnitus
- Squamous cell cancer usually presents with pain and facial paralysis

CONDITIONS OF THE INNER EAR

Congenital sensorineural hearing loss

Half of congenital sensorineural hearing loss is genetic and half is acquired. Of the genetic hearing loss 75% is non-syndromic, of which the most common is a connexin 26

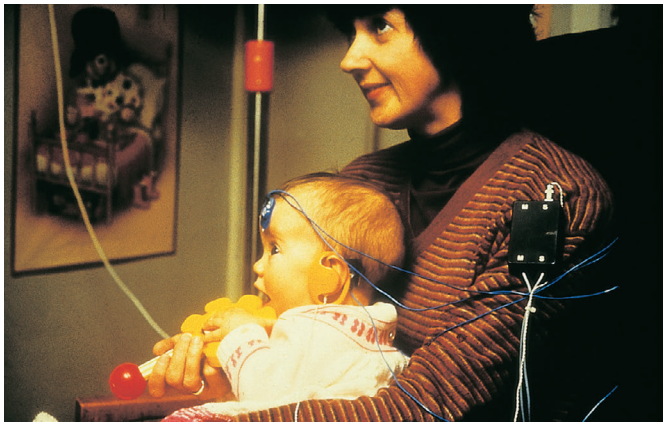

Figure 51.26 Evoked-response audiometry. A simple non-invasive objective test of hearing thresholds. (Reproduced with permission from O'Donoghue GM, Bates GJ, Narula A. *Clinical ENT: an illustrated textbook*. Oxford: Oxford University Press, 1991.)

gene mutation. Syndromic causes include Usher, Pendred, Jervell and Lange-Nielsen, Waardenburg, Treacher Collins, Alport, Stickler, neurofibromatosis type 2 and branchio-oto-renal syndromes.

Acquired causes are intrauterine infections, including rubella, toxoplasmosis and cytomegalovirus infection; perinatal hypoxia, jaundice and prematurity; and postnatal meningitis.

All newborn babies in the UK are now screened at birth for deafness by measuring otoacoustic emissions in response to 'clicks' in the ear. Children failing this are referred for auditory brainstem response to establish hearing thresholds (***Figure 51.26***). If some hearing is present, the early fitment of hearing aids can maximise the neural plasticity that is present in the developing brain. If a child has a profound hearing loss, early intervention with a cochlear implant is essential for the development of the auditory cortex (***Figure 51.27***). Most cases of profound sensorineural hearing loss are due to loss of cochlear hair cells, so an implant inserted through the round window can selectively stimulate the cochlear neurones, which usually remain intact.

Presbycusis

Presbycusis is characterised by a gradual loss of hearing in both ears, with or without tinnitus. The hearing loss usually affects the higher frequencies and a classical audiogram is shown in ***Figure 51.28***. The consonants of speech lie within the high-frequency range, which makes speech discrimination difficult.

Many patients with presbycusis are concerned that they may lose their hearing completely and need reassurance. Hearing aid technology has improved dramatically over recent years and most patients can derive benefit (***Figure 51.29***).

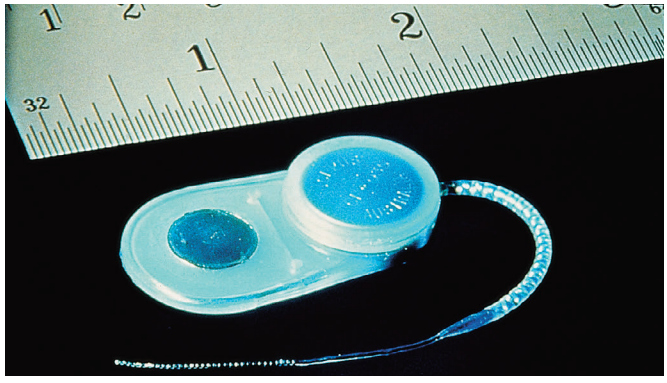

Figure 51.27 Multichannel cochlear implant (Cochlear Corporation).

Tinnitus

Tinnitus is the perception of sound when no external sound source is present. It may have an extrinsic cause; for example, the pulsatile tinnitus of a glomus tumour. Usually, however, the tinnitus is generated within the internal auditory pathway. Thirty per cent of people will experience tinnitus at some time in their lives. Tinnitus frequently accompanies presbycusis, as well as any other condition that affects hearing. Most individuals habituate to the presence of tinnitus but in some patients it proves intrusive. Treatment is with reassurance, masking and hearing aids (for patients with hearing loss).

Sudden sensorineural hearing loss

Defined as >30 dB sensorineural hearing loss at three frequencies within 3 days. History and examination should focus on a cause, which may be infective, neoplastic, traumatic, ototoxic, neurological or autoimmune. Investigations such as MRI are important (1% of acoustic neuromas present as sudden sensorineural hearing loss) but screening blood tests are of low yield where there is nothing in the history to suggest a cause. The majority are idiopathic and the recommended treatment is oral steroids with/without intratympanic steroids with salvage intratympanic steroids for those who do not recover after 2 weeks.

Trauma

Noise exposure

Hair cells within the cochlea are damaged by sudden acoustic trauma (blast injury or gunfire) or prolonged exposure to excessive noise. The sensorineural hearing loss that results is greatest between 3 and 6 kHz and is often accompanied by tinnitus (***Figure 51.30***). The law in the UK requires that workers are protected from noise.

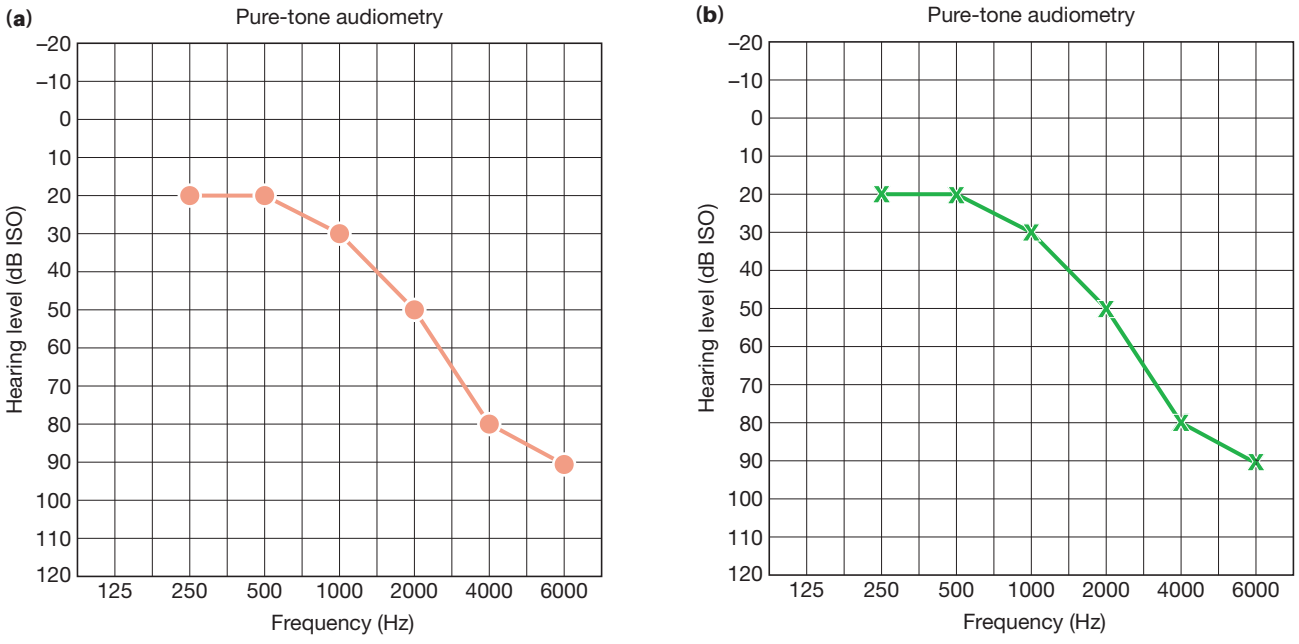

Figure 51.28 Typical audiogram of presbycusis: **(a)** right ear; **(b)** left ear.

Figure 51.29 Modern hearing aid.

Head injury

The otic capsule is the hardest bone in the body but, if trauma to the head is severe, temporal bone fractures may occur. These are traditionally described as either longitudinal (80%) or transverse (20%); however, the majority have longitudinal and transverse components. Longitudinal fractures may lead to fracture of the external auditory canal, conductive hearing loss and CSF otorrhoea. Transverse fractures may involve the facial nerve, leading to palsy, and labyrinth, leading to a sensorineural hearing loss that is permanent. Profound vertigo occurs initially, followed by gradual compensation.

Drug ototoxicity

Antibiotics such as aminoglycosides, vancomycin and erythromycin, loop diuretics such as frusemide, chemotherapy agents such as cisplatin and carboplatin, and salicylates such as aspirin and quinine are all ototoxic. Recognition of risk factors, such as poor renal function in patients being treated with aminoglycosides, is therefore important. Although many topical ear drops contain aminoglycosides, there is little evidence that short periods of topical treatment cause sensorineural hearing loss.

Balance disorders

Vertigo is the hallucination of movement.

Benign paroxysmal positional vertigo

Benign paroxysmal positional vertigo (BPPV) is the most common form of vertigo. It is caused by otoliths (calcium carbonate crystals) most commonly within the posterior semicircular canal abnormally triggering the ampullary hair cells. Typically, the vertigo is triggered by turning, only lasts for a few seconds and is not associated with other otological symptoms. A positive Hallpike test confirms the diagnosis. The condition is usually self-limiting but recovery may be expediated by an Epley manoeuvre.

Charles Skinner Hallpike, 1900–1979, aural surgeon, National Hospital for Neurology and Neurosurgery, London, UK.
John W Epley, contemporary, Director, Portland Otology Clinic, Portland, OR, USA, established his clinic in 1975; he developed the Epley manoeuvre for treating benign paroxysmal positional vertigo (BPPV).

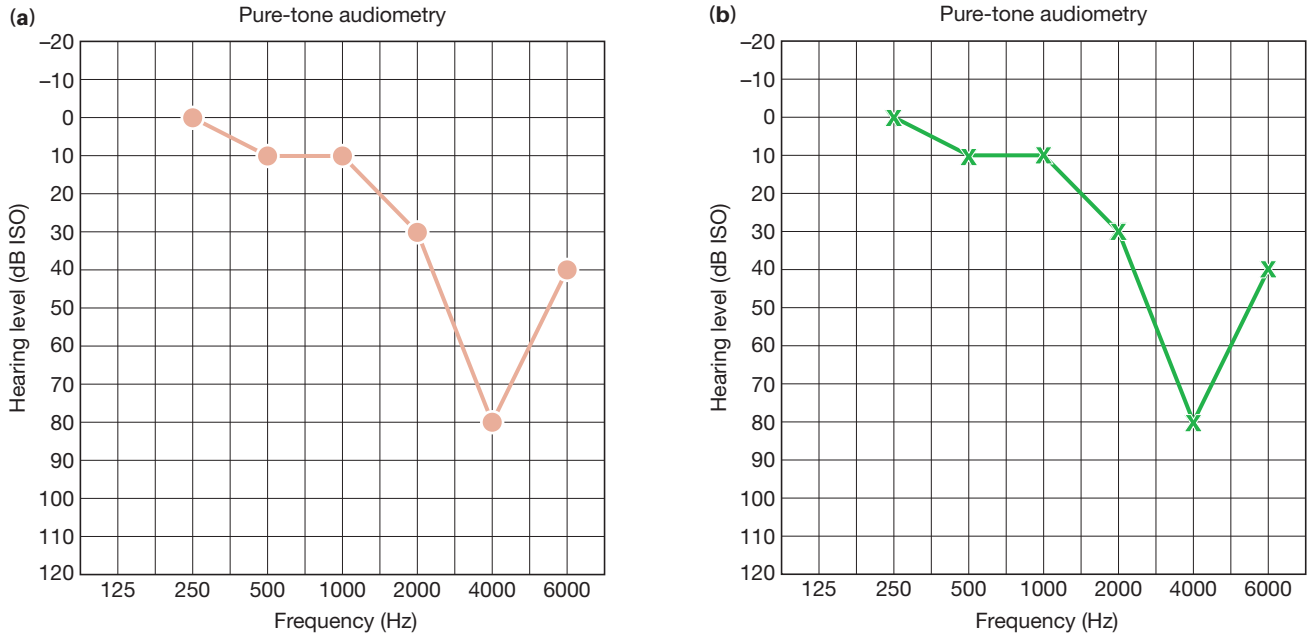

Figure 51.30 A typical audiogram of noise damage: **(a)** right ear; **(b)** left ear.

Vestibular neuronitis

Infection or inflammation of the superior vestibular nerve results in persistent vertigo lasting a few days. If the hearing is also affected, this is known as labyrinthitis. Treatment is supportive with vestibular sedatives, such as prochlorperazine, in the first few days, early mobilisation and consideration of systemic steroids.

Menière's disease

It has been said that clinicians not only disagree on the cause of Menière's disease, but they also disagree on the spelling. There is certainly evidence of endolymphatic hydrops (longstanding high-pressure changes within the inner ear) in pathological specimens of patients who have had the condition. The condition is characterised by a triad of symptoms: intermittent attacks of vertigo, a unilateral fluctuating sensorineural hearing loss and tinnitus. The patient often has a sensation of pressure in the affected ear before an attack. The hearing loss typically affects the lower frequencies. The vertigo characteristically lasts between 30 minutes and 6 hours and is often accompanied by nausea and vomiting. The investigations include pure tone audiometry and an MRI scan (to exclude an acoustic neuroma). The only evidence-based medical treatment is intratympanic injections of dexamethasone or gentamicin into the middle ear.

Vestibular migraine

Often confused with Menière's disease, this condition is five times more prevalent, presenting with similar symptoms but without the hearing loss or tinnitus. The migrainous process affects the labyrinth in up to 40% of migraineurs. Treatment includes addressing the risk factors, such as lifestyle and dietary triggers, with prophylactic medication such as propranolol, tricyclic antidepressants and antiepileptic medication for those with ongoing symptoms.

Facial paralysis

Seventy-five per cent of all facial palsies are due to Bell's palsy. This probably results from a herpes simplex viral infection of the facial nerve. The nerve swells and is compressed within the temporal bone. Early treatment with high-dose steroids and eye protection is mandatory. Not all facial nerve palsies are due to viral infection and a thorough otoneurological examination is required. The facial nerve can be damaged at the cerebellopontine angle, within the internal auditory meatus, within the middle ear, at the skull base and within the parotid gland. It is essential to consider these potential sites of facial nerve damage in any patient with CN VII paralysis and perform an MRI scan if appropriate.

Summary box 51.7

Facial paralysis

- The facial nerve passes through the middle ear and mastoid
- When considering a paralysis, think 'complete' or 'partial'
- Protect the eye: carry out a full otoneurological examination to find the cause
- If acute, consider steroids

Prosper Menière, 1799–1862, physician, The Institute of Deaf Mutes, Paris, France, described this condition in 1861.
Sir Charles Bell, 1774–1842, surgeon, The Middlesex Hospital, London UK, and from 1835 until his death, Professor of Surgery, The University of Edinburgh, Edinburgh, UK.

Figure 51.31 Herpes zoster infection of right cranial nerve (CN) VII **(a)** and right CN VIII **(b)** with vesicles on the pinna.

Ramsay Hunt syndrome

This is caused by herpes zoster virus and is characterised by facial paralysis, pain and the appearance of vesicles on the tympanic membrane, ear canal, pinna or inside of the cheek (***Figure 51.31***). It may be accompanied by vertigo and sensorineural hearing loss (CN VIII). Treatment with aciclovir is effective if given early.

Neoplasms

These are uncommon but can present with sensorineural hearing loss, tinnitus and vertigo. Acoustic neuromas, which are actually schwannomas of the vestibular division of CN VIII, are the most common, followed by meningiomas. Acoustic neuromas grow slowly and somewhat unpredictably and as they expand can cause CN palsies, brainstem compression and raised intracranial pressure. The early symptoms are a unilateral sensorineural hearing loss or unilateral tinnitus, or both. Therefore, it is essential to perform MRI on all patients with persistent unilateral sensorineural hearing loss or tinnitus. Relatively asymptomatic acoustic neuromas that are less than 2 cm in diameter and growing less than 2 mm/year (70%) are generally treated with a 'watch, wait and rescan' policy or occasionally stereotactic radiotherapy. Tumour volumes greater than 2 cm in diameter are often best treated by skull base surgery in the form of a translabyrinthine, retrolabyrinthine or middle fossa approach.

Summary box 51.8

Conditions of the inner ear

- Presbycusis is the bilateral high-frequency loss associated with ageing
- Unilateral tinnitus or sensorineural hearing loss needs to be investigated to exclude acoustic neuroma
- Sudden sensorineural hearing loss needs immediate treatment with steroids and routine MRI to exclude acoustic neuroma
- Menière's disease presents with the triad of sensorineural hearing loss, tinnitus and vertigo

THE NOSE AND SINUSES

BASIC ANATOMY OF THE NOSE AND PARANASAL SINUSES

The supporting structures of the nose are shown in ***Figure 51.32***. The septum consists of the anterior quadrilateral cartilage, the perpendicular plate of the ethmoid and the vomer (***Figure 51.33***). The lateral wall of the nasal cavity contains the superior, middle and inferior turbinates, which warm and moisten nasal airflow (***Figure 51.34***). There are paired frontal, sphenoid, maxillary and anterior and posterior ethmoid sinuses. The anterior nasal sinuses (frontal, maxillary and anterior ethmoid) drain into the middle meatus (between

James Ramsay Hunt, 1874–1937, Professor of Neurology, Columbia College of Physicians and Surgeons, New York, USA.

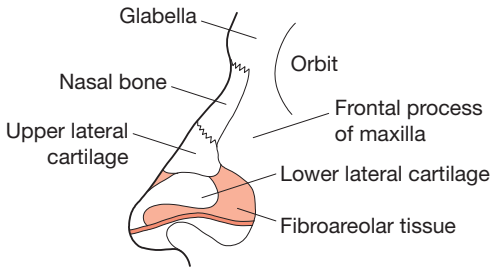

Figure 51.32 The nasal skeleton.

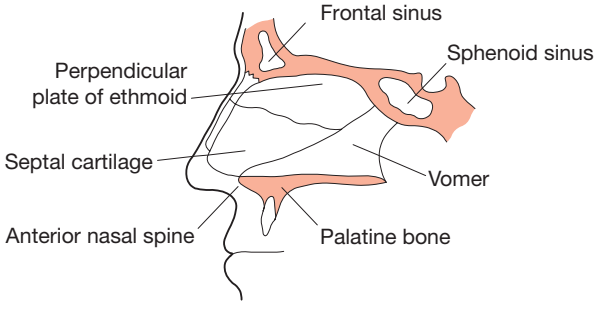

Figure 51.33 The left side of the nasal septum.

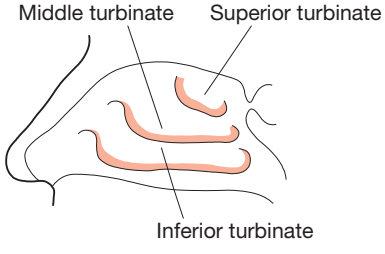

Figure 51.34 The right lateral nasal wall.

the middle turbinate and lateral wall of the nose). The posterior ethmoid and sphenoid sinuses drain into the superior meatus and sphenoethmoidal recess (between the superior turbinate and nasal septum), respectively (***Figures 51.35 and 51.36***).

The nasal fossae and sinuses receive their blood supply via the external and internal carotid arteries. The external carotid artery supplies the interior of the nose via the maxillary and sphenopalatine arteries. The greater palatine artery supplies the anteroinferior septum via the incisive canal. The contribution from the internal carotid artery is via the anterior and posterior ethmoidal arteries, which are branches of the ophthalmic artery (***Figure 51.37***). All these arteries anastomose to form a plexus of vessels (Kiesselbach's plexus) on the anterior part of the nasal septum. Venous drainage is via the ophthalmic and facial veins and the pterygoid and pharyngeal plexuses. Intracranial drainage into the cavernous sinus via the ophthalmic vein is of particular clinical importance because of the potential for intracranial spread of nasal sepsis.

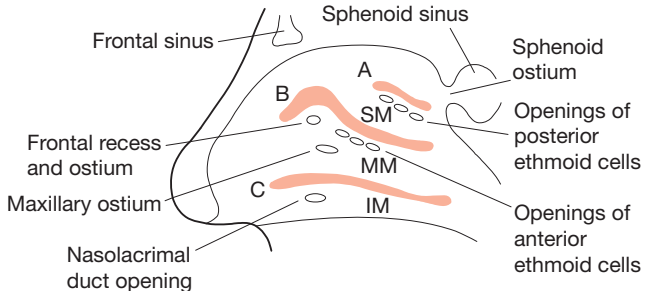

Figure 51.35 The right lateral nasal wall with turbinates removed to show the sinus ostia. A, insertion of superior turbinate; B, insertion of middle turbinate; C, insertion of inferior turbinate; IM, inferior meatus; MM, middle meatus; SM, superior meatus.

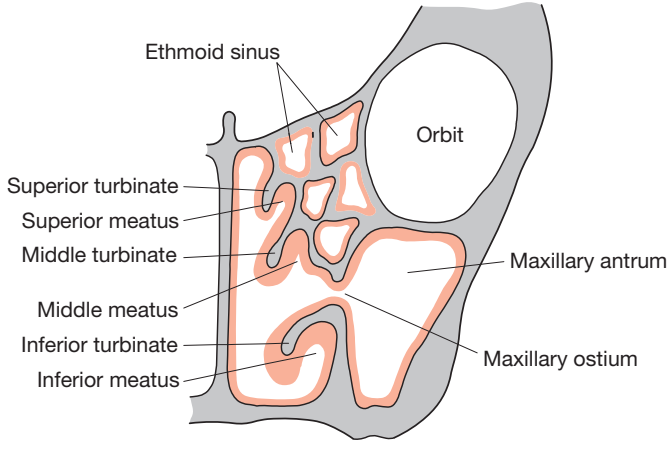

Figure 51.36 Coronal section through the left maxillary and ethmoid sinuses.

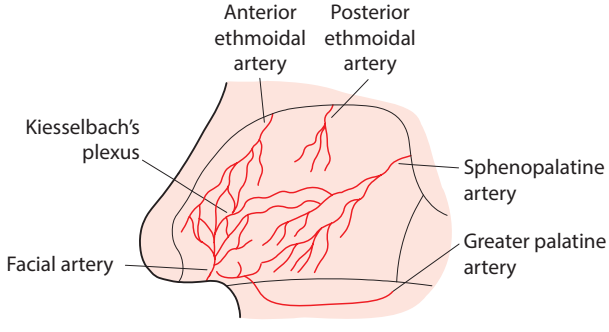

Figure 51.37 Arterial blood supply to the left side of the nasal septum.

EXAMINATION OF THE NOSE AND PARANASAL SINUSES

Internal inspection of the nasal fossae can be achieved to a limited extent with the use of a Thudichum speculum. The anterior nasal septum, nasal vestibule and anterior inferior turbinate can be assessed. A more detailed examination of the nose is possible with the use of either rigid or flexible endoscopes

Wilhelm Kiesselbach, 1839–1902, Professor of Otology, Erlangen, Germany.
Johann Ludwig Wilhelm Thudichum, 1829–1901, biochemist and general practitioner, London, UK.

(***Figure 51.38***). The endoscopes are attached to a light source and camera and the image is displayed on a monitor.

Figure 51.38 Rigid nasendoscope.

IMAGING OF PARANASAL SINUSES

Plain radiographs are of limited value in the assessment of sinus disease. CT is far superior in demonstrating sinus pathology and for assessing bony anatomy to plan any surgical intervention. CT scans are acquired and reconstructed to produce images in axial, coronal and sagittal planes. The three planes allow the drainage of the frontal sinus to be identified and important surgical landmarks can be reviewed preoperatively, including the cribriform plate, anterior skull base, lamina papyracea and location of the anterior ethmoid artery. MRI is useful in sinus pathology to assess any intracranial or orbital extension of disease.

TRAUMA TO THE NOSE AND PARANASAL SINUSES

Fracture of the nasal bones

Blunt injury to the nose may fracture the nasal bones (***Figure 51.39***). The fracture line can extend into the lacrimal bone and tear the anterior ethmoidal artery, producing catastrophic haemorrhage. This may be delayed, occurring only as the soft-tissue swelling subsides, reducing the tamponade effect on the torn vessel.

Violent trauma to the frontal area of the nose can result in a fracture of the frontal and ethmoid sinuses with potential extension into the anterior cranial fossa. Dural tears and brain injuries, either open or closed, are then at risk from sinonasal ascending infection, which may progress to meningitis or brain abscess. CSF rhinorrhoea is a certain sign of a dural tear. CSF rhinorrhoea can be confirmed by collecting a sample of the fluid and sending for β_2-transferrin assay. A bony defect in the anterior skull base following trauma can be identified on high-resolution CT. The CSF leak will often settle with conservative management but, if persistent, it can be repaired endoscopically.

Management of fractured nasal bones

Fractured nasal bones are normally accompanied by extensive overlying soft-tissue swelling and bruising, which may hinder the assessment of any underlying bony deformity. Reviewing after 4–5 days when the soft-tissue swelling has diminished will allow a better assessment of any deformity. If there is a significant degree of nasal deformity, this can be corrected by manipulation of the nasal bones under local or general anaesthesia. This should be carried out within 3 weeks of the injury while the bony fragments are still mobile. After this period, if there is significant cosmetic or functional issues, a septorhinoplasty can be performed at least 6 months following the injury.

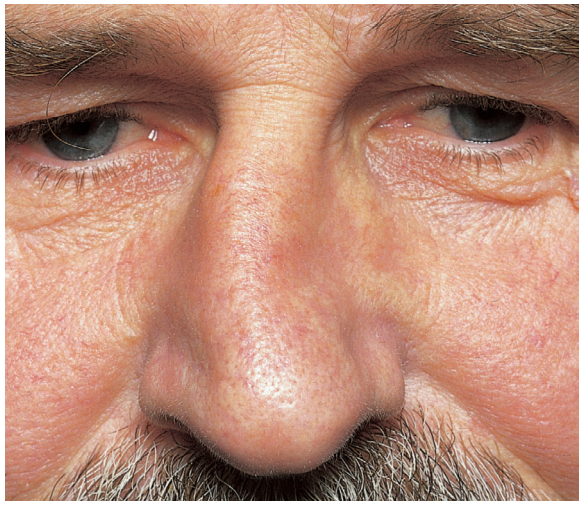

Figure 51.39 Fracture of the nasal bones with displacement of the bony nasal complex to the right side.

Septal injury

A blunt injury of moderate force may lead to lateral displacement or deformity of the septal cartilage, restricting the nasal airway. Unlike the nasal bones the nasal septum cannot be manipulated back into position and requires a formal septoplasty procedure to restore the anatomy and the patency of the nasal airways.

Bleeding under the mucoperichondrium of the septum will cause a septal haematoma and nasal obstruction. Untreated, a septal haematoma will progress to abscess formation and ultimately result in necrosis of the septal cartilage, septal perforation and nasal collapse. A septal haematoma should be treated by incision and drainage of the blood clot, insertion of a small silicone drain and packing of the nasal fossa. A broad-spectrum prophylactic antibiotic should be prescribed.

Summary box 51.9

Nasal trauma

- Do not overlook a septal haematoma
- Displaced nasal bone fractures should be reduced within 3 weeks of injury
- Severe persistent epistaxis after trauma suggests lacrimal bone fracture and injury to the anterior ethmoid artery
- CSF rhinorrhoea indicates a fracture involving the anterior skull base with a dural tear

THE NASAL SEPTUM

Septal deformity

Deviation of the nasal septum may occur naturally or arise as a result of nasal trauma and is readily apparent on anterior rhinoscopy (***Figure 51.40***). Surgical correction can be achieved by a submucous resection (SMR) of the septum where the deformed septal cartilage is excised while preserving a caudal and dorsal strut for support (***Figure 51.41***). The alternative is a septoplasty procedure during which the septal cartilage is preserved but the anatomical abnormalities giving rise to its deformity, such as a twisted maxillary crest or inclination of the bony septum posteriorly, are corrected.

Complications of septal surgery include septal perforation. If too much cartilage is excised in the SMR procedure, loss of support to the dorsum of the nose may result in a supra-tip depression or drooping of the tip of the nose.

Septal perforation

A hole in the nasal septum causes turbulent airflow through the nose and a resulting sensation of nasal blockage, extensive nasal crusting, bleeding and whistling. The causes of septal perforation are listed in ***Summary box 51.10***.

Septal perforations seldom heal spontaneously. A great variety of operations have been described to close septal perforations but none has met with universal success. These have included closing the perforation using cartilage or synthetic material and covering with local flaps. Alternatively, the perforation may be occluded by inserting a Silastic biflanged prosthesis or 'septal button' (***Figures 51.42 and 51.43***). In some cases, particularly those patients with significant whistling and bleeding from the posterior edge, the perforation can be enlarged and mucosa folded around the posterior edge to stabilise it.

Granulomatosis with polyangiitis is a systemic idiopathic autoimmune disease affecting the nose, lungs and kidneys.

Summary box 51.10

Causes of septal perforations

- Trauma
  - Iatrogenic following septal surgery
  - Nose picking
  - Following a septal haematoma from nasal injury
- Infection
  - Syphilis
  - Tuberculosis
- Vasculitis
  - Granulomatosis with polyangiitis
- Tumours
- Toxins
  - Chrome salts
  - Cocaine
- Idiopathic

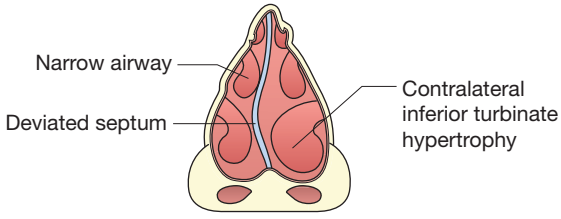

Figure 51.40 Coronal section through the anterior nasal fossae with deviated nasal septum to the right side.

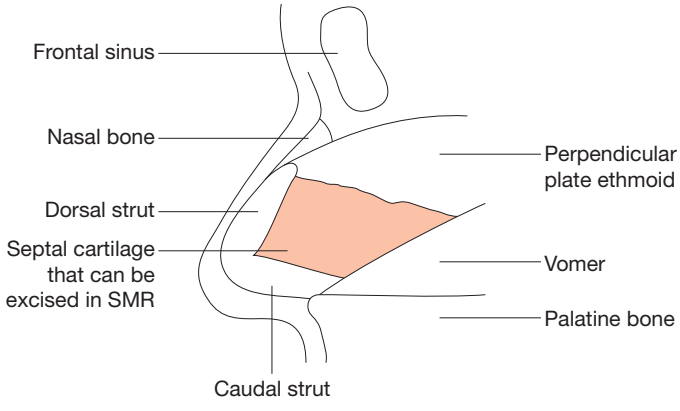

Figure 51.41 Area of cartilage that can be removed in submucous resection (SMR) leaving dorsal and caudal strut for support.

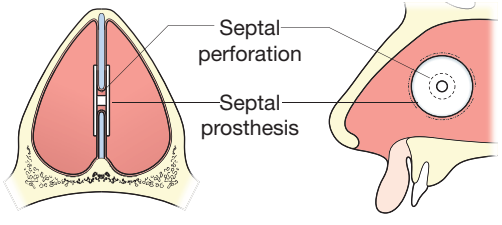

Figure 51.42 Anterior and lateral views of septal perforation occluded with a prosthesis.

Mucosal granulations on the nasal septum destroy cartilage, producing a septal perforation with saddle deformity of the nose. Laboratory findings include a high erythrocyte sedimentation rate, impaired creatinine clearance and antineutrophil cytoplasmic antibodies (c-ANCA) in most cases.

EPISTAXIS

The causes of epistaxis are listed in ***Table 51.2***. The most common site of bleeding is from Kiesselbach's plexus in Little's area of the anterior portion of the septum (***Figure 51.37***). Anterior bleeding is common in children and young adults owing to nose blowing or picking. In the elderly, anticoagulants and hypertension are the underlying causes of arterial bleeding from the posterior part of the nose.

James Laurence Little, 1836–1885, Professor of Surgery, The University of Vermont, Montpelier, VT, USA.

Figure 51.43 Silastic prosthesis for septal perforation.

Hereditary haemorrhagic telangiectasia (HHT) (Osler's disease) gives rise to recurrent multifocal bleeding from thin-walled vessels deficient in muscle and elastic tissue (***Figure 51.44***).

Juvenile angiofibroma is an uncommon condition that affects adolescent boys and may lead to massive life-threatening episodes of bleeding. Diagnosis is made with contrast CT or MRI. Anterior bowing or indentation of the posterior antral wall (Holman–Miller or antral sign) is the classical finding but may be seen in other expansive lesions in this area. It is a very vascular tumour, which should not be biopsied because of the risk of uncontrollable haemorrhage. Excision is best carried out by an experienced surgeon and is usually performed endoscopically, often using image guidance (***Figure 51.45***). Preoperative embolisation of the feeding blood vessels may help to reduce blood loss during surgery.

TABLE 51.2 Causes of epistaxis.

Local	• Nose picking • Nasal trauma • Nasal foreign bodies • Tumours • Infection • Granulomatous disorders • Juvenile angiofibroma
Systemic	• Hypertension • Warfarin therapy • New anticoagulants (rivaroxaban) • Aspirin, clopidogrel therapy • Haemophilia • von Willebrand's disease • Leukaemia • Hereditary haemorrhagic telangiectasia (Osler's disease)

Management of epistaxis

Anterior bleeding from Kiesselbach's plexus may be controlled by silver nitrate cautery under local anaesthesia. Even in more posterior epistaxis, the bleeding point can often be identified using rigid nasendoscopy and controlled with the use of a topical vasoconstrictor, and then dealt with directly using electrocautery. However, posterior bleeding, as seen in the elderly, may require anterior nasal packing either with Vaseline-impregnated ribbon gauze or a non-absorbable sponge. There are also many haemostatic, absorbable materials that can be used to pack the nose to help control bleeding. An alternative to anterior packing is the use of an inflatable epistaxis balloon catheter (***Figure 51.46***). The catheter is passed into the nose and the distal balloon is inflated in the nasopharynx to secure it. The proximal balloon, which is sausage shaped, is then inflated within the nasal fossa to compress the bleeding point. Although usually effective, they can be uncomfortable.

Postnasal packing may be required in refractory cases whereby a gauze pack is positioned in the nasopharynx under general anaesthesia. Endoscopic sphenopalatine artery clipping is an effective treatment for significant epistaxis not responding to direct cautery or nasal packing.

For uncontrolled life-threatening epistaxis in which the above methods have proved ineffective, haemostasis is secured by vascular ligation. Depending on the origin of bleeding it may be necessary to ligate the internal maxillary artery in the pterygopalatine fossa (which can be accessed endoscopically) and the anterior and posterior ethmoidal arteries. An alternative measure is external carotid artery ligation above the origin of the lingual artery. Another option is to involve the interventional radiologist for possible embolisation. It is also important to recognise, and treat, any factors contributing to the epistaxis, such as clotting or platelet abnormalities.

Figure 51.44 Hereditary haemorrhagic telangiectasia (Osler's disease) showing multiple telangiectasia.

Sir William Osler, 1849–1919, Professor of Medicine, successively at McGill University, Montreal, Canada, University of Pennsylvania, Philadelphia, PA, and Johns Hopkins University, Baltimore, MD, USA, finally becoming Regius Professor of Medicine at Oxford University, Oxford, UK, in 1904.
Colin B Holman, 1917–2008, American radiologist, Mayo Clinic.
W Eugene Miller, American radiologist, Mayo Clinic, with Colin Holman described the eponymous sign on plain radiographs in 1965.
Erik Adolf von Willebrand, 1870–1949, physician, Diakonissanstaltens Hospital, Helsinki, (Helsingfors), Finland, described hereditary pseudohaemophilia in 1926.

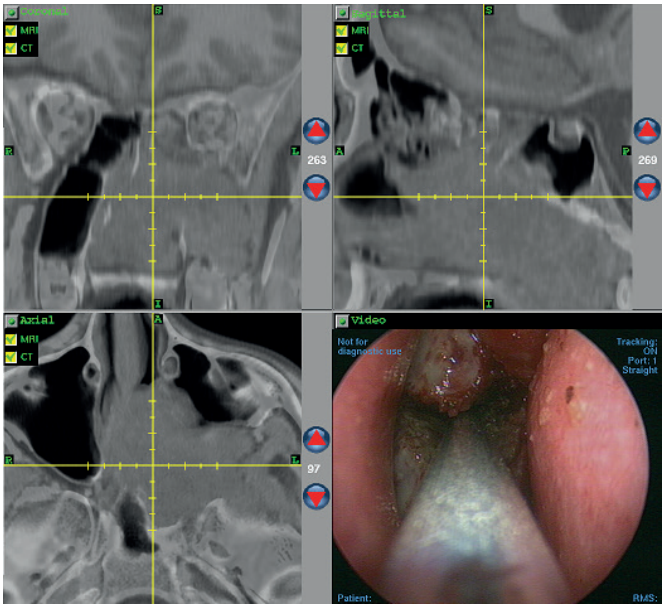

Figure 51.45 Endoscopic resection of juvenile angiofibroma using image guidance (merged computed tomography and magnetic resonance imaging scans).

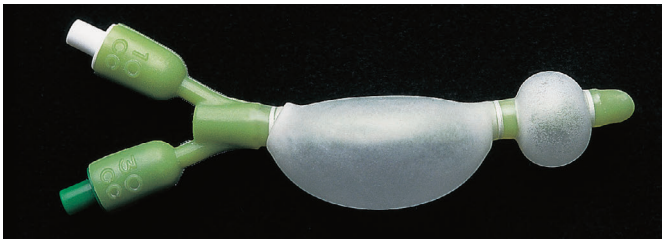

Figure 51.46 Epistaxis balloon catheter.

In HHT, anterior nasal packing is best avoided if at all possible because it is most likely to lead to further mucosal trauma and bleeding. High-dose oestrogen induces squamous metaplasia of the nasal mucosa and has been used effectively in treating this condition. Medications that block vessel growth, such as bevacizumab, and those that slow the disintegration of clots, such as tranexamic acid, help reduce the bleeding associated with HHT. There are also surgical options, including cautery/ablation of the telangiectasia, septodermoplasty or surgical closure of the nostril (Young's procedure).

RHINOSINUSITIS

Rhinosinusitis is inflammation of the sinonasal mucosa and is defined as the presence of nasal congestion or nasal discharge and at least one of facial pain or hyposmia with endoscopic and/or CT changes to confirm the diagnosis. It can be divided into acute rhinosinusitis (ARS) and chronic rhinosinusitis (CRS) depending on the timing of symptoms. Symptoms are present for less than 12 weeks in ARS and more than 12 weeks in CRS.

Summary box 51.11

Epistaxis

- The most common causes are nose picking, hypertension and anticoagulant therapy
- Young people bleed from the anterior septum – Kiesselbach's plexus
- Elderly people bleed from the posterior part of the nose
- Epistaxis is ideally treated with direct cautery to the bleeding point under endoscopic guidance
- Silver nitrate cautery can be used to control anterior bleeding
- Moderate bleeding may require anterior nasal packing
- Severe bleeding may require anterior and posterior nasal packing
- Persistent bleeding may require endoscopic sphenopalatine artery ligation

Acute rhinosinusitis

ARS is thought to result from bacterial superinfection of virally damaged mucosa. The commonest bacteria involved are *S. pneumoniae*, *H. influenzae* and *Moraxella catarrhalis*. Upper dental sepsis may also predispose to acute maxillary sinusitis. Patients with maxillary sinusitis have a mucopurulent discharge, facial pain and nasal obstruction. Irritation of the superior alveolar nerve may give rise to referred upper toothache. In ARS nasendoscopy reveals inflamed and swollen nasal mucosa with mucopurulent secretions in the middle meatus. Dental sepsis from anaerobic organisms causes around 10% of cases of maxillary sinusitis. The resultant mucopurulent nasal secretion has a foul taste and smell. Plain sinus radiographs may show a fluid level in the antrum or complete opacity (***Figure 51.47***). However, plain radiographs are now seldom used and have been superseded by CT scans to investigate ARS. CT scans confirm opacification and mucosal thickening of the maxillary sinus as well as providing anatomical detail prior to endoscopic surgical intervention (***Figure 51.48***).

Acute frontoethmoidal sinusitis can also occur and presents with mucopurulent discharge, facial pain (including frontal headache), nasal congestion and hyposmia. Again, mucopus is seen on endoscopy in the middle meatus and is investigated with CT.

Treatment

Penetration of antibiotics into chronically inflamed sinus mucosa is reduced and, therefore, treatment may need to be prolonged. Topical nasal decongestants, such as ephedrine nasal drops, will often encourage the sinus to drain and topical corticosteroids are used to reduce inflammation. Saline douches can also be beneficial.

Antral lavage under local or general anaesthesia was previously used to confirm the diagnosis and provided the opportunity to obtain samples for bacteriology. Nowadays, pus in the middle meatus can simply be sampled endoscopically in clinic and antral lavage is rarely performed. Endoscopic sinus surgery allows a more functional approach to diseases of the paranasal sinuses and enables the drainage pathways of the paranasal

Austen Young, 1914–2005, ENT surgeon, Sheffield, UK, first described surgical closure of the nostril for the management of atrophic rhinitis.

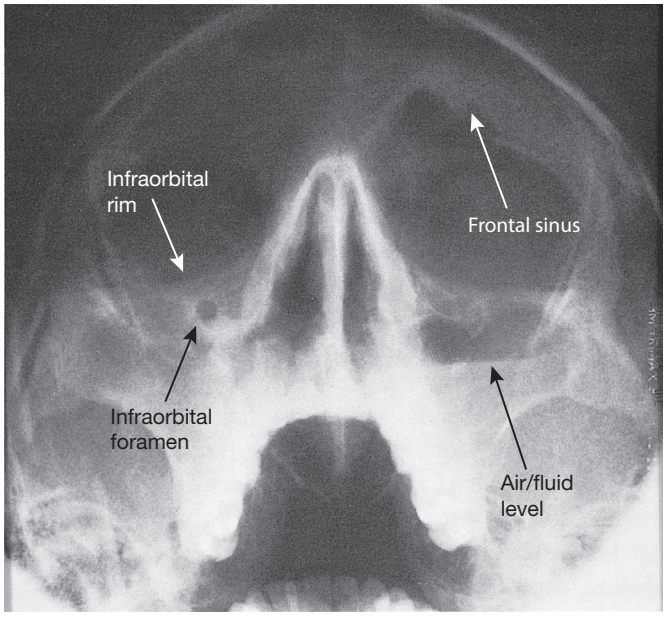

Figure 51.47 Plain radiograph showing the fluid level in the left maxillary antrum and total opacity of the right antrum.

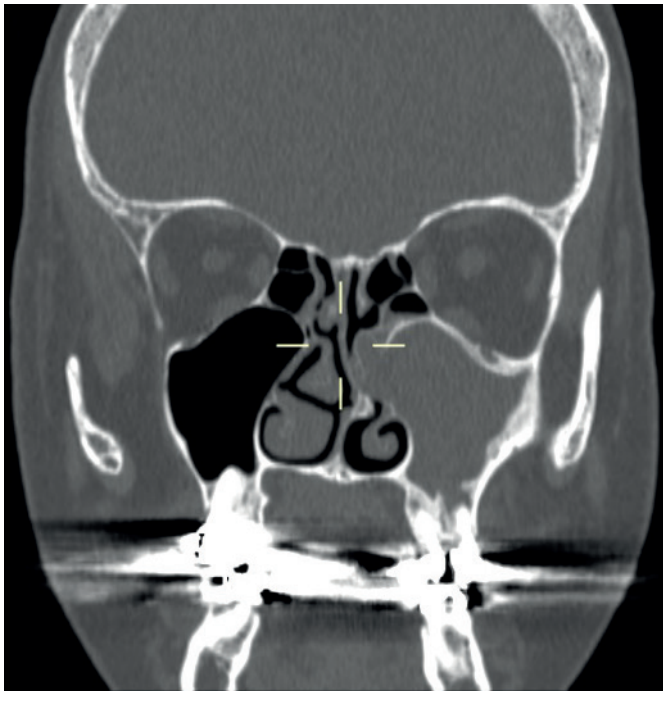

Figure 51.48 Coronal computed tomography scan showing left-sided maxillary sinus opacification due to maxillary sinusitis.

sinuses to be opened. Most cases of ARS can be treated conservatively with antibiotics and topical treatment. Surgery is used for those patients unresponsive to medical management or with complications. The majority of patients with ARS who require surgery are treated endoscopically. However, in some cases an open surgical approach may be necessary.

Summary box 51.12

Acute rhinosinusitis

- The most common causative organisms are *S. pneumoniae, H. influenzae, M. catarrhalis*
- Anaerobic infection of the maxillary sinus may result from dental sepsis
- Acute infection should be treated with antibiotics, topical decongestants and corticosteroids
- Endoscopic sinus surgery may be required

Complications

Complications of ARS include orbital and intracranial problems. The spread of infection from the sinuses occurs either through diploic veins or directly through bone erosion. This can result in epidural, subdural or cerebral abscesses or in meningitis/encephalitis. Cavernous sinus thrombosis may also result and can present with bilateral ptosis, proptosis, retro-ocular pain, ophthalmoplegia, papilloedema and spiking fevers.

Orbital complications of ARS are more common. Most often this is related to ethmoid sinus infection (***Figure 51.49***). An ophthalmology review is essential because of the threat to vision and intravenous antibiotics covering aerobic and anaerobic organisms are used. If there are any concerns regarding the eye, including proptosis, chemosis, ophthalmoplegia or reduced visual acuity, then CT with contrast is required (***Figure 51.50***). If an abscess is identified, this should be drained (endoscopically or open).

Summary box 51.13

Complications of acute rhinosinusitis

- Orbital – cellulitis, abscess
- Orbital infections may threaten sight
- Intracranial spread may cause meningitis, cerebral abscess or cavernous sinus thrombosis
- Osteomyelitis of the bones, particularly frontal, may occur

Summary box 51.14

Chandler classification of orbital complications of sinusitis

- I – preseptal cellulitis
- II – orbital cellulitis
- III – subperiosteal abscess
- IV – orbital abscess
- V – cavernous sinus thrombosis

Osteomyelitis of the frontal bones can also occur as a complication of ARS. If the anterior table of the frontal sinus is involved and becomes dehiscent, it can present with significant swelling of the skin of the forehead and a mass – Pott's puffy tumour (***Figure 51.51***).

Percivall Pott, 1714–1788, surgeon, London, UK.

Figure 51.49 Left periorbital cellulitis complicating acute left ethmoiditis.

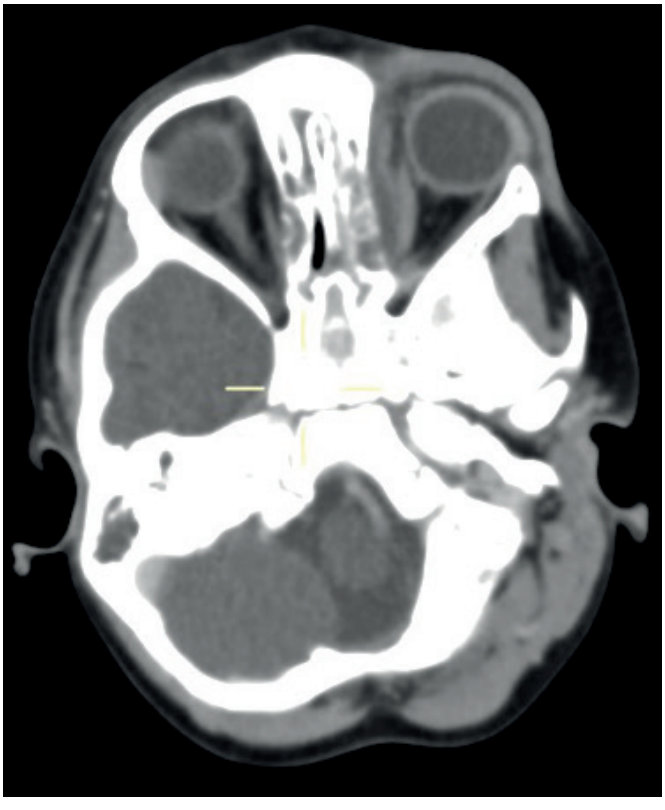

Figure 51.50 Axial computed tomography scan showing a subperiosteal abscess in the left orbit.

Chronic rhinosinusitis

CRS is common, affecting around 11% of the population. The aetiology is multifactorial and a number of factors have been linked to CRS, including ciliary dyskinesia, allergy, asthma, bacteria (*Staphylococcus aureus*), fungi and a number of host factors, including anatomical variations (deviated septum, concha bullosa of the middle turbinates). CRS has traditionally been divided into CRS with nasal polyps (CRSwNPs) and without (CRSsNPs). More recently CRS has been classified into primary or secondary, and local or diffuse disease.

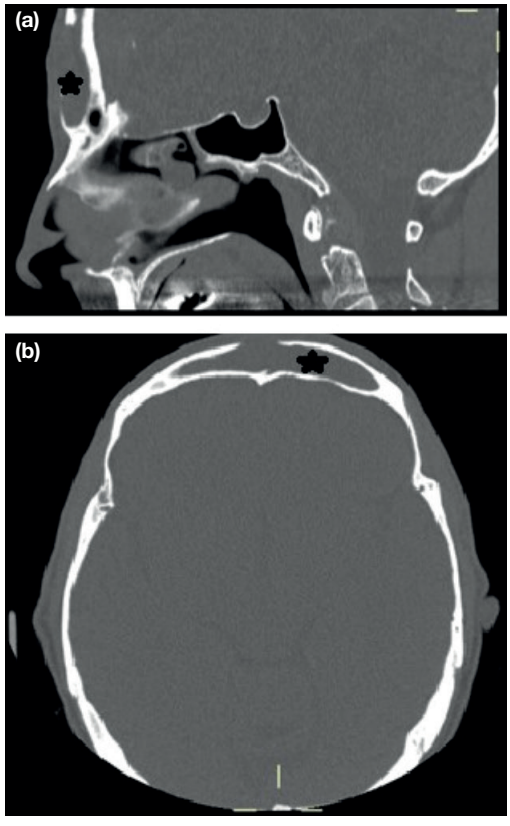

Figure 51.51 Sagittal **(a)** and axial **(b)** computed tomography scans showing complete opacification of the frontal sinus (marked with an asterisk) due to frontal sinusitis. The anterior wall of the frontal sinus is absent owing to infection.

Pathology

Nasal polyps are benign swellings of the sinus mucosa of unknown origin. Histologically, the polyps contain an oedematous stroma infiltrated with inflammatory cells and eosinophils. Inflammatory polyps tend to be bilateral and extend into the middle meatus. A single large polyp arising from the maxillary antrum is referred to as an antrochoanal polyp (***Figure 51.52***). This usually fills the nose and eventually prolapses posteriorly down into the nasopharynx.

Clinical features

Patients with CRSwNPs present with nasal obstruction, watery rhinorrhoea, postnasal drip and often hyposmia/anosmia. Pain does not tend to be a significant feature. Polyps are easily identifiable within the nose as pale semitransparent grey masses, which are mobile and insensitive when palpated with a fine probe (***Figure 51.53***). This allows them to be distinguished from hypertrophied turbinates. In CRSsNPs the middle meatus is often congested, with mucopus present.

Malignancy should be considered in adults with unilateral nasal polyps whereas in children such polyps must be distinguished from a meningocele or encephalocele by high-resolution CT scanning of the anterior cranial fossa. Nasal polyps are unusual in children; however, they do occur in conjunction with cystic fibrosis in 10% of cases.

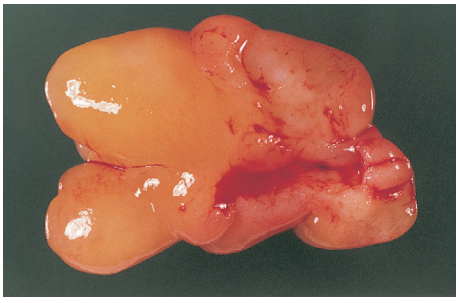

Figure 51.52 Antrochoanal polyp.

Figure 51.53 Nasal polyp in the right nasal vestibule.

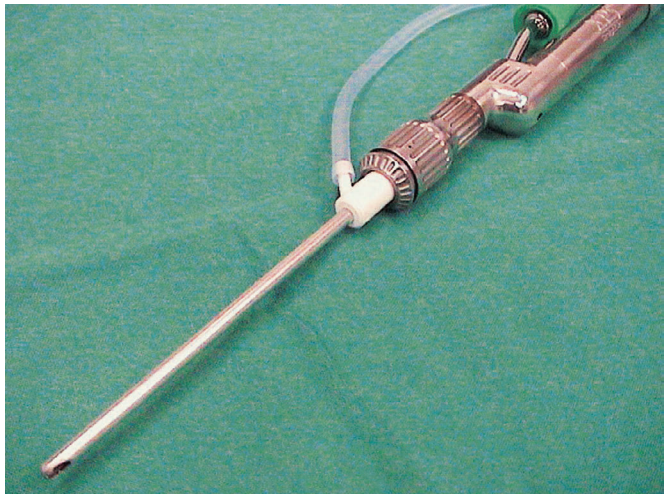

Figure 51.54 Powered nasal microdebrider.

Summary box 51.15

Nasal polyps

- Polyps are insensitive to touch and are mobile
- Inflammatory polyps are usually bilateral
- Unilateral nasal polyps should be removed for histology
- Bleeding polyps may indicate malignancy
- Meningocele and encephalocele must be excluded in children with polyps
- Polyps are removed using a powered microdebrider

Management

Medical treatment of CRSwNPs with systemic steroids will often reduce the size of the nasal polyps and give short-term relief of nasal blockage. Unfortunately, the polyps tend to recur when the treatment stops. Topical corticosteroid drops and sprays are also used along with saline douching. Biological treatments using monoclonal antibodies are a potential new therapy for CRSwNPs. In CRSsNPs, in addition to topical treatments, a long course of low-dose antibiotics (macrolides) can be used in those patients with a normal level of immunoglobulin E. Surgical treatment is indicated in patients who do not respond to medical treatment. Endoscopic nasal polypectomy and functional endoscopic sinus surgery (FESS) is performed following a CT scan that confirms the extent of disease and shows the important bony anatomy preoperatively. Serious complications following FESS include CSF leak and orbital problems, including orbital haematoma, and so it is important to review the level and symmetry of the anterior skull base and the integrity of the lamina papyracea on the CT scan prior to surgery. Endoscopic polypectomy is performed using a powered nasal microdebrider (***Figure 51.54***).

Image guidance can be used in endoscopic sinus surgery and extended endoscopic procedures such as pituitary and anterior skull base surgery to provide real-time feedback of instrument position in the nose based on preoperative CT or MRI scans.

TUMOURS OF THE NOSE AND SINUSES

Tumours arising in the nose or paranasal sinuses may present with unilateral nasal obstruction, persistent unilateral anterior rhinorrhoea, postnasal drip, epistaxis, unilateral bloodstained rhinorrhoea, facial swelling or proptosis.

Benign tumours

Simple papillomas or viral warts can grow inside the nasal vestibule. They can be confused with carcinomas and are best excised for histological diagnosis.

Osteomas of the nasal skeleton are not uncommon and are often detected on radiology as an incidental finding (***Figure 51.55***). In symptomatic individuals the osteoma can be removed endoscopically or via an open procedure.

Inverted (transitional cell) papillomas can occur in both the nasal cavity and the nasal sinuses. They are inverted papillomas because histologically the hyperplastic epithelium inverts into the underlying stroma. The papillomas are covered with transitional epithelium. Calcification within the tumour may be seen on CT along with sclerosis of the bone at the margins of the growth (***Figure 51.56***). Inverted papillomas can undergo malignant change. Full surgical resection is required, and this can usually be performed endoscopically.

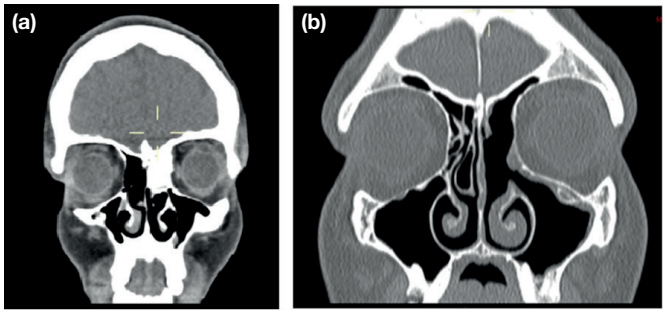

Figure 51.55 Coronal computed tomography (CT) scan showing an osteoma in the left anterior ethmoid sinus adjacent to the orbit **(a)**. The second coronal CT scan is following endoscopic excision of the osteoma **(b)**.

Figure 51.56 Coronal computed tomography scan showing an extensive inverted papilloma involving the left maxillary sinus; arrow indicates calcification within the tumour.

Figure 51.57 Squamous cell carcinoma of the nasal septum.

Figure 51.58 Maxillary antral carcinoma presenting through an oro-antral fistula.

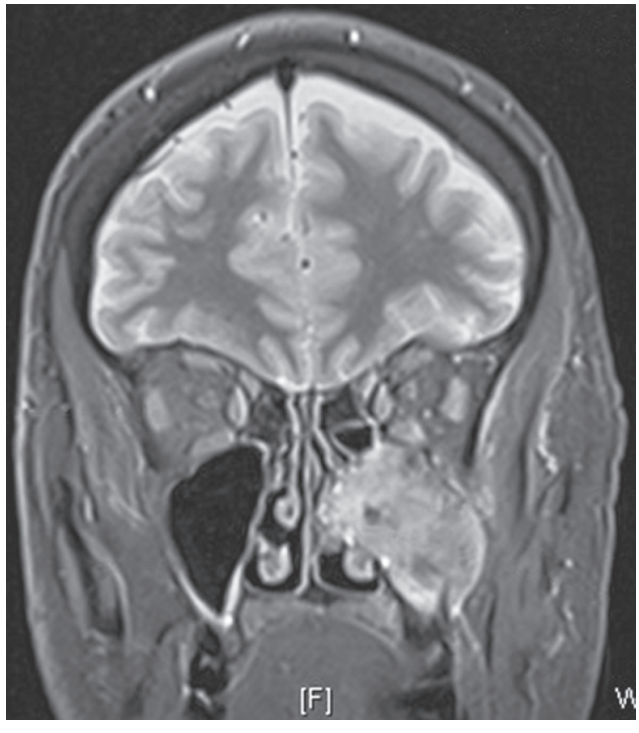

Figure 51.59 Coronal magnetic resonance imaging scan of the paranasal sinuses showing extensive left maxillary antral carcinoma invading adjacent structures.

Malignant tumours

The most common malignant tumours to occur within the nasal cavity and paranasal sinuses are squamous cell carcinomas (***Figure 51.57***), adenoid cystic carcinomas and adenocarcinomas. Adenocarcinoma has been linked to exposure to hard wood dust in the furniture industry. Adenoid cystic carcinomas arise from minor salivary glands, which can be found in the nose. Suspicious signs of invasion of neighbouring tissues include diplopia, proptosis, loosening of the teeth (***Figure 51.58***), trismus, CN palsies and regional lymphadenopathy. ***Figure 51.59*** shows invasion of a left maxillary antral carcinoma into adjacent structures, including the orbit, on an MRI scan.

Patients with sinus or intranasal malignancy are best managed in a combined clinic where the expertise of ENT surgeons, maxillofacial surgeons and oncologists can be employed.

Summary box 51.16

Tumours of the nose and sinuses

- Unilateral nasal blockage, discharge and bleeding are often presenting symptoms in nasal or sinus tumours
- Osteomas are often asymptomatic
- Inverted papilloma is a benign tumour, which presents as a unilateral polyp that can undergo malignant change
- Squamous cell carcinoma is the most common malignant tumour
- Almost 50% of sinonasal cancers arise on the lateral nasal wall and 33% in the maxillary antrum
- Multidisciplinary management of malignant sinonasal tumours requires input from ENT surgeons, maxillofacial surgeons and oncologists

PART 7 | Head and neck

CHAPTER 52

The pharynx, larynx and neck

Learning objectives

To understand:

- The relevant anatomy, physiology, disease processes and investigations of the pharynx, the larynx and the neck
- The diagnosis and emergency treatment of airway obstruction
- The aetiology, natural history and management of squamous cell carcinoma of the upper aerodigestive tract

CLINICAL ANATOMY AND PHYSIOLOGY

The pharynx

The pharynx is a fibromuscular tube forming the upper part of the respiratory and digestive passages. It extends from the base of the skull to the level of the sixth cervical vertebra at the lower border of the cricoid cartilage, where it becomes continuous with the oesophagus. It is divided into three parts: the nasopharynx, oropharynx and hypopharynx (***Figure 52.1***).

Nasopharynx

The nasopharynx lies anterior to the first cervical vertebra. The adenoids, which constitute the superior component of Waldeyer's ring, are situated at the junction of the roof and posterior wall of the nasopharynx. Waldeyer's ring is a ring of lymphoid tissue comprising, in addition to the adenoids, the palatine and lingual tonsils of the oropharynx. It is situated at the entry to the air and food passages and is constantly exposed to new inspired or ingested antigenic stimuli. Accordingly, it is an important part of the mucosa-associated lymphoid tissue (MALT), which processes antigens and presents them to T-helper cells and B cells (***Figure 52.2***), thereby facilitating a first-line immune response mechanism, which is particularly important in childhood. The tissue of Waldeyer's ring undergoes physiological hypertrophy during early childhood as the child is exposed to increasing amounts of antigenic stimuli, and there is often a similar hypertrophy of the cervical lymph nodes.

The Eustachian tubes, leading from the middle ear cleft, open into the posterosuperior aspect of the lateral wall. Dorsal and superior to the openings, bounded anteriorly by a ridge formed by the salpingopharyngeus muscle, are the fossae of Rosenmüller, a common site for the development of nasopharyngeal carcinoma (***Figure 52.3***).

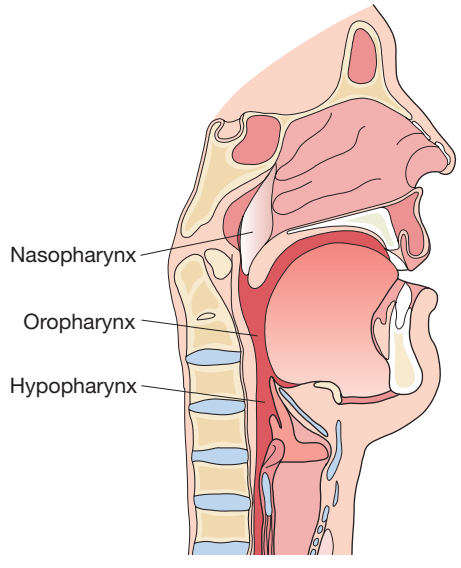

Figure 52.1 The component parts of the pharynx.

Oropharynx

This is bounded superiorly by the soft palate, inferiorly by the lingual surface of the epiglottis and anteriorly by the anterior faucial pillars and the circumvallate papillae of the tongue. The palatine tonsils are situated in the lateral wall between the anterior and posterior pillars of the fauces. The lateral wall, and in particular the tonsil, takes its blood supply from the facial artery, which may be closely related to the lower pole,

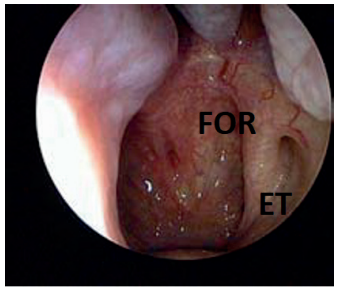

Figure 52.3 Endoscopic view of the left nasopharynx. ET, Eustachian tube; FOR, fossa of Rosenmüller.

and laterally a plexus of paratonsillar veins, which may be the source of significant venous bleeding following tonsillectomy.

Hypopharynx

The superior border of the hypopharynx is at the level of the laryngeal inlet. Its inferior border is the lower border of the cricoid cartilage where it continues into the oesophagus. The hypopharynx is commonly divided into three areas: the right and left piriform fossae, the posterior pharyngeal wall and the postcricoid region. The mucosa of these areas is, however, continuous so disease processes, such as squamous cell carcinomas, often involve more than one area as a result of overt or submucosal spread.

The multifaceted complex process of swallowing, which consists of the oral, pharyngeal and oesophageal phases (***Figure 52.4***), is mediated via afferent fibres passing to the medulla oblongata through the second division of the trigeminal nerve (V), glossopharyngeal nerve (IX) and vagus nerve (X). The efferent pathway is from the nucleus ambiguus and is mediated via the glossopharyngeal (IX), vagus (X) and hypoglossal (XII) nerves. Damage to these major cranial nerves at any point along their pathway, by trauma or disease, may cause dysphagia and/or aspiration.

Videofluoroscopy, in which the passage of a bolus of radiopaque food of different textures from the point at which it enters the oral cavity down to its passage within the stomach is examined radiologically, is the investigation of choice when investigating swallowing (dys)function.

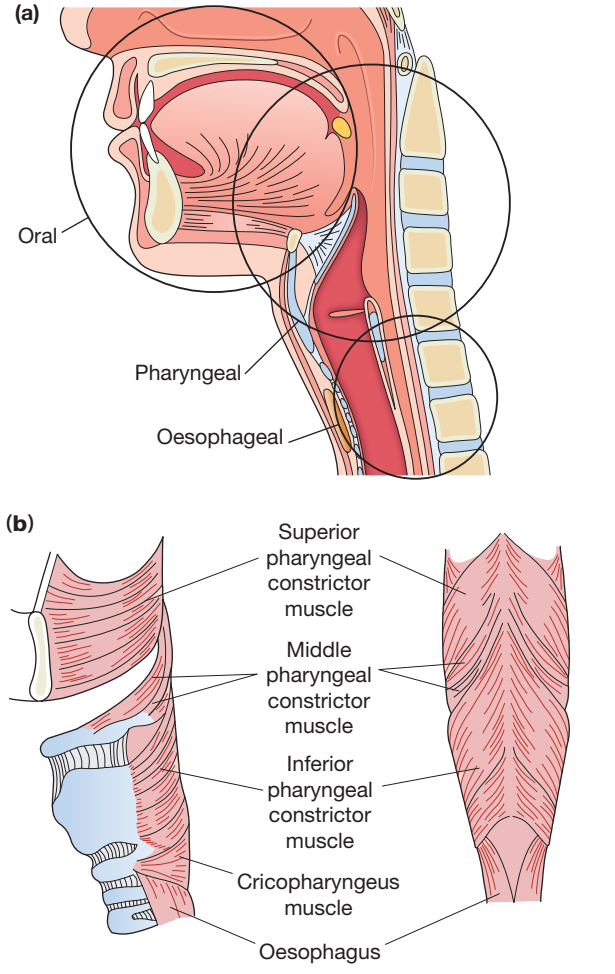

Figure 52.4 The three phases of swallowing **(a)** and the muscles **(b)**.

Anatomical relationships of the pharynx

Some of these are illustrated in ***Figure 52.5***.

Parapharyngeal space

This potential space lies lateral to the pharynx and is shaped like an inverted pyramid with its base at the base of the skull and its apex at the level of hyoid. It is divided into a prestyloid space, which contains the deep lobe of the parotid gland, blood vessels, lymph nodes and fat tissue, and a poststyloid space (also known as carotid space), which contains cranial nerves IX–XII, the carotid artery, internal jugular vein, deep cervical lymph nodes and cervical sympathetic trunk.

Infection and necrosis of the cervical lymph nodes in the parapharyngeal space most commonly occur from infections of the tonsils or teeth (particularly the third lower molar tooth). As the parapharyngeal space is not anatomically divided, infection may therefore spread from the skull base cranially to the superior mediastinum caudally and consequently often presents a surgical challenge.

Retropharyngeal space

This potential space lies posterior to the pharynx, bounded anteriorly by the constrictor muscles and the covering

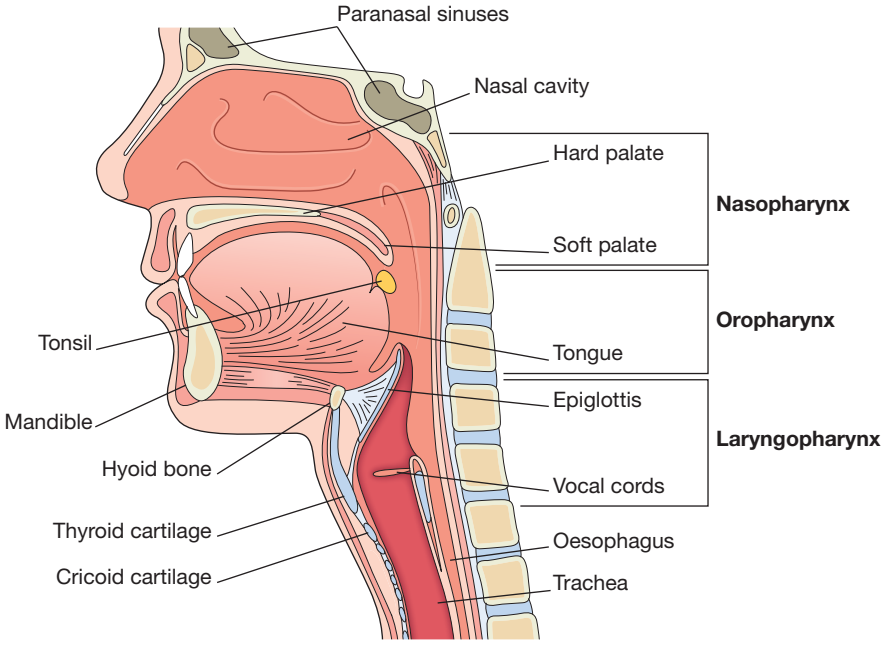

Figure 52.5 Sagittal diagram of the upper aerodigestive tract.

buccopharyngeal fascia and posteriorly by the prevertebral musculature and its overlying prevertebral fascia. It contains the retropharyngeal lymph nodes, which are usually paired lateral nodes but which are separated by a tough midline fibrous condensation that connects the prevertebral and buccopharyngeal fascia.

As with the lymphoid tissue of Waldeyer's ring, these nodes are more active in infancy and young children, and it is at this age that they are most likely to be involved in inflammatory processes, which, if severe, may affect swallowing and respiration as a consequence of gross swelling and suppuration of the retropharyngeal space.

Larynx

It is important to appreciate that the main function of the larynx is not the production of voice but the protection of the tracheobronchial airway and lungs. In order to achieve this, the larynx, together with the base of the tongue, forms the protective sphincter that closes off the airway during swallowing. It is only an evolutionary by-product that, in humans and some other mammals, the larynx is responsible for the production of sound.

The larynx comprises a cartilaginous framework (that may ossify in later life), which consists of the hyoid bone above, the thyroid and cricoid cartilages and the intricate arytenoid cartilages posteriorly.

The cricoid cartilage is the only complete ring in the entire airway and bounds the subglottis, which is the narrowest point of the airway in children. This is the most common site for damage from an endotracheal tube used for intensive care unit ventilation in seriously ill patients.

A purely anatomical description of the larynx divides it into the supraglottis, glottis and subglottis (***Figure 52.6***). The true

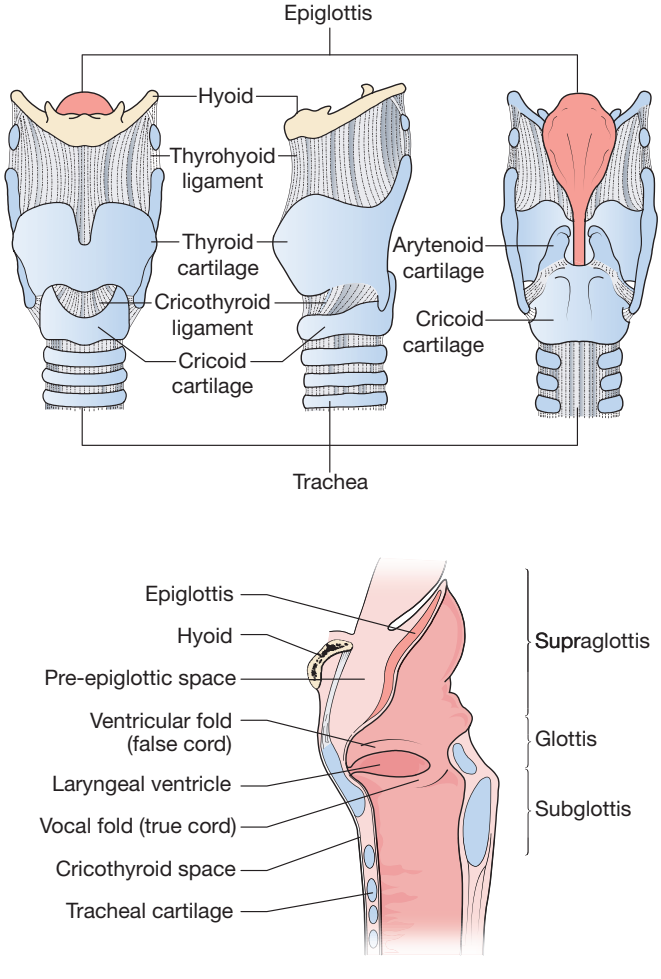

Figure 52.6 Anatomy of the larynx.

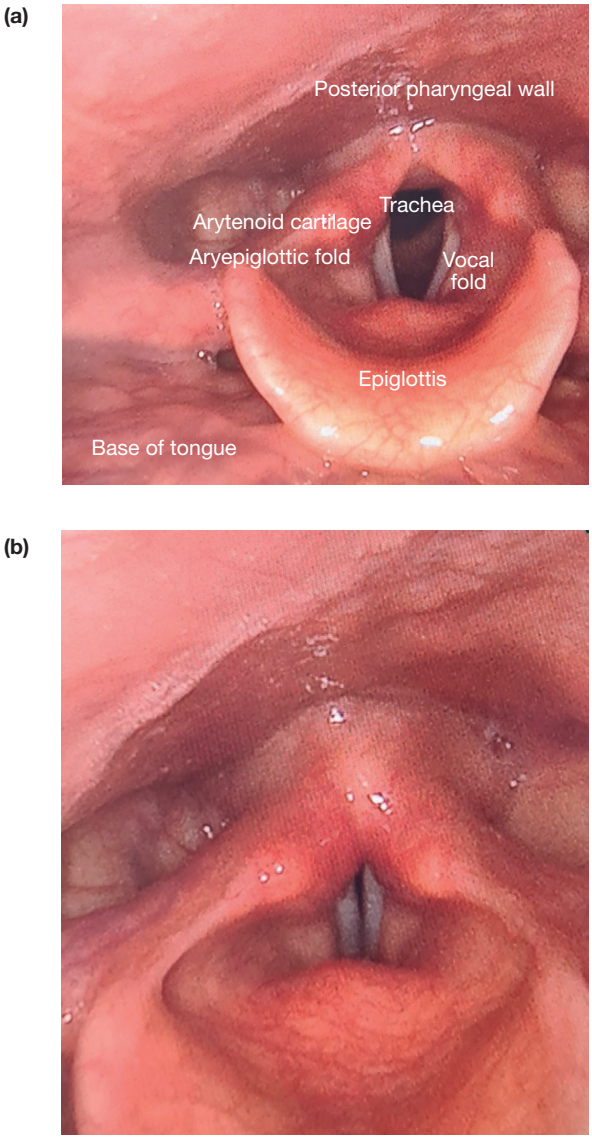

Figure 52.7 (a) Flexible nasendoscopy view of the larynx with the vocal folds abducted. **(b)** Flexible nasendoscopy view of the larynx with the vocal folds adducted.

vocal folds (often incorrectly called the vocal cords) are normally white, in contrast to the pink mucosa of the rest of the larynx and airway. The true vocal folds meet anteriorly at the midlevel of the thyroid cartilage, whereas posteriorly they are separate and attached to an arytenoid cartilage. This arrangement produces the 'V' shape of the glottis (***Figure 52.7***).

Nerve supply

The sensory nerve supply to the larynx above the true vocal folds is from the internal branch of the superior laryngeal nerve and, below, it is from the recurrent laryngeal nerve. Both these nerves are branches of the vagus nerve (X). The motor nerve supply to the larynx is from the recurrent laryngeal nerve, which supplies all intrinsic muscles except the cricothyroid, which is supplied by the external branch of the superior laryngeal nerve. Only one of these intrinsic muscles, the posterior cricoarytenoid, abducts the vocal folds during respiration. All other intrinsic muscles adduct the cords. Damage to the recurrent laryngeal or vagus nerve above the recurrent laryngeal nerve branch will cause paralysis of the vocal fold on the side of the damage. Additionally, cadaver studies have described the 'human communicating nerve', which is an anastomosis between the external branch of the superior laryngeal nerve and the recurrent laryngeal nerve, seen in 70% of human larynges. This nerve provides the sensory supply to the subglottis and motor innervation to the thyroarytenoid muscle.

Phonation/speech

The larynx functions by closing the vocal fold against the air being exhaled from the lungs, but the rise in subglottic pressure forces the vocal folds apart slightly for an instant of time, resulting in an accompanying sinusoidal wave-like vibration of the vocal fold epithelium. The human vocal folds have a specialised tissue morphology with resultant biomechanical properties that allow phonation. The opening and closing occurs in rapid sequence to produce a vibrating column of air, which is the source of sound that can be articulated by the structure of the oral cavity to produce speech.

Paralysis or disease of the vocal folds or closely associated laryngeal structures will give rise to disturbance of the sound, producing hoarseness.

The functions of the larynx are given in ***Summary box 52.1***.

Summary box 52.1

Functions of the larynx

- Protection of the lower respiratory tract by:
  - Closure of the laryngeal inlet
  - Closure of the false cords
  - Closure of the glottis
  - Cessation of respiration
  - Cough reflex
- Phonation
  - Vocal folds produce sound by quasiperiodic vibration
- Respiration
  - Control of pressure
- Fixation of chest
  - Aids lifting, straining and climbing

Neck

The neck is divided into anterior and posterior triangles by the sternocleidomastoid muscle. The anterior triangle extends from the inferior border of the mandible to the sternum below and is bounded by the midline and the posterior border of the sternocleidomastoid muscle. The posterior triangle extends backwards to the anterior border of the trapezius muscle and inferiorly to the clavicle. The upper part of the anterior triangle, above the hyoid bone, is commonly subdivided into the submandibular triangle above the digastric muscle bellies, and the submental triangle anteriorly, between the anterior digastric bellies of each side. The lymphatic drainage of the head and neck is of considerable clinical importance (***Figure 52.8***).

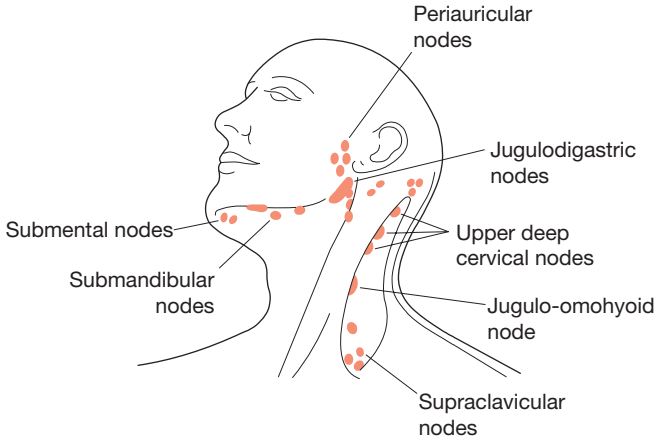

Figure 52.8 Distribution of cervical lymph nodes.

The most important chain of nodes are the jugular nodes, which run adjacent to the internal jugular vein. The other main groups are the submental, submandibular, pre- and postauricular, occipital and posterior triangle nodes.

A system of levels is used to describe the location of these neck nodes (***Figure 52.9***). Of particular note are the jugular nodal levels, which include levels II, III and IV; these relate to the upper, middle and inferior third of the carotid sheath, respectively. The level II nodes, which contain the large jugulodigastric node, drain the naso- and oropharynx, including the tonsils, posterolateral aspects of the oral cavity and the superior aspects of the larynx and piriform fossae. They are the most common sites of enlargement and may be palpated along the anterior border of the sternocleidomastoid muscle.

Metastatic spread of squamous cell carcinoma (80% of head and neck cancers) most commonly occurs from tumours arising in the upper aerodigestive tract mucosa, which comprises the following sites: oral cavity, nasopharynx, oropharynx, larynx and hypopharynx. When an enlarged neck node is detected and malignant disease is suspected, these sites must be carefully examined.

CLINICAL EXAMINATION

Pharynx and larynx

Before examination of the pharynx, the oral cavity should be examined with the aid of a good light and tongue depressors. Historically, a reflecting mirror on the head was used as a source of examination light. However, a headband-mounted fibreoptic light source is widely available and more commonly used. Either option permits the use of both hands to hold instruments. Inspection should include the buccal mucosa and lips, the palate, the tongue and floor of the mouth, all surfaces of the teeth and gums, the salivary ductal orifices, opening and closing of the mouth and dental occlusion. Patients should be asked to elevate the tongue to the roof of the mouth and protrude the tongue towards both the right and the left. Grasping the protruded tongue with a gauze aids the examination. Intraoral palpation may be required gently using one

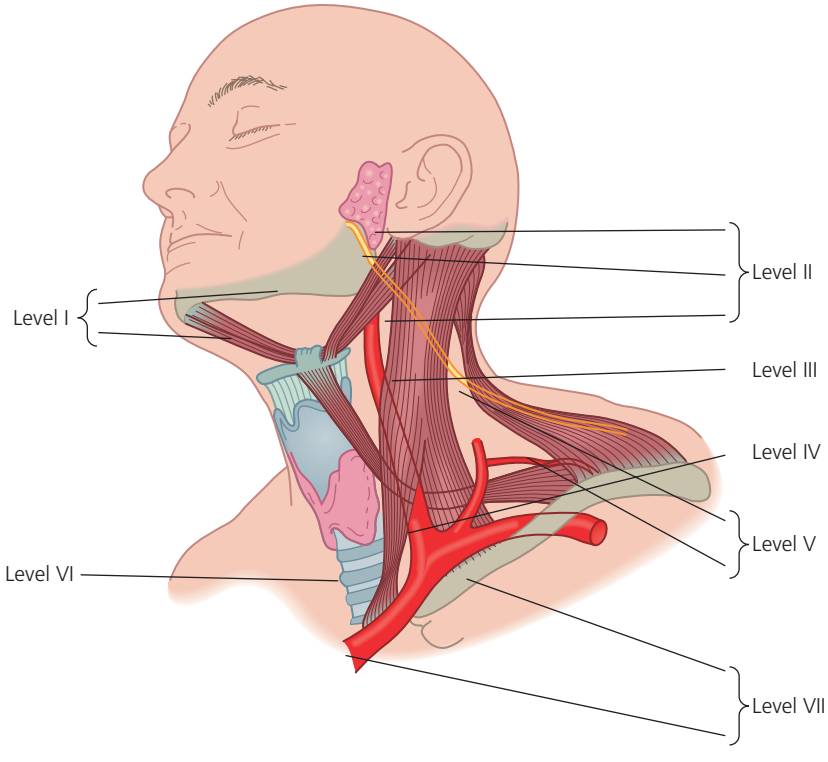

Figure 52.9 The level system for describing the location of lymph nodes in the neck. Level I, submental and submandibular group; level II, upper jugular group; level III, middle jugular group; level IV, lower jugular group; level V, posterior triangle group; level VI, anterior compartment group; level VII, superior mediastinal nodes. (Reproduced with permission from Watkinson JC, Gilbert RW. *Stell & Maran's textbook of head and neck surgery and oncology*, 5th edn. Boca Raton, FL: Hodder Arnold/CRC Press, 2012.)

or two fingers to feel any swellings. Intraoral palpation may be combined with extraoral bimanual palpation of the submental and submandibular lymph nodes and salivary glands to aid the characterisation and/or localisation of any swelling detected.

Following examination of the oral cavity, the oropharynx is then inspected with the tongue depressor placed firmly onto the tongue base to depress it inferiorly. Care must be taken to, if possible, avoid provoking a gag reflex. The anterior and posterior faucial pillars, the tonsil, retromolar trigone and posterior pharyngeal wall should all be inspected for colour changes, ulceration, mass lesions, mucopus, foreign bodies and swellings. Pain and trismus as a consequence of pharyngolaryngeal or neck pathology may add to the difficulty of the examination but are significant clinical findings in their own right.

While angled mirrors and a headlight may be used in expert hands, modern flexible fibreoptic endoscopes passed through the nose, with or without topical anaesthesia, allow high-quality examination of the entire nasopharynx, oropharynx, larynx and often the hypopharynx in almost every patient. Moreover, a camera attached to the endoscope permits the taking of high-quality photographs to record and present pertinent clinical findings. A rigid 0° fibreoptic endoscope (Hopkins' rod) is often used in preference to inspect the nasal cavities and nasopharynx.

Neck

The patient should be examined in the sitting position with the whole neck exposed so that both clavicles are clearly seen. The neck is inspected from the front and the patient asked to swallow, preferably with the aid of a sip of water. Movements of the larynx and any swellings in the neck are noted. The patient should be asked to protrude the tongue if there is a midline neck swelling, as a thyroglossal duct cyst will move upwards with the tongue protrusion. The neck is then examined from behind, one side at a time, with the chin flexed slightly downwards and the neck tilted to the same side being palpated to remove any undue tension in the strap muscles, platysma and sternocleidomastoids.

On examining for a lump in the neck, it is often helpful to ask the patient to point to the lump first. Ask if the lump is tender. All five palpable neck node levels (I–V) should be examined systematically.

If malignancy is suspected (hard, irregular or fixed to overlying skin or to deep structures), inspection of the upper aerodigestive tract mucosa, as described above, is mandatory.

Summary box 52.2

Key points of history and examination

Mouth

- Adequate light source and two spatulas to examine the mouth
- Examine
  - Lips
  - Teeth, gums, gingival sulci
  - Buccal mucosa, opening of parotid ducts
  - Floor of mouth and opening of submandibular salivary ducts
  - Hard and soft palate
  - Retromolar trigone region
  - Anterior and posterior faucial pillars, tonsils
  - Posterior pharyngeal wall
  - Tongue (observe full movements)
- Palpate
  - Salivary glands/ducts
  - Any mass lesions or ulcers in the mouth

Larynx, oropharynx and hypopharynx

- Indirect laryngoscopy
  - Mirror and headlight
- Flexible fibreoptic pharyngolaryngoscopy

Nasopharynx

- Rigid Hopkins' rod endoscopy
- Flexible fibreoptic nasendoscopy

Neck

- Inspection
  - Tongue protrusion
  - Observe swallowing
- Palpation
  - If a mass is palpable, evaluate for size, site, shape, consistency, superficial and deep fixation, fluctuation, transillumination, auscultation

INVESTIGATION OF THE PHARYNX, LARYNX AND NECK

Plain lateral radiographs

Plain lateral radiographs of the neck and cervical spine may show soft-tissue abnormalities, although their sensitivity and specificity is low; of particular importance is the depth and outline of the prevertebral soft-tissue shadow on sagittal section as an indication of retropharyngeal pathology. The outline of the laryngotracheal airway may be a useful guide to the presence of disease in the pharynx and larynx. There should be no air within the upper oesophagus. If air is seen, endoscopy is advised. Radio-opaque foreign bodies may be seen impacted in the pharynx, larynx or upper oesophagus on these radiographs (***Figures 52.10 and 52.11***).

Barium swallow and videofluoroscopy

Barium (or water-soluble contrast if a pharyngeal or oesophageal perforation is suspected) is used to perform dynamic videofluoroscopic studies, which record the movement of a small quantity of radio-opaque food of various textures and allow detailed evaluation of the oral and pharyngeal phases of swallowing (***Figure 52.12***).

Harold Horace Hopkins, 1918–1994, Professor of Applied Optics, University of Reading, Reading, UK, invented the rigid rod endoscope (Hopkins' rod, 1954) and contributed to the development of the fibres for flexible endoscopes.

Figure 52.10 Plain lateral radiograph showing normal anatomy.

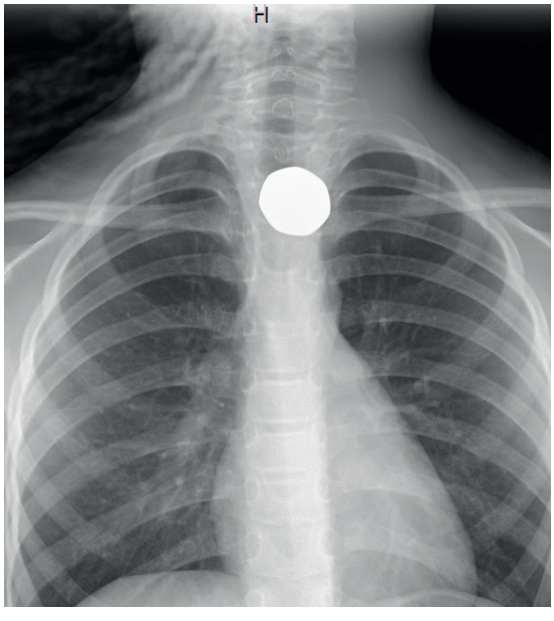

Figure 52.11 Plain radiograph demonstrating a coin in the oesophagus.

Computed tomography scanning

Computed tomography (CT) scanning provides high-resolution imaging of disease in the pharynx, larynx and neck. Intravenous contrast given at the same time as the CT scan (dynamic scanning) further improves the demonstration of disease in these areas (***Figure 52.13***).

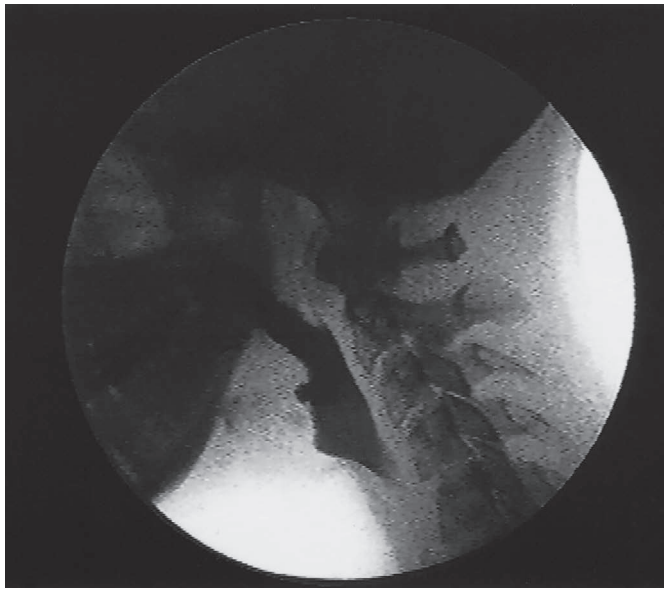

Figure 52.12 Static image grab from a videofluoroscopy sequence showing liquid barium in the upper pharynx in a normal swallow.

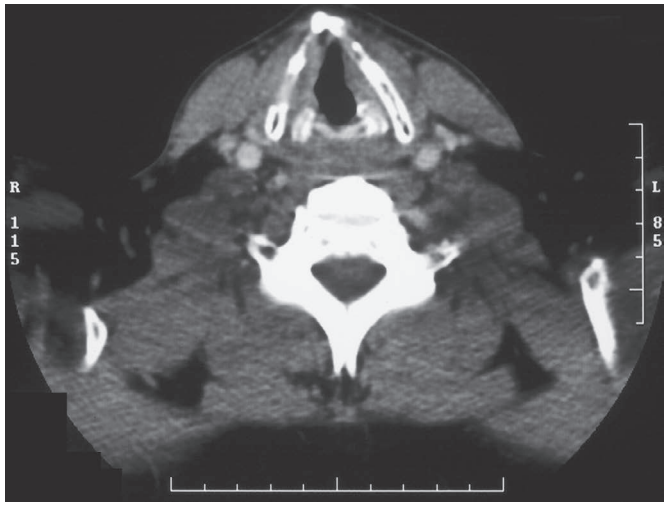

Figure 52.13 Axial computed tomography scan through the neck and larynx at the level of the glottis.

Other imaging

Magnetic resonance imaging (MRI) gives better soft-tissue definition and is preferred for primary tumour staging except for paranasal sinus cancers. Drawbacks of this approach include a reduction in image quality as a result of movement artefact, poorer definition of bony and cartilaginous structures and upstaging of tumours as a result of oversensitivity (***Figure 52.14***). Ultrasound scanning can be useful in differentiating solid lesions (e.g. malignant lymph nodes) from cystic lesions such as a branchial cyst and is particularly helpful when fine-needle aspiration is needed to establish the diagnosis; this modality is also invaluable for salivary gland pathology.

If a head and neck malignancy is suspected, then CT imaging of the thorax should also be performed to detect distant

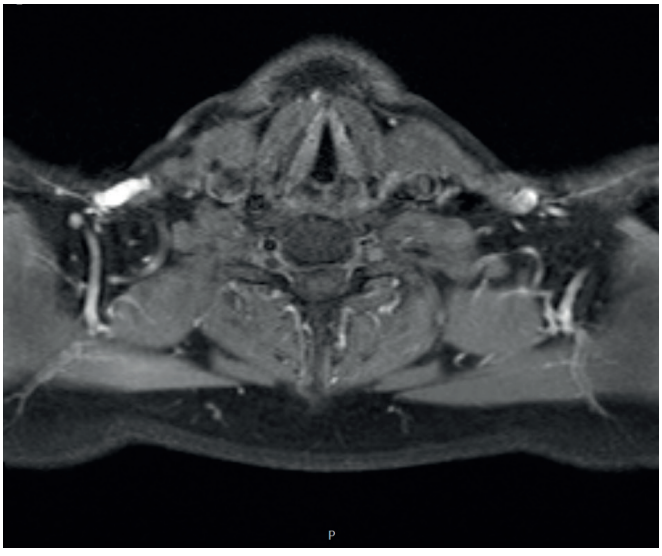

Figure 52.14 An axial magnetic resonance imaging scan at the same level as ***Figure 52.13***.

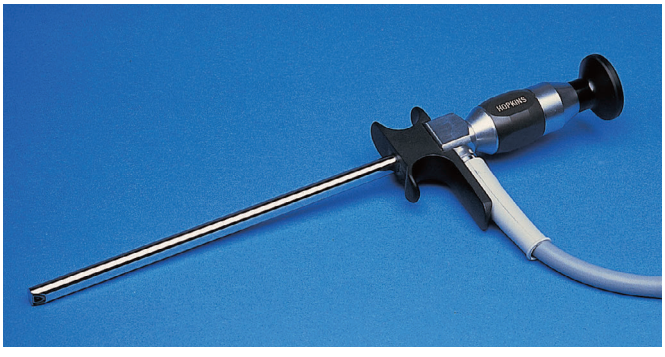

Figure 52.15 A rigid Hopkins' rod or endoscope.

metastases and synchronous primary bronchogenic tumours (approximately 5%), as the presence of these diagnoses will change treatment options.

Positron emission tomography (PET)-CT scans are performed during a single examination, in which the cross-sectional anatomical detail of a CT is fused with the metabolic information available from using a radiotracer. 18-Fluorodeoxyglucose (FDG) is the most commonly used radiotracer, with molecules similar to glucose; it accumulates in areas of high metabolic activity, which may represent tumour or inflammation. PET-CT is particularly used in patients being investigated for carcinoma of unknown primary to help identify the primary site of tumour, to look for distant metastases and to assess response to cancer treatment.

Fine-needle aspiration cytology and core biopsy

This is the investigation of choice when attempting to determine the nature of a neck or thyroid mass. Fine-needle aspiration cytology (FNAC) is aided by ultrasound (CT guided for deep-seated lesions) to the extent that ultrasound-guided FNAC or core biopsy is now the standard of care in many units around the world. Core biopsy is the preferred technique in investigating a neck node as immunohistochemistry tests can be performed on the tissue samples to determine positivity to human papillomavirus (HPV) or Epstein–Barr virus (EBV) in current-day practice. The technique is safe and well tolerated and has high diagnostic sensitivity and specificity, especially when diagnosing cervical lymph node enlargement.

Angiography or digital subtraction vascular imaging

These techniques may be indicated if a vascular lesion such as a carotid body tumour is suspected. Angiography may have a therapeutic role to play by facilitating embolisation of vascular tumours prior to planned surgical procedures. Magnetic resonance angiography (MRA) offers excellent resolution of vascular anatomy and is less invasive.

Direct pharyngoscopy and laryngoscopy

Examination of the pharynx, larynx and neck under general anaesthesia may be required to assess the stage and resectability of the primary site, or in instances where comprehensive examination has not been possible; such scenarios include an inadequate clinical examination caused by trismus from pain, poor patient compliance or large obstructive pharyngeal or laryngeal pathology. These examinations may be further aided by the use of an operating microscope or rigid straight and angled (30° and 70°) endoscopes (Hopkins' rods) (***Figure 52.15***).

The advantages and disadvantages of laryngeal examination techniques are given in ***Summary box 52.3***.

Summary box 52.3

Advantages and disadvantages of larynx and pharynx examination techniques

- Flexible nasolaryngoscopy
  - Well-tolerated examination
  - Can also examine nasal passages and postnasal space
  - Need fibreoptic light source
- Rigid endoscopy
  - Can be used with stroboscope for evaluation of voice
  - High-definition view
  - Needs fibreoptic light source
  - Bulky and difficult if prominent gag reflex present
- Laryngeal mirror
  - Does not need fibreoptic light source
  - No record of examination
  - Low-resolution image
  - Difficult if prominent gag reflex present

Michael Anthony Epstein, b. 1921, formerly Professor of Pathology, University of Bristol, Bristol, UK.
Yvonne Barr, 1931–2016, virologist who emigrated to Australia. Epstein and Barr discovered this virus in 1964.

DISEASES OF THE PHARYNX

NASOPHARYNX

Enlarged adenoid

The most common cause of an enlarged adenoid (there is only one nasopharyngeal adenoid, despite the common use of the term 'adenoids') is physiological hypertrophy in childhood. The size of the adenoid alone is not an indication for removal. Of more importance is the consequence of hypertrophy (e.g. nasal obstruction). Adenoid hypertrophy (***Figure 52.16***) is often associated with hypertrophy of the other lymphoid tissues of Waldeyer's ring. Of particular note, if excessive adenoidal hypertrophy causes blockage of the nasopharynx in association with tonsil hypertrophy, the upper airway may become compromised during sleep causing, obstructive sleep apnoea (OSA).

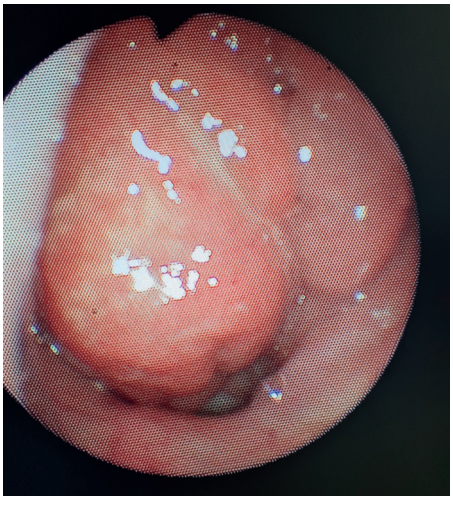

Figure 52.16 Adenoid hypertrophy.

Obstructive sleep apnoea

This condition is becoming increasingly diagnosed in children and is important because it can cause sleep deprivation and secondary cardiac complications. It has been implicated in some cases of sudden infant death syndrome. The most common symptom is snoring, which is typically irregular, with the child ceasing respiration (apnoea) and then restarting with a loud inspiratory snort. The child is often restless and may take up strange sleep positions as he or she tries to improve the pharyngeal airway. Surgical removal of the tonsils and adenoid is curative, but it is important to avoid sedative premedications and opiate analgesics postoperatively because they may further depress the child's respiratory drive.

OSA may also occur in adults, where the obstruction may result from nasal deformity, a hypertrophic soft palate associated with an altered nasopharyngeal isthmus, obesity and general narrowing of the pharyngeal airway, or supraglottic laryngeal pathology. The initial investigation may include a sleep study, during which measurements of the patient's sleep pattern and arterial oxygenation are undertaken. Continuous positive airway pressure devices may ameliorate OSA by splinting the obstruction open. Surgery may also be indicated, depending on the level(s) of the obstruction.

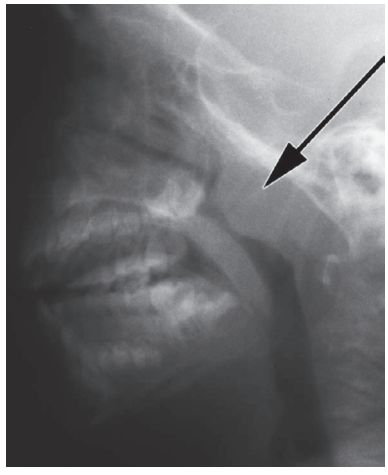

Figure 52.17 Plain lateral radiograph showing a large pad of adenoid tissue (arrow) in the postnasal space.

Hypertrophy of adenoid tissue most commonly occurs between the ages of 4 and 10, but the adenoid tissue usually undergoes spontaneous atrophy during puberty, although some remnants may persist into adult life (***Figure 52.17***). The relationship of adenoid enlargement to recurrent secretory otitis media or recurrent acute otitis media is not entirely clear.

Adenoidectomy

Adenoid tissue can be removed alone or in conjunction with a tonsillectomy. The indications for adenoidectomy are:

- OSA associated with postnasal obstruction;
- recurrent acute otitis media or prolonged serous otitis media, usually longer than 3 months' duration;
- recurrent rhinosinusitis*;
- postnasal discharge*.

*Relative indications

Operative technique

With the patient placed in a supine position with the neck in a neutral position, the adenoid tissue is removed with a guarded curette pressed against the roof of the nasopharynx before sweeping downwards to deliver the excised adenoid into the oropharynx (***Figures 52.18 and 52.19***). A postnasal swab is placed into the nasopharynx until all haemorrhage has ceased. A mirror can be used to guide the direction of the adenoid curette. Alternatively, suction monopolar diathermy or a coblator may be used to remove adenoid tissue.

Reactionary or secondary haemorrhage during the recovery period may require a nasopharyngeal pack under a further anaesthetic. This can occasionally cause respiratory depression in children and adults, and strict observation is required while the pack is in place.

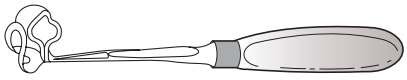

Figure 52.18 St Clair Thomson adenoid curette.

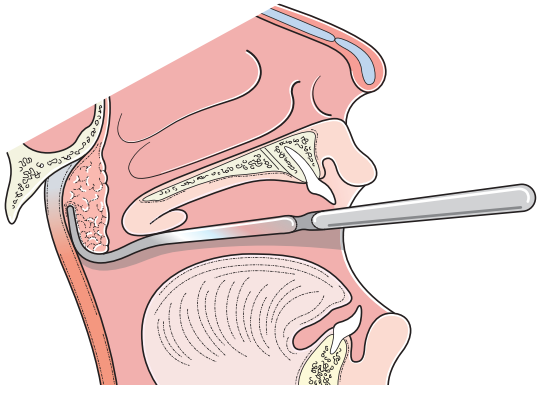

Figure 52.19 Curettage of the adenoid.

Tumours of the nasopharynx

Benign

There are two main types of benign tumours of the nasopharynx: the angiofibroma and the antrochoanal polyp. Both are rare.

Angiofibroma

This tumour is confined to young male patients most commonly between the ages of 8 and 20 years. It usually causes progressive nasal obstruction, recurrent severe epistaxis, purulent rhinorrhoea and occasionally loss of vision because of compression of the optic nerve by superior extension of the tumour through the skull base. Although the tumour is rare, these symptoms in a young male patient should always arouse suspicion. The tumour is more common in northern India, although the reasons for this are unknown. Clinical examination typically shows a mass in the nasal cavity or nasopharynx, but CT scanning best demonstrates the extent of the tumour and any associated bony erosion. MRI scanning defines the soft-tissue extent and, with these two modalities, combined with the history and clinical examination, a diagnosis can safely be arrived at. Angiography and embolisation are usually performed 24–48 hours prior to surgery to minimise intraoperative bleeding. Biopsy should be avoided unless clinical and radiological examinations are not diagnostic because of the risk of bleeding.

Surgical resection requires adequate exposure through either a midfacial degloving approach or lateral rhinotomy (***Figures 52.20 and 52.21***). Both allow ligation of the feeding maxillary artery. More recently, endoscopic resection has been used for smaller lesions.

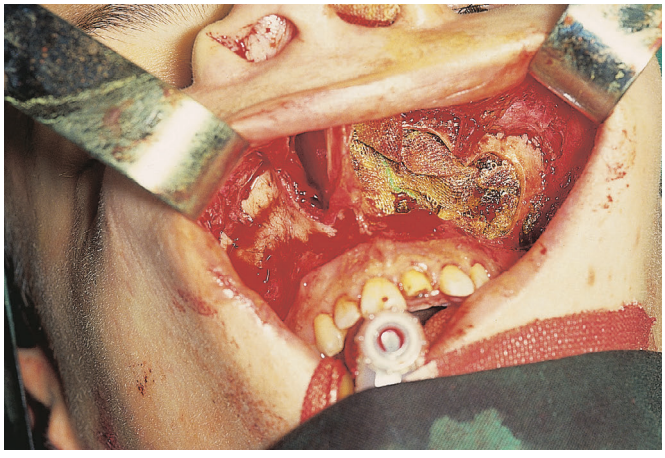

Figure 52.20 Intraoperative photograph showing exposure during a midfacial degloving approach.

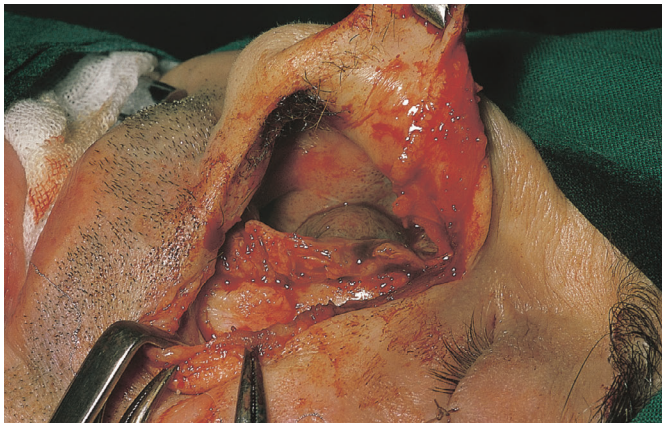

Figure 52.21 Intraoperative photograph showing an incision in lateral rhinotomy.

Antrochoanal polyp

This relatively uncommon lesion is a benign mucosal polyp that arises in the maxillary antrum and prolapses into the nasal cavity, where it expands backwards into the nasopharynx and occasionally into the oropharynx (***Figures 52.22 and 52.23***). It may mimic an angiofibroma, from which it is distinguished by its avascularity and pale colour, as well as its site of origin, which is determined on endoscopic examination and imaging. It requires complete removal via an endoscopic approach through the middle meatus of the maxillary sinus or, rarely, via an open Caldwell–Luc approach.

Malignant

Nasopharyngeal carcinoma

Nasopharyngeal carcinoma has a marked geographically variable incidence. There is classically a tumour involving the nasopharynx that may extend into the nasal cavity, oral

Sir St Clair Thomson, 1859–1943, British surgeon and professor of laryngology.
George Walter Caldwell, 1834–1918, otolaryngologist, who practised successively in New York, San Francisco and Los Angeles, USA, devised this operation for treating suppuration in the maxillary antrum in 1893.
Henri Luc, 1855–1925, otolaryngologist, Paris, France, described his operation in 1889.

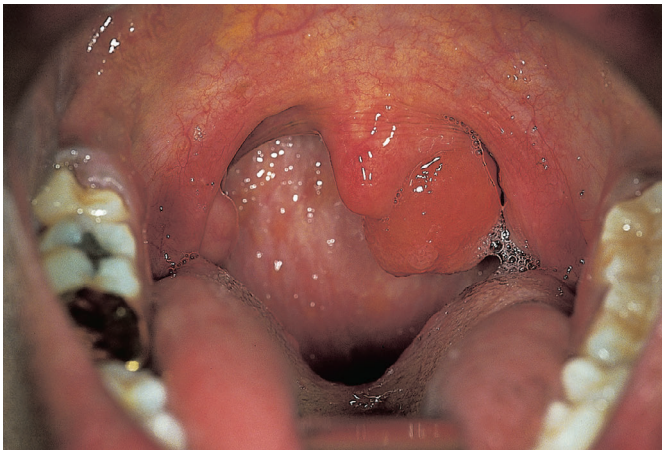

Figure 52.22 Intraoral view showing a fleshy polyp hanging in the oropharynx.

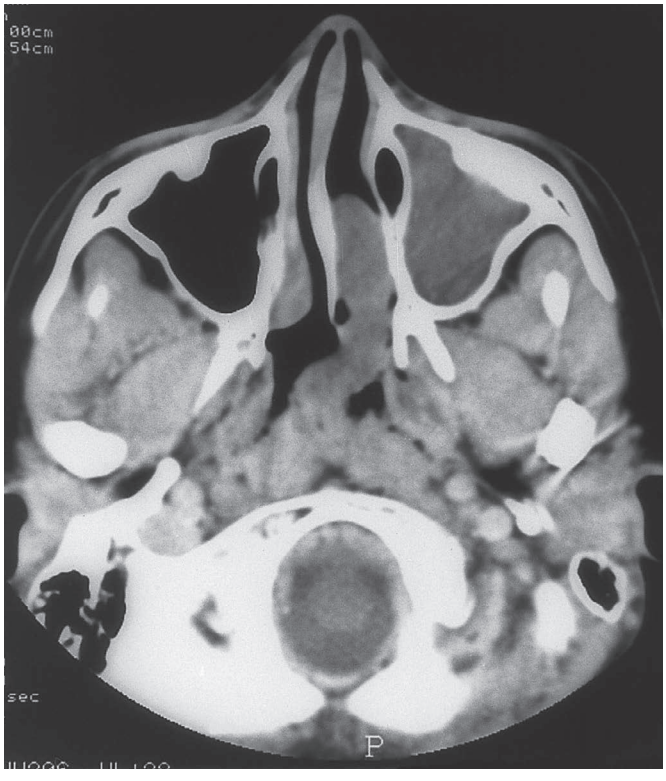

Figure 52.23 Axial computed tomogram of an antrochoanal polyp (as seen in ***Figure 52.22***), with an opaque maxillary antrum and a mass in the nasal cavity and nasopharynx.

cavity, parapharyngeal space, bones and sinuses or brain. It has a male-to-female ratio of 3:1. In most parts of the world, it is rare with an annual incidence of 1 case per 100 000 population; however, among southern Chinese populations the rate is 30–50 cases per 100 000 population. The aetiology of nasopharyngeal carcinoma is multifactorial. Genetic susceptibility, tobacco smoking, early infection by EBV and consumption of traditional diets, particularly salted fish, are known to contribute.

Summary box 52.4

Aetiological factors in nasopharyngeal carcinoma

- Genetic (e.g. Cantonese population)
- Infective (e.g. EBV)
- Environmental (e.g. salted fish)
- Tobacco smoking

The majority of nasopharyngeal tumours are undifferentiated with a characteristic morphology, constituting over 90% of nasopharyngeal malignancy in endemic areas. Rare epithelial tumours are adenocarcinoma and adenoid cystic carcinoma, which arise from minor salivary glands. B- and T-cell lymphomas also occur in the nasopharynx and should not be confused with the more common undifferentiated carcinoma. Nasopharyngeal carcinoma has a bimodal distribution with an increased incidence in teenagers and young adults and then again in the 50- to 60-year-old age group.

Clinical features. Symptoms are closely related to the position of the tumour in the nasopharynx and the degree of regional and/or distant spread. Early symptoms are often minimal and may be ignored by both patient and doctor. Approximately 50% of patients will present with a malignant node or nodes in the neck, indicating an advanced tumour. While investigation of the lymph node will involve fine-needle aspiration or a biopsy, such a clinical presentation mandates an immediate thorough examination of the nasopharynx. In about 5% of patients, the nasopharynx may look normal or minimally asymmetrical but contains submucosal nasopharyngeal carcinoma. MRI or CT of the head and neck should be performed as part of the diagnostic work-up; even if a nasopharyngeal mass is not identified clinically or radiologically, a biopsy of the nasopharynx, targeting the fossa of Rosenmüller, will reveal the site of the primary tumour in patients with a malignant neck lump that shows EBV positivity. In contrast, nasal complaints (obstruction with/without rhinorrhoea) occur in one-third of patients and aural symptoms of unilateral deafness as a consequence of Eustachian tube obstruction and secretory otitis media occur in approximately 20% of patients. Neurological complications with cranial nerve palsies as a result of disease in the skull base occur relatively late in the disease, but are a poor prognostic sign, as is trismus resulting from tumour involvement of the pterygoid musculature.

Summary box 52.5

Nasopharyngeal carcinoma: main presenting complaints

- Regional
  - Cervical lymphadenopathy
- Local
  - Hearing loss (unilateral serous otitis media), otalgia
  - Nasal obstruction, bloody discharge, epistaxis
  - Cranial nerve palsies, especially III–VI then IX–XII
  - Trismus

Investigation. This is by direct inspection with a flexible or rigid nasendoscope and biopsy under topical or general anaesthesia. Serological investigation for EBV-associated antigenic markers in combination with the clinical and histological examination is valuable for the early detection of disease. Highly sensitive assays for antiviral antibodies together with virus-associated serological markers are useful in early detection and in post-treatment surveillance. Immunoglobulin (Ig) A antiviral capsid antigen antibody and early antigen antibody have been evaluated in mass surveys in southern China and have been found to be an excellent screening method for early detection of nasopharyngeal carcinoma in high-risk groups.

Imaging. This is essential for staging and to determine the extent of disease. The imaging of choice is MRI, which allows for assessment of brain parenchyma, cavernous sinus and the closely associated cranial foramina and for treatment planning. CT or PET-CT of the head, neck and chest has a major role in planning radiotherapy and assessing the response to treatment, diagnosing recurrence and detecting complications.

Treatment. The primary treatment of nasopharyngeal carcinoma is non-surgical as it is highly radiosensitive and depends on the stage of the disease. Intensity-modulated radiotherapy is the treatment of choice for early stages I and II and cisplatin-based chemotherapy with concurrent radiation therapy for stages III and IV. Surgery is reserved for local recurrence that would require a nasopharyngectomy, which can be performed either transorally with a robot, transnasally with a rigid telescope or via an open approach; regional recurrence in the neck is managed by a neck dissection. Given the complexity of the anatomy and proximity of vital neurovascular structures, ongoing trials with proton beam therapy at selected centres around the world have demonstrated promising results with lesser adverse effects. For early disease, 5-year disease-free survival rates of more than 75% are common; however, in advanced disease the results are less good, with 5-year disease-free survival rates of 30–50%.

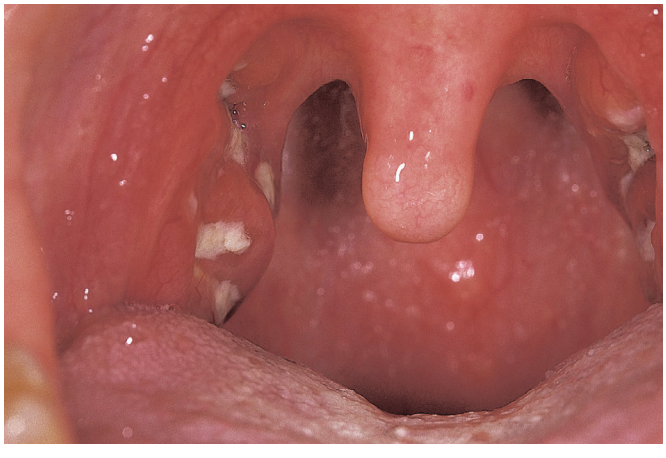

Figure 52.24 Acute follicular tonsillitis.

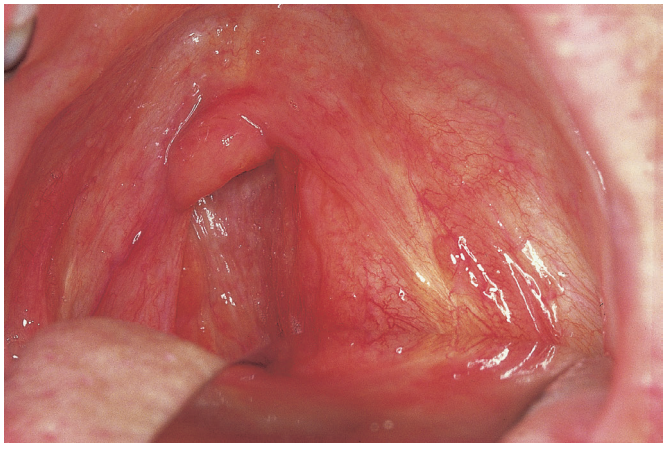

Figure 52.25 Quinsy (peritonsillar abscess).

OROPHARYNX

Acute tonsillitis

This common condition is characterised by a sore throat, fever, general malaise, dysphagia, enlarged upper cervical nodes and sometimes referred otalgia. Approximately half the cases are bacterial, the most common cause being a pyogenic group A *Streptococcus*. The remainder are viral and a wide variety of viruses have been implicated, in particular infectious mononucleosis (glandular fever), which may be mistaken for bacterial tonsillitis.

On examination, the tonsils are swollen and erythematous, and yellow or white pustules may be seen on the palatine tonsils, hence the name 'follicular tonsillitis' (***Figure 52.24***). A throat swab should be taken at the time of examination as well as blood for EBV testing to confirm or refute the diagnosis of glandular fever.

Treatment

Paracetamol and/or other analgesia may be administered to relieve pain and saline gargles are soothing. The condition is frequently sensitive to benzyl- or phenoxymethylpenicillin (penicillin V) and these are given until antibiotic sensitivities are established. Ampicillin is avoided as it may precipitate a rash in patients with infectious mononucleosis. Most cases resolve in a few days.

Quinsy

This is an abscess in the peritonsillar region that causes severe pain and trismus (***Figure 52.25***). The trismus, which is caused by spasm induced in the pterygoid muscles, may make examination difficult but may be overcome by instillation of local anaesthesia into the posterior nasal cavity (anaesthetising the sphenopalatine ganglion) and the oropharynx. Inspection reveals a diffuse swelling of the soft palate just superior or lateral to the involved tonsil, displacing the uvula medially. In more advanced cases, pus may be seen pointing underneath the thin mucosa.

Treatment

In the early stages, intravenous broad-spectrum antibiotics may produce resolution. However, if there is frank abscess

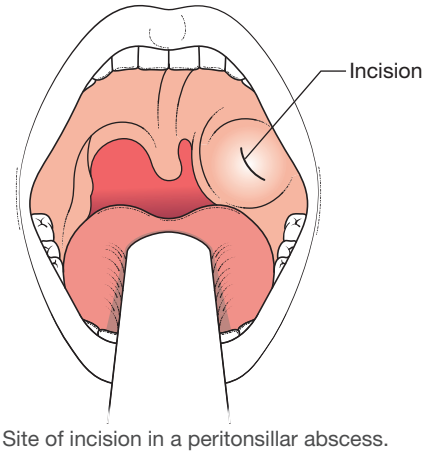

Figure 52.26 Site of incision in a peritonsillar abscess.

formation, incision and drainage of the pus can be carried out under local anaesthesia. A small scalpel is best modified by winding a strip of adhesive tape around the blade so that only 1 cm of the blade projects. In teenagers and young adults, the patient sits upright and an incision is made approximately midway between the base of the uvula and the third upper molar tooth (***Figure 52.26***). This may produce immediate release of pus, but, if not, a dressing forceps is pushed firmly through the incision and, on opening, pus may then be encountered. Needle aspiration of the pus, with or without ultrasound guidance, is an alternative treatment. In small children, general anaesthesia is required.

Chronic tonsillitis

Chronic tonsillitis usually results from repeated attacks of acute tonsillitis in which the tonsils become progressively damaged by inflammatory processes and provide a reservoir for infective organisms.

Tonsillectomy

The indications for a tonsillectomy are either diagnostic, therapeutic or for surgical access. Recurrent acute tonsillitis is the most common relative indication for tonsillectomy in children and adolescents, although it is important that these attacks are well documented, frequent and do not simply constitute a minor viral sore throat. Chronic tonsillitis more frequently affects young adults, in whom it is important to establish that chronic mouth breathing secondary to nasal obstruction is not the main problem rather than the tonsils themselves. Tonsillectomies are occasionally performed as a means to gain surgical access to the parapharyngeal space laterally in the oropharynx or to access an elongated styloid process. Absolute indications for tonsillectomy are when the size of the tonsils is contributing to airway obstruction or a malignancy of the tonsils is suspected (***Table 52.1***).

Ideally, the procedure should be undertaken when the tonsils are not acutely infected, and it is important to discuss factors that may increase the tendency to bleed. Blood transfusion is rarely required, but it is normal practice to type and screen blood for cross-match in children under 15 kg in weight.

TABLE 52.1 Indications for tonsillectomy.

Absolute	• Sleep apnoea, chronic respiratory tract obstruction, cor pulmonale • Suspected tonsillar malignancy
Relative	• Documented recurrent acute tonsillitis • Chronic tonsillitis • Peritonsillar abscess (quinsy) • Tonsillar asymmetry • Tonsillitis resulting in febrile convulsions • Diphtheria carriers • Systemic disease caused by β-haemolytic *Streptococcus* (nephritis, rheumatic fever)

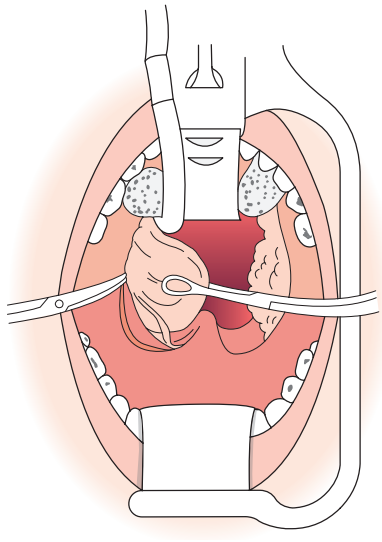

Figure 52.27 Removal of the tonsils.

Dissection tonsillectomy is carried out under general anaesthesia. The mucosa of the anterior faucial pillar is incised and the tonsil capsule identified. Using blunt dissection, the tonsil is separated from its bed until only a small inferior pedicle is left (***Figure 52.27***). It is then separated from the lingual tonsil. A tonsil swab is placed in the tonsillar bed and pressure applied for some minutes, following which bleeding points may be controlled by ligature or by bipolar diathermy. (Coblation and laser dissection is commonly used in the resource-rich world in an attempt to reduce postoperative pain and bleeding.)

Following surgery, the patient is kept under close observation for any systemic or local evidence of bleeding, with regular pulse and blood pressure measurements and observation to monitor whether the patient is swallowing excessively (***Figure 52.28***). Postoperatively, patients are encouraged to eat normally and take regular oral analgesics. Patients are allowed home on the same or following day and are warned that they may experience otalgia as a result of referred pain from the glossopharyngeal nerve and that secondary haemorrhage may occur up to 10 days following the surgery.

Haemorrhage is the most common complication in the immediate postoperative period. Local pressure may help in mild cases, but reactionary haemorrhage usually requires return to theatre for definitive treatment, particularly in

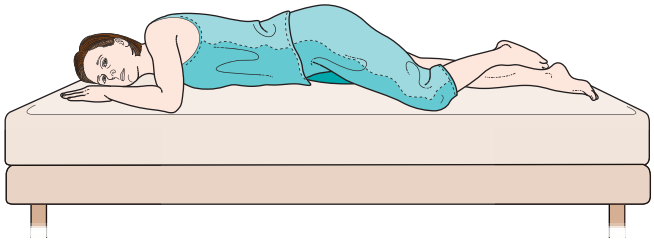

Figure 52.28 Positioning of the patient after tonsillectomy.

younger patients. Under general anaesthesia, it may be possible to identify a bleeding spot, but often a more generalised ooze is observed and suturing of the tonsil bed combined with the application of haemostatic gauze and bipolar diathermy is often more successful than attempted placement of ligatures.

Late haemorrhage is sometimes secondary to infection and patients are usually started on broad-spectrum intravenous antibiotics. Any residual clot in the tonsil fossa should be removed and regular gargling with a dilute solution of hydrogen peroxide may be beneficial. Significant or persistent bleeding may require a further general anaesthetic and haemostasis, which may require diathermy and/or undersewing of the granulating, sloughy tonsil fossa. Postoperative tonsillar haemorrhage is still a serious and life-threatening complication and should not be underestimated, particularly in the younger patient.

Summary box 52.6

Complications of tonsillectomy

- Haemorrhage (immediate or late)
- Infection
- Pain/otalgia
- Postoperative airway obstruction
- Velopharyngeal insufficiency
- Injury to oral cavity and oropharyngeal structures

Parapharyngeal abscess

Parapharyngeal abscess may be confused with a peritonsillar abscess, but the maximal swelling is behind the posterior faucial pillar and there may be little or no oedema of the soft palate. The patient is usually a young child and there may be a severe general malaise and obvious neck swelling. A large parapharyngeal abscess may compromise both the airway and swallowing. MRI or CT scanning of the head and neck is often an invaluable aid to diagnosis and management as it allows assessment of the extent of the abscess and facilitates planning of the optimal surgical approach. In early cases, admission to hospital and the institution of fluid replacements coupled with intravenous antibiotics may produce resolution. However, when a collection is evident, transcervical drainage is required under general anaesthesia, which usually requires the expertise of a senior anaesthetist. In instances where an obvious abscess points into the oropharynx, drainage may be carried out with a blunt instrument (*Figure 52.29*).

Acute retropharyngeal abscess

This is the result of suppuration of the retropharyngeal lymph nodes and, again, is most commonly seen in children, with most cases occurring under the age of 1 year. It is associated with infection of the upper aerodigestive tract and is frequently accompanied by severe general malaise, neck rigidity, dysphagia, drooling, a croupy cough, an altered cry and marked dyspnoea.

Dyspnoea may be the prominent symptom and may also be accompanied by febrile convulsions and vomiting. These children should always be carefully examined by the most senior clinicians available. Inspection of the posterior wall of the pharynx may show gross swelling and an abscess pointing beneath the thinned mucosa.

In countries where diphtheria still occurs, an acute retropharyngeal abscess may be confused with this, but the presence of the greyish-green membrane aids differentiation. Occasionally, a foreign body, most commonly a fish bone that has perforated the posterior pharyngeal mucosa, will give rise to a retropharyngeal abscess in older children and young adults. Intravenous antibiotics are commenced immediately but surgical drainage of the abscess is often necessary. It requires an experienced anaesthetist because, on induction, care must be taken to avoid rupturing the abscess. The airway is protected by placing the child in a head-down position while a pair of dressing forceps, guided by the finger, may be thrust into an obvious abscess in the posterior wall and the contents evacuated. On other occasions, an approach anterior and medial to the carotid sheath via a cervical incision may be preferable.

Chronic retropharyngeal abscess

This condition is now rare and is most commonly the result of an extension of tuberculosis (TB) of the cervical spine, which has spread through the anterior longitudinal ligament to reach the prevertebral space. In addition to the pharyngeal

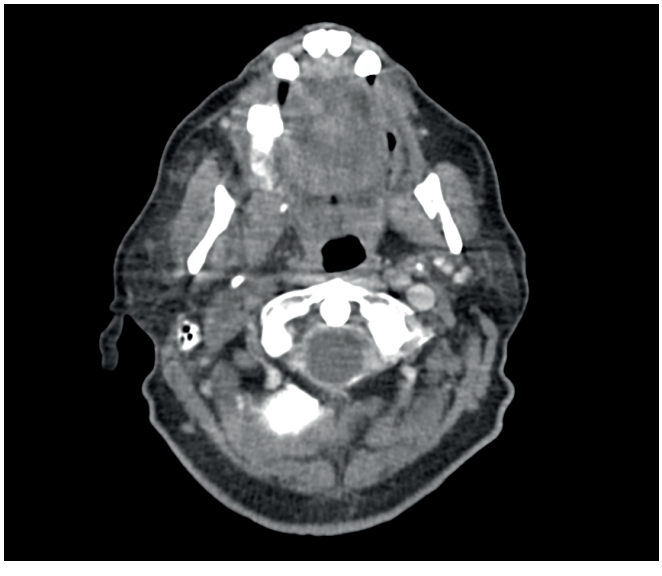

Figure 52.29 Axial computed tomography scan of the neck demonstrating right parapharyngeal abscess.

Figure 52.30 Infectious mononucleosis.

swelling seen intraorally, there may be fullness behind the sternocleidomastoid muscle on one side. In contrast to an acute retropharyngeal abscess, this condition occurs almost solely in adults. Radiology usually shows evidence of bone destruction and loss of the normal curvature of the cervical spine. The spine may be quite unstable and undue manipulation may precipitate a neurological event.

In contrast to an acute abscess, a chronic retropharyngeal abscess must not be opened into the mouth, as such a procedure may lead to secondary infection. Drainage of the abscess may not be necessary if suitable treatment of the underlying TB disease is instituted. If it is necessary, drainage should be carried out through a cervical incision anterior to the sternocleidomastoid muscle with an approach anterior and medial to the carotid sheath to enter the retropharyngeal space. The cavity is opened and suctioned dry after taking biopsy material. Occasionally, surgery is required to decompress or stabilise the spinal cord if there is a progressive neurological deficit.

Glandular fever (infectious mononucleosis)

This systemic condition is usually caused by EBV, but similar features can be caused by cytomegalovirus or toxoplasmosis. The tonsils are typically erythematous with a creamy grey exudate and appear almost confluent, usually symmetrical (***Figure 52.30***). In addition to the discomfort and dysphagia, patients may drool saliva and have respiratory difficulty, particularly on inspiration. They commonly have a high temperature and gross general malaise with marked cervical or generalised lymphadenopathy. Occasionally, an enlarged spleen or liver may be detected. The condition is most frequent in teenagers and young adults. The diagnosis can be confirmed by serological testing for EBV, which has now commonly replaced Paul–Bunnell testing, an absolute and relative lymphocytosis, and the presence of atypical monocytes in the peripheral blood.

Treatment

Analgesia and maintenance of fluid intake are important. A small number of patients require admission to hospital if the airway is compromised or if oral intake of fluids is not possible, and a short course of steroids may be helpful. Antibiotics are of little value and ampicillin is contraindicated because of the frequent appearance of a widespread skin rash. Rarely, if the airway is severely compromised, an elective tracheostomy under local anaesthesia is safer and less traumatic than an emergency intubation. Emergency tonsillectomy is contraindicated because of the generalised pharyngeal oedema and compromised airway.

Human immunodeficiency virus (HIV)

Acquired immunodeficiency syndrome (AIDS) can affect the ear, nose and throat (ENT) system at any point during the disease. The initial seroconversion may present with the symptoms of glandular fever; this is followed by an asymptomatic period of variable length. In the pre-AIDS period, before the full-blown symptoms of the AIDS-related complex, many patients have minor upper respiratory tract symptoms that are often overlooked, such as otitis externa, rhinosinusitis and a non-specific pharyngitis. As the patient moves into the full-blown AIDS-related complex, a persistent, generalised lymphadenopathy is frequently found affecting the cervical nodes, which is usually due to follicular hyperplasia. However, patients may also develop tumours such as Kaposi's sarcoma, sometimes seen in the oral cavity, and high-grade malignant B-cell lymphoma affecting the cervical lymph nodes and nasopharynx. In addition, multiple ulcers may be found in the oral cavity or pharynx associated with herpesvirus infection. Severe *Candida* may affect the oral cavity, pharynx, oesophagus or even larynx, and a hairy leukoplakia may affect the tongue (***Figure 52.31***).

Figure 52.31 Intraoral view showing a hairy tongue in a human immunodeficiency virus-positive patient.

John Rodman Paul, 1893–1971, Professor of Preventative Medicine, Yale University, New Haven, CT, USA.
Walls Willard Bunnell, 1902–1966, American physician. Paul and Bunnell described this test in 1932.
Moritz Kaposi, 1837–1902, Professor of Dermatology, Vienna, Austria, described pigmented sarcoma of the skin in 1872.

The globus syndrome

A wide variety of patients experience the feeling of a lump in the throat (from the Latin *globus* = lump). The symptom most commonly affects adults between 30 and 60 years of age. This feeling is not true dysphagia as there is no difficulty in swallowing. Most patients notice the symptom more if they swallow their own saliva (i.e. a forced, dry swallow) rather than when they eat or drink.

The aetiology of this common symptom is unknown, but some patients may have gastro-oesophageal reflux or spasm of their cricopharyngeus muscle. Radiological and endoscopic investigation may be necessary to exclude an underlying cause and/or for patient reassurance.

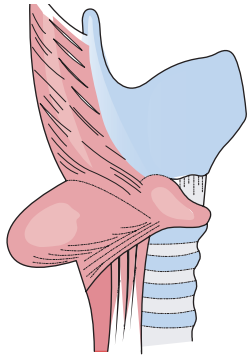

Figure 52.32 A pharyngeal pouch.

Pharyngeal pouch

A pharyngeal pouch is a protrusion of mucosa though Killian's dehiscence, a weak area of the posterior pharyngeal wall between the oblique fibres of the thyropharyngeus and the transverse fibres of cricopharyngeus at the lower end of the inferior constrictor muscle (***Figure 52.32***). These fibres, along with the circular fibres of the upper oesophagus, form the physiological upper oesophageal sphincter mechanism. Videofluoroscopic and manometric studies have been unable to elucidate the cause of the pouch. Many patients with pharyngeal pouches have been demonstrated to have normal relaxation of the upper oesophageal sphincter mechanism in relation to swallowing, but others have been shown to have incomplete pharyngeal relaxation, early cricopharyngeal contraction and abnormalities of the pharyngeal contraction wave. When enlarged, the pouch almost invariably deviates to the left side of the neck.

Figure 52.33 Pharyngeal pouch on barium swallow.

Clinical features

Patients with this condition are commonly more than 60 years of age and it is more common in men than in women. As the diverticulum enlarges, patients may experience regurgitation of undigested food, sometimes hours after a meal, particularly if they are bending down or turning over in bed at night. They sometimes wake at night with a feeling of tightness in the throat and a fit of coughing. Occasionally, they may present with recurrent, unexplained chest infections as a result of aspiration of the contents of the pouch. As the pouch increases in size, patients may notice gurgling noises from the neck on swallowing and the pouch may become large enough to form a visible swelling in the neck. Dysphagia may also be a presenting symptom.

Radiological examination

A thin emulsion of barium is given to the patient as a barium swallow (***Figure 52.33***) or ideally as part of a videofluoroscopic swallowing study. Care should be exercised in patients who cough on swallowing, indicating they may have aspiration. A small volume of barium is sufficient to outline the pharynx, pouch and upper oesophagus. The videofluoroscopic study gives additional information about the pharyngeal contraction waves and the performance of the upper oesophageal sphincter.

Treatment

Surgery is indicated when the pouch is associated with progressive symptoms and particularly when a prominent cricopharyngeal bar of muscle is associated with abnormality of the upper oesophageal sphincter mechanism and causes considerable dysphagia. In elderly patients, a decision to operate may be influenced by their general condition. However, surgical intervention is mandated in all but the most poorly patients as, in most cases, it is the pouch that is contributing significantly to the underlying debilitation. Of particular importance is the risk of recurrent pneumonia from aspiration and overspill of pouch contents, as well as increasing dysphagia as the pouch opening becomes larger than the oesophageal opening and the enlarged pouch exerts extramural pressure on the oesophagus. Accordingly, preoperative chest physiotherapy and attention to the respiratory, cardiovascular and nutritional aspects of the patient are important.

Gustav Killian, 1860–1921, Professor of Laryngology at Freiburg, and later at Berlin, Germany.

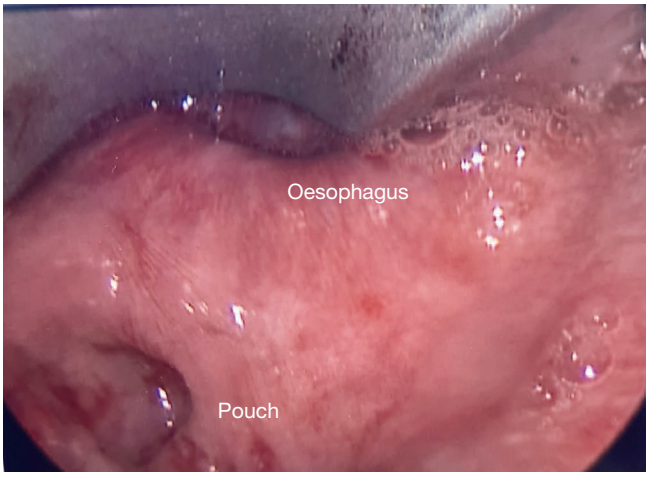

Figure 52.34 Endoscopic view of a pharyngeal pouch.

The surgical technique typically used is endoscopic stapling of the diverticular wall. A double-bladed rigid endoscope (diverticuloscope) is passed, with one blade in the diverticulum and one blade positioned in the oesophagus (***Figure 52.34***). Opening of the bivalve scope reveals the pathognomonic 'bar' formed by the cricopharyngeus muscle and overlying mucosa, which forms the boundary between the posterior wall of the oesophagus and the anterior wall of the pouch. At this stage the pouch should be emptied of food content and the mucosa should be inspected for the rare occurrence of carcinoma in the pouch. An endoscopic linear stapler is then introduced to sit astride the 'bar'. One jaw of the stapler is placed in the oesophagus, the other in the pouch. The stapler is fired, dividing the wall separating the two. The process should be repeated until the bottom of the pouch is reached. This has the effect of opening the pouch, incorporating it as part of the oesophageal wall and dividing the cricopharyngeus muscle. If the patient is symptom free after the procedure, they may start graded oral intake and be discharged early. Division of the 'bar' using a carbon dioxide laser, as an alternative to stapling, is gaining popularity in some centres. Flexible endoscopic division of the cricopharyngeal bar is a new technique popularised over the last decade, with equally good results, and can be used in patients who have poor access with rigid endoscopes.

In instances where endoscopic access is difficult or for very large pouches, an open excision of the pouch becomes necessary. In the classic external operation, the opening to the pouch is first identified using a pharyngoscope and a nasogastric tube placed into the oesophageal lumen for postoperative nutrition. This initial endoscopy is often difficult because the normal oesophageal opening is small compared with the lumen of the pouch, but it may be better visualised using a Dohlman's rigid endoscope. The pouch may be packed with ribbon gauze to further aid identification of its neck.

A lower neck incision along the anterior border of the left sternocleidomastoid muscle, or a transverse crease incision, is used and the muscle and carotid sheath are retracted laterally and the trachea and larynx medially. The pouch is found medially behind the lower pharynx and is carefully isolated and dissected back to its origin at Killian's dehiscence. It is then excised and the pharynx closed in two layers or, if it is small, the pouch may be invaginated into the pharyngeal lumen before closing the muscle layers. Care must be taken to protect the recurrent laryngeal nerve during the procedure. In all cases, a myotomy dividing the fibres of the cricopharyngeus muscle and the upper oesophageal circular muscle fibres must be performed. The wound is usually closed with drainage and the patient fed through a nasogastric tube for 3–7 days. A water-based swallow test is performed on day 5 to ascertain that there is no leak prior to commencing oral feeds.

The average operating time with an endoscopic procedure is 20–30 minutes compared with 60–90 minutes with an external procedure. Inpatient stay is also decreased for patients undergoing an endoscopic procedure. The endoscopic technique is associated with a high symptomatic success rate and a low morbidity, which is particularly important in the elderly.

Complications

The classic operation has been associated with wound infection, mediastinitis, pharyngeal fistula formation, recurrent laryngeal nerve palsy and stenosis of the upper oesophagus. Endoscopic division is associated with the same risks but at much lower rates. The recurrence rates between the two procedures appears to be equal; longer term follow-up will establish this. Endoscopic stapling will also allow for safe reoperation if necessary. It must be noted that contrast swallows will demonstrate the pouch in patients who have undergone stapling and are an inappropriate modality to evaluate recurrences.

Sideropenic dysphagia

Prolonged iron deficiency anaemia may lead to dysphagia, particularly in middle-aged women. In addition, they may have koilonychia, cheilosis and angular stomatitis together with lassitude and poor exercise tolerance. The dysphagia is caused by a postcricoid or upper oesophageal web and these patients have a higher incidence of postcricoid malignancy. The syndrome is associated with the names of Plummer and Vinson, Paterson and Brown Kelly.

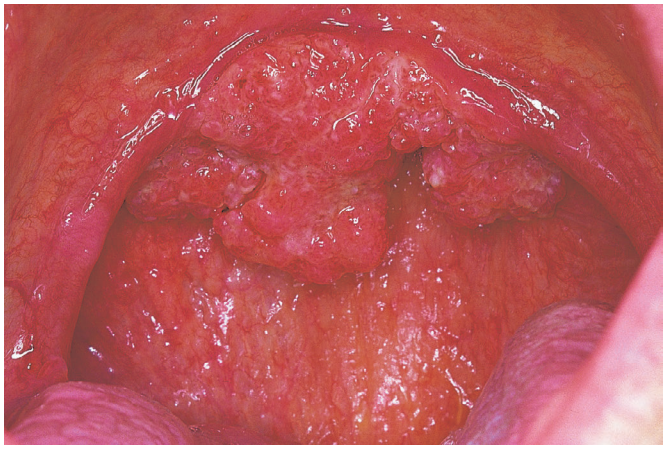
Tumours of the oropharynx

Benign

Benign tumours of the oropharynx are rare, papillomas being the most common. These are usually incidental findings and are rarely of any importance.

Gösta Dohlman, 1890–1983, Swedish physician and professor.
Henry Stanley Plummer, 1874–1937, physician, The Mayo Clinic, Rochester, MN, USA, described this syndrome in 1912.
Porter Paisley Vinson, 1890–1959, physician, The Mayo Clinic, Rochester, MN, who later practised in Richmond, VA, USA.
Donald Rose Paterson, 1863–1939, surgeon, The Ear, Nose and Throat Department, The Royal Infirmary, Cardiff, UK.
Adam Brown Kelly, 1865–1941, surgeon, The Ear, Nose and Throat Department, The Royal Victoria Infirmary, Glasgow, UK. Vinson, Paterson and Kelly all described this syndrome independently in 1919.

Figure 52.35 Squamous cell carcinoma of the right tonsil.



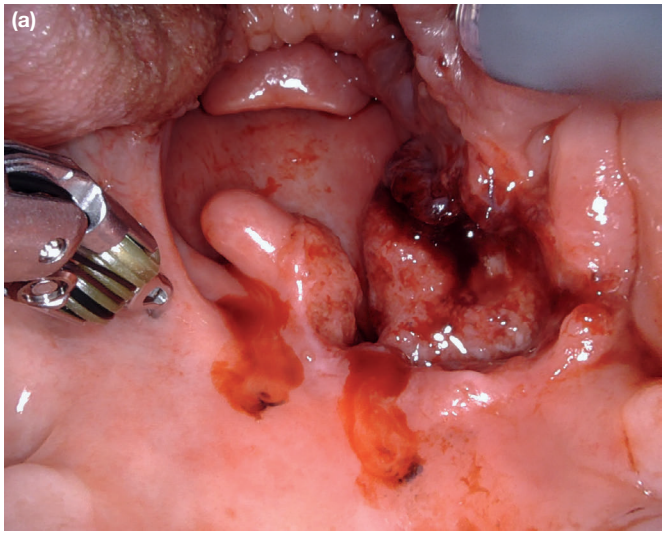


Figure 52.36 Squamous cell carcinoma of the soft palate.

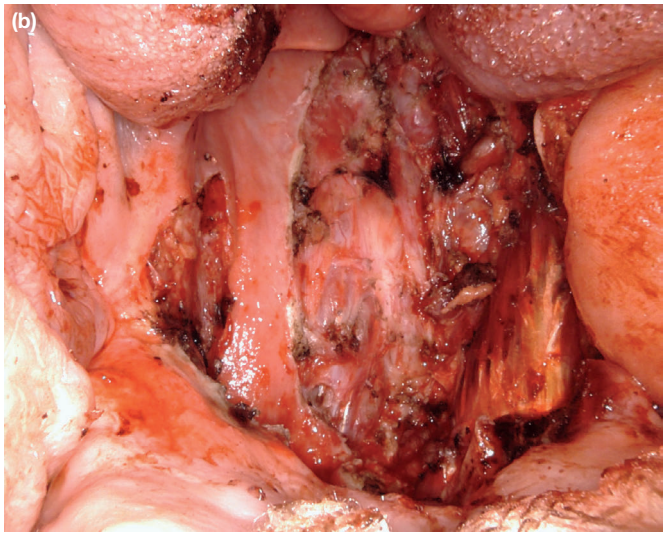

Figure 52.37 (a) Recurrent cancer of the soft palate and tonsil set up for transoral robotic resection. (b) Completed resection of the cancer. Note prevertebral fascia that is now continuous with the parapharyngeal fat.

Malignant

The most important epithelial tumour is squamous cell carcinoma, which constitutes approximately 90% of all epithelial tumours in the upper aerodigestive tract (***Figures 52.35 and 52.36***). In the oropharynx, the proportion is less (70%) because of the higher incidence of lymphoma (25%) and salivary gland tumours (5%). Because of the rich lymphatic drainage of the oropharynx, cervical node metastases are common. They may be the only presenting feature with a primary pharyngeal tumour often being unsuspected and missed in the tonsil or tongue base.

Aetiology

While it has been long established that oropharyngeal squamous cell carcinoma (OPSCC) is strongly associated with cigarette smoking and consumption of alcohol, over recent decades there has been a near epidemic increase in HPV-associated OPSCC (HPV+OPSCC) in the resource-rich world, with prevalences of up to 70% being commonly reported in the USA, UK and northern Europe. That HPV+OPSCC constitutes a separate disease entity is undoubted, as these patients are typically younger with less or no history of alcohol and tobacco use. The presenting features of HPV+OPSCC include multiple large cystic cervical lymph nodes with a small primary; these are usually associated with better outcomes after treatment.

Treatment

Treatment varies with facilities around the world, but early-stage tumours may be cured by transoral laser surgery, transoral robotic surgery or radiotherapy. Intermediate- or late-stage disease is usually managed with concurrent chemoradiotherapy or based on institutional choices, with open surgery and reconstruction using myocutaneous pedicles or free flaps. Recurrent disease following radiotherapy with/without chemotherapy is a surgical challenge; smaller tumours can be treated by transoral robotic surgery (***Figure 52.37***), but larger recurrences require open surgery and reconstruction. Neck dissection is required in most cases where surgery is the

primary treatment modality and is also required for patients who have only partially responded following chemoradiotherapy. Postoperative dysphagia with aspiration as a result of interference in the complex neuromuscular control of the second phase of swallowing is a particular problem in these patients. The advent of HPV+OPSCC has created a clinical need to define novel de-intensified treatments that maintain current advantageous survival rates while reducing the late morbidity of treatment. Management of such tumours should be multidisciplinary and is best carried out at tertiary centres undertaking this work on a regular basis.

Lymphoma of the head and neck

Lymphomas of the head and neck may arise in nodal or extranodal sites and both Hodgkin's disease and non-Hodgkin's lymphoma commonly present as lymph node enlargement in the neck. Hodgkin's disease is rare in the oropharynx, but non-Hodgkin's lymphoma accounts for 15–20% of tumours at this site in some countries. Most are of the B-cell type and have features in common with other MALT tumours. Further evaluation with CT scanning of the thorax and abdomen and bone marrow evaluation are essential. Core biopsy, or, often, excision biopsy to improve tissue yield, is frequently required to establish a firm diagnosis and aid in the classification of lymphomas.

Radiotherapy is the treatment of choice for localised non-Hodgkin's lymphoma; for widespread non-Hodgkin's lymphoma, systemic treatment is needed.

HYPOPHARYNX

Tumours of the hypopharynx

Benign

Benign tumours of the hypopharynx are very rare, the most common being the fibroma and the leiomyoma. They show a smooth, submucosal mass lying in the lumen of the hypopharynx or oesophagus.

Malignant

Malignant tumours of the hypopharynx are almost exclusively squamous cell carcinomas and typically behave aggressively. The tumours are usually classified according to their probable anatomical site of origin from the piriform fossa, postcricoid region or posterior pharyngeal wall. Marked differences in the incidence of these tumours occur globally because of factors such as iron deficiency anaemia (see ***Sideropenic dysphagia***). They may be associated with marked submucosal spread, which further complicates evaluation. Tumours arising from the piriform fossa and posterior pharyngeal wall may spread to upper or lower cervical nodes. Tumours arising in the postcricoid area typically metastasise to paratracheal and paraoesophageal nodes, which may not be palpable. As with other non-HPV head and neck cancers, alcohol and tobacco are two principal carcinogens. Postcricoid carcinoma, though rare, is more common in women than in men.

The diagnosis of hypopharyngeal carcinoma should be considered in all patients presenting with dysphagia, hoarseness or referred otalgia, particularly if they have a history of smoking or significant alcohol consumption.

Fibreoptic endoscopic examination in the clinic may show only subtle signs such as oedema or pooling of saliva unilaterally in the piriform fossa. Note should also be made that this region is not well seen on flexible gastroscopy. The preferred investigation is with direct rigid pharyngoscopy and oesophagoscopy with biopsy under a general anaesthetic. All regions of the neck must be assessed in a systematic manner. Fine-needle aspiration is advocated for suspicious nodes.

Radiological examination

As for other head and neck cancers, a suspected primary tumour requires an MRI or CT scan of the neck together with a CT scan of the thorax and upper abdomen.

Treatment

Squamous cell carcinoma of the hypopharynx commonly presents late and carries a poor prognosis. Early lesions may be treated with radiotherapy or transoral robotic or transoral laser microsurgical resection and a neck dissection plus postoperative radiotherapy. Non-surgical strategies, designed to preserve function, rely on chemoradiotherapy. Major open excisional surgery is generally used for recurrence after radiotherapy or as primary excision in advanced disease. Total laryngectomy and either partial or total pharyngectomy followed by pharyngeal reconstruction involving myocutaneous or free flap reconstruction (e.g. jejunum or anterolateral thigh) or gastric transposition is commonly required (***Figure 52.38***). Swallowing and voice

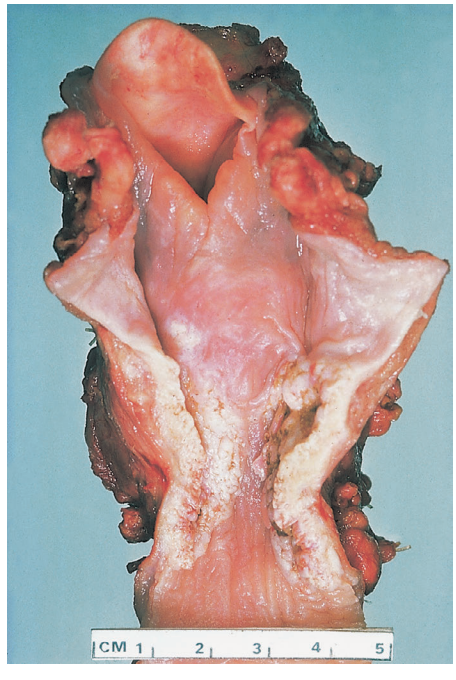

Figure 52.38 Total pharyngolaryngectomy specimen showing hypopharyngeal carcinoma (hypopharynx opened from the posterior aspect of the resection).

Thomas Hodgkin, 1798–1866, Curator of the Museum and Demonstrator of Morbid Anatomy, Guy's Hospital, London, UK, described lymphadenoma in 1832.

rehabilitation are necessary to support patients after this major surgery if they are to adjust and maintain some quality of life.

Summary box 52.7

Tumours of the hypopharynx

- Variable symptoms – discomfort, pain, dysphagia, hoarseness
- Incidence increased by history of smoking and alcohol
- Expert examination with nasendoscopy
- Late presentation
- Referral to multidisciplinary team for detailed assessment and treatment – radiotherapy with/without chemotherapy, transoral or open surgery

DISEASES OF THE LARYNX

EMERGENCIES

Stridor

Stridor means noisy breathing. It may be inspiratory or expiratory or occur in both phases of respiration. Inspiratory stridor is usually due to an obstruction at or above the vocal folds and is most commonly the result of an inhaled foreign body or acute infections such as epiglottitis. Expiratory stridor is usually from the lower respiratory tract and gives rise to a prolonged expiratory wheeze. It is most commonly associated with acute asthma or acute infective tracheobronchitis. Biphasic stridor is usually due to obstruction or disease of the tracheobronchial airway and distal lungs.

Summary box 52.8

Stridor

- Inspiratory
  - Foreign body or epiglottitis
- Expiratory
  - Acute asthma or infective tracheobronchitis
- Biphasic
  - Obstruction, disease of tracheobronchial airway or distal lungs

Stridor in children

Infants and children presenting with stridor need careful assessment with a full history and examination as appropriate. If, on presentation, a child is cyanosed and severely unwell, the airway must be secured as soon as possible, but a brief history with important pointers can often be obtained from the parents.

History

In infants in the first year of life, it is important to establish if the stridor is associated with particular activities such as swallowing, crying or movement. These may suggest congenital laryngomalacia or subglottic stenosis. If the stridor is exacerbated by feeding, particularly in the first 4 weeks of life, this suggests a vascular ring compressing the oesophagus or tracheo-oesophageal fistula. If the cry is weak or abnormal, this suggests a vocal fold palsy. If the problem only occurs in association with an upper respiratory tract infection and, in particular, is biphasic, this suggests congenital subglottic stenosis. In a young child, inspiratory stridor and drooling suggest acute epiglottitis, whereas biphasic stridor without drooling suggests laryngotracheobronchitis or croup.

Examination

It is important, when possible, to observe the child carefully at rest. Once a baby starts to cry, it may be impossible to study its resting respiratory pattern for some time. Ask the mother, not a nurse or a colleague, to move a baby or young child into different positions, such as face down and supine, and watch for changes in respiratory pattern and level of distress. Observe any drooling and, with neonates and infants, always try to watch the child being fed, listening to the trachea and chest with a stethoscope if possible. Always examine the whole child, looking for any evidence of congenital abnormalities before attempting any examination of the throat.

Summary box 52.9

Acute paediatric stridor

Congenital

- Laryngomalacia
- Laryngeal web
- Subglottic stenosis

Acquired

- Inflammatory
  - Angioneurotic oedema
- Traumatic
  - Impacted foreign body, laryngeal fracture
- Infective
  - Epiglottitis, laryngotracheobronchitis
- Neurological
  - Vocal fold palsy
- Neoplasia
  - Benign laryngeal papillomatosis

If a child is stridulous and drooling, do not attempt to lay them down and do not attempt to look inside the mouth. These manoeuvres are potentially life-threatening as the child may aspirate a large quantity of thick saliva contained within the oral cavity. It is particularly important in acute epiglottitis as the aspiration of thick saliva may be associated with further laryngeal spasm and a respiratory arrest. Restlessness, increasing tachycardia and cyanosis are important signs of hypoxia. If the child is not distressed and drooling, and not markedly stridulous, they may be cooperative enough that it is possible to look inside the mouth and check the palate, tongue and

oropharynx. In stridulous children, particularly neonates and infants, a transcutaneous oximeter is invaluable. A resuscitation trolley with the necessary equipment for emergency intubation or tracheostomy should be close at hand before commencing examination.

Investigation

Plain lateral radiographs of the neck and a chest radiograph can be obtained but only if the child's condition permits. If a child is severely stridulous, they should not be sent to a radiography department without access to medical staff or resuscitation equipment.

Examination under anaesthesia is essential in all children whose diagnosis remains in doubt. This requires a high level of anaesthetic and surgical skill, with appropriate selection of rigid laryngoscopes, bronchoscopes and telescopes. Equipment for an urgent tracheostomy should also be readily available at all times.

Acute epiglottitis

In children acute epiglottitis is of rapid onset. It tends to occur in children of 2 years of age and over. Stridor is usually associated with drooling of saliva. The condition is caused by *Haemophilus influenzae* infection, which initially causes a severe pharyngitis that extends to involve the laryngeal inlet, causing inflammation and oedema. Further progression involves the whole of the supraglottic larynx, with severe oedema of the aryepiglottic folds and epiglottis being the most notable component, hence the commonly used term 'acute epiglottitis'.

These children frequently require intensive management with emergency intubation or tracheostomy followed by oxygenation, humidification, continuous oximetry and antibiotics. There may be associated septicaemia, so blood cultures should be obtained. Attempted examination with a spatula into the mouth may precipitate a respiratory arrest and should be avoided. The incidence of acute epiglottitis has plummeted where *H. influenzae* vaccination programmes are in place.

Laryngotracheobronchitis (croup)

Croup is usually of slower onset than acute epiglottitis and occurs most commonly in children under 2 years of age. It is usually viral in origin and the cases often occur in clusters. The children have biphasic stridor and are often hoarse with a typical barking cough. Airway intervention is required less often, but admission to hospital with oxygenation and humidification, coupled with antibiotics, may be necessary if there are signs of secondary infection.

Foreign bodies

Both children and adults may inhale foreign bodies. Young children will attempt to swallow a wide variety of objects, but coins, beads and parts of toys are particularly common. In adults, the aspiration is usually food, particularly inadequately chewed bones and meat. This is more common in elderly edentulous adults. Occasionally, portions of dentures may be inhaled, particularly in association with road traffic accidents.

Clinical features

The history is paramount and a history of foreign body ingestion or inhalation in a child, even though the pain, dysphagia, coughing, etc. may have settled, should always be taken seriously.

Adults usually have a clear recall, which facilitates diagnosis. Fish bones may lodge in the tonsils or base of tongue with minimal symptoms, but small fish bones may give rise to delayed para- and retropharyngeal abscess formation.

Examination

Examination may be prevented by trismus, pain and anxiety, but the presence of a foreign body may be suspected by salivary pooling within the piriform fossa or adjacent oedema and erythema of the pharyngolaryngeal mucosa.

Radiology

Radiology may be helpful but is not critical. Fish bones are often invisible on plain radiographs and a normal plain radiograph does not exclude a foreign body within the pharynx, larynx, oesophagus or lungs.

Specialised studies may help in cases of doubt, using a CT scan or a contrast swallow in the case of a suspected oesophageal foreign body.

Treatment

In the case of an inhaled foreign body causing severe stridor in a neonate or infant, it may be removed either by hooking it from the pharynx with a finger or by inverting the child carefully by the ankles and slapping their back. In a larger child, it may be more appropriate to bend the child over your knee with the child's head hanging down and again strike the child firmly between the shoulders. In the case of adults, an impacted laryngeal foreign body may be coughed out using abdominal thrusts (often referred to as a Heimlich manoeuvre). This involves standing behind the patient, clasping the arms around the lower thorax, such that the knuckles of the clasped hands come into contact with the patient's xiphisternum, and then a brief, firm compression of the lower thorax may aid instant expiration of the foreign body. If none of these immediate emergency measures removes the foreign body and the patient is cyanosed and severely stridulous, an immediate cricothyroidotomy or tracheostomy may be necessary. In less urgent cases, and when a foreign body is strongly suspected, endoscopy under general anaesthesia may be indicated.

Other causes of acute pharyngolaryngeal oedema

Angioneurotic oedema, radiotherapy and laryngeal trauma associated with road traffic accidents, corrosives, scalds and smoke ingestion may all cause significant pharyngolaryngeal oedema, in addition to the acute infective conditions

Henry Jay Heimlich, 1920–2016, thoracic surgeon, Xavier University, Cincinnati, OH, USA.

mentioned above. Hoarseness is the predominant symptom along with dysphagia prior to the increase in dyspnoea. If flexible laryngoscopic examination is possible, marked oedema of the supraglottis and pharynx can be seen. Humidified oxygen, adrenaline (epinephrine) nebulisers, systemic antihistamines and steroids may be valuable. Opioids should not be given as they may cause respiratory depression and respiratory arrest. If the dyspnoea progresses, intubation or tracheostomy will be necessary.

TRACHEOSTOMY AND OTHER EMERGENCY AIRWAY MEASURES

This procedure relieves airway obstruction or protects the airway by fashioning a direct entrance into the trachea through the skin of the neck. Tracheostomy may be carried out as an emergency for acute airway obstruction when the larynx cannot be intubated, but it is not always an easy procedure, particularly in an obese patient. An easier alternative for the inexperienced is insertion of a large intravenous cannula or a small tube into the cricothyroid membrane, which lies in the midline immediately below the thyroid cartilage. The time to do a tracheostomy is when you first think it may be necessary.

If time allows, the following should be undertaken:

- inspection and palpation of the neck to assess the laryngotracheal anatomy in the individual patient;
- indirect or direct laryngoscopy;
- assessment of pulmonary function by auscultation.

Whenever possible, the procedure should be adequately explained to the patient beforehand, with particular emphasis on the inability to speak immediately following the operation. Ample reassurance is required that they will not have 'lost' their voice permanently. The indications for tracheostomy are shown in ***Summary box 52.10***.

Within the theatre or intensive care setting, the 'can't intubate, can't oxygenate' situation occurs after attempts to secure the airway by a facemask, a supraglottic airway device and an endotracheal tube have failed. Only a narrow window exists to avoid profound hypoxia and its consequences and local protocols should be agreed upon to manage these situations beforehand using appropriate emergency front of neck access options (cricothyroidotomy or tracheostomy).

Emergency tracheostomy

If a skilled anaesthetist is unavailable, local anaesthesia is employed, but in desperate cases when the patient is unconscious, none is required. In patients who have suffered severe head and neck trauma and who may have an unstable cervical spine fracture, cricothyroidotomy may be more suitable. If it is possible, the patient should be laid supine with padding placed under the shoulders and the extended neck kept as steady as possible in the midline. This aids palpation of the thyroid and cricoid cartilage between the thumb and index finger of the free hand. The movements of the fingers of the free hand are important in this technique. The operation is more difficult in small children and thick-necked adults as the landmarks are difficult to palpate (***Figures 52.39 and 52.40***).

Summary box 52.10

Indications for tracheostomy

- Acute upper airway obstruction
  - For example, an inhaled foreign body, a large pharyngolaryngeal tumour or acute pharyngolaryngeal infections in children
- Potential upper airway obstruction
  - For example, after or prior to major surgery involving the oral cavity, pharynx, larynx or neck
- Protection of the lower airway
  - For example, protection against aspiration of saliva in unconscious patients as a consequence of head injuries, maxillofacial injuries, comas, bulbar poliomyelitis or tetanus
- Patients requiring prolonged artificial respiration
  - Best performed within 10 days of ventilation

A vertical midline incision is made from the inferior aspect of the thyroid cartilage to the suprasternal notch and continued down between the infrahyoid muscles. There may be heavy bleeding from the wound at this point, particularly if the neck is congested as a result of the patient's efforts to breathe around an acute upper airway obstruction. No steps should be taken to control this haemorrhage, although an assistant and suction are valuable. The operator should feel carefully for the cricoid cartilage using the index finger of the free hand while retracting the skin edges by pressure applied by the thumb and middle finger. If the situation is one of extreme urgency, a further vertical incision straight into the trachea at the level of the second, third and fourth rings should be made immediately without regard to the presence of the thyroid isthmus. The knife blade is rotated through 90°, thus opening the trachea. At this point the patient may cough violently as blood enters the airway. The operator should be aware of this possibility and avoid losing the position of the scalpel in the open trachea. Any form of available tube should be inserted into the trachea as soon as possible and blood and secretion sucked out. Once an airway has been established, haemostasis is then secured. With the emergency under control, the tracheostomy should be refashioned as soon as possible.

Should additional equipment and more time be available once the cricoid cartilage has been identified, blunt finger dissection inferiorly can be used to mobilise the thyroid isthmus, which should be clipped and divided, clearing the trachea before making a vertical incision through the second to the fourth rings. A tracheal dilator is inserted through the tracheal incision and the edges of the tracheal wound are separated gently. This is likely to induce coughing and so, particularly in cases where there is a suspected infection risk, as far as possible care should be taken to minimise the risk of contaminating the operator(s). A tracheostomy tube is inserted into the trachea and the dilator removed. It is important that the surgeon/assistant keeps a finger on the tube while it is secured with sutures to the neck skin. Additional securing of the tube is achieved by means of tapes attached to the flange of the device passed behind the neck and secured to the opposite side with the neck in a neutral position.

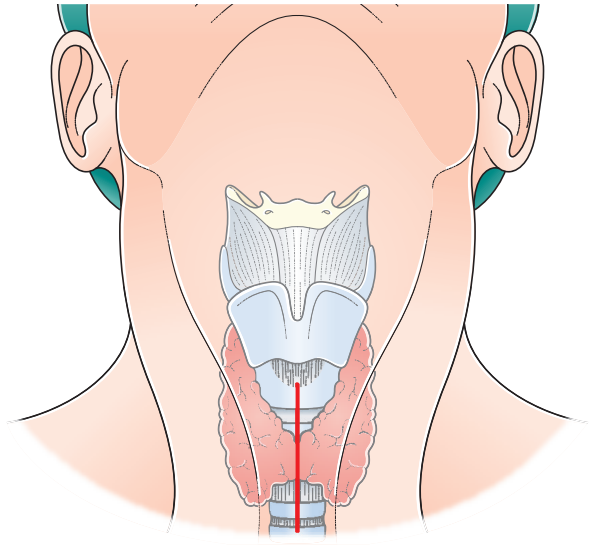

Figure 52.39 Position of the skin incision in an emergency tracheostomy.

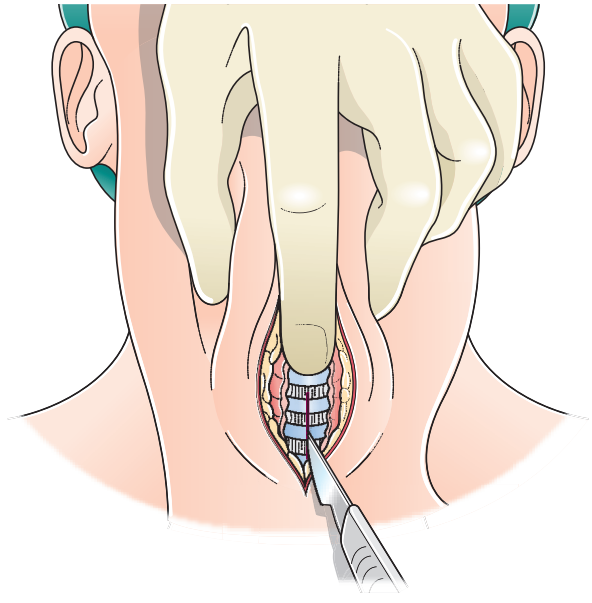

Figure 52.40 An incision in the trachea in an emergency tracheostomy.

Elective tracheostomy

The advantage of an elective surgical procedure is that there is complete airway control at all times, unhurried dissection and careful placement of an appropriate tube. Close cooperation between the surgeon, anaesthetist and scrub nurse is essential, and attention to detail will markedly reduce possible complications and morbidity from the procedure.

Following induction of general anaesthesia and endotracheal intubation, the patient is positioned with a combination of head extension and placement of an appropriate sandbag under the shoulders (***Figure 52.41***). There should be no rotation of the head. Children's heads should not be overextended, as it is possible to enter the trachea in the fifth and sixth rings in these circumstances. A transverse incision may be used in the elective situation (***Figure 52.42***). The thyroid isthmus is divided carefully and oversewn and tension sutures placed either side of the tracheal fenestration in children (***Figure 52.43***). A Bjork flap may be used in adults (***Figures 52.44 and 52.45***).

The advantages of a Bjork flap outweigh the potential disadvantages, as performed correctly it is safe and allows reintroduction of a displaced tube with the minimum of difficulty, reducing the risk of replacing the displaced tube in a false track anterior to the trachea into the superior mediastinum. Although not routinely used, this is described here for completion.

The inferiorly based flap is created by starting with an incision into the trachea between the first and second or second and third tracheal rings. In order to reduce the risk of subglottic stenosis, damage to the first tracheal ring should be avoided at all costs. A stay suture is inserted around the cartilage at the free edge of the flap. Lateral incisions are made in a caudal direction extending through two tracheal rings to create the flap. One option is to leave the stay suture attached and taped to the chest wall to allow retraction of the flap to obliterate the pretracheal space when replacing a displaced tube. An alternative is to suture the free edge of the flap to the edge of the inferior transverse skin incision.

In a paediatric patient a vertical incision is made between the second and third tracheal rings. No tracheal tissue is removed. A cuff of anterior neck subcutaneous fat pad may be removed in children for adequate access. Prior to incision of the trachea, vertical stay sutures are placed lateral to the midline through the tracheal rings and left in place. These can provide traction for the trachea and allow for rapid tracheostomy tube reinsertion if accidental decannulation occurs prior to the establishment of the tract. Some surgeons will suture skin flaps to the trachea for additional safety (maturation sutures). It is essential to stick to the midline during dissection as more lateral dissection risks a pneumothorax, as the cupula of the cervical pleura extends into the neck on either side of the trachea.

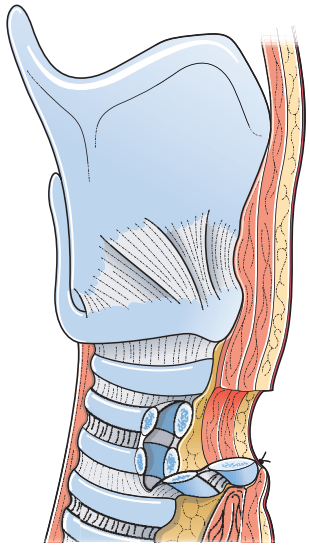

Figure 52.44 Bjork flap.

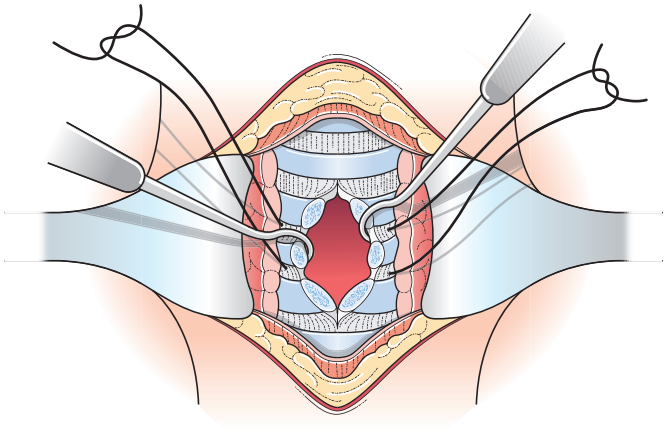

Figure 52.43 Tracheal fenestration in an elective tracheostomy.

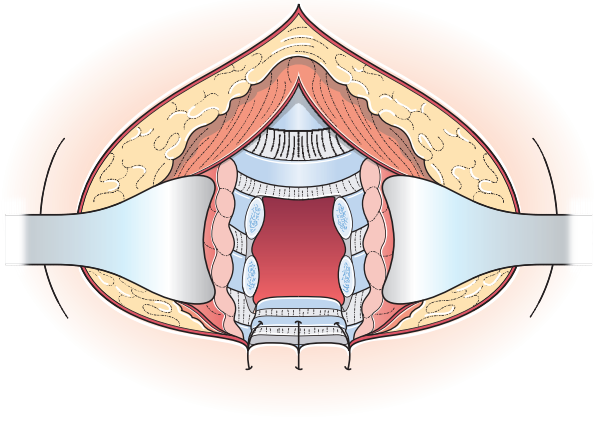

Figure 52.45 Fenestration in a Bjork flap.

Percutaneous tracheostomy

As an alternative to open tracheostomy, a percutaneous tracheostomy is commonly performed in the critical care setting in an intubated patient. A transverse skin incision is made at the level of the first and second tracheal rings; blunt dissection of the midline is then performed. A 22-gauge needle is inserted between the second and third tracheal rings. When air is aspirated into the syringe, the guidewire is introduced. Sequentially larger dilators are then inserted over the guidewire to create a suitable-sized tracheostome. Finally, the tracheotomy tube is introduced along the guidewire and dilator. The guidewire and dilator are removed, the cuff of the tracheotomy tube is inflated and the breathing circuit is connected. The endotracheal tube can then be removed.

Patients must have appropriate anatomy and no limitation of neck movement. If any doubt arises as to the suitability of a patient for percutaneous tracheostomy, a surgical approach should be adopted. Percutaneous tracheostomy is rarely performed in children.

Tracheostomy tubes

Most modern tracheostomy tubes are made of plastic (***Figure 52.46***). Tubes of various sizes with varying curves, angles, cuffs, inner tubes and speaking valves are available. After a newly fashioned tracheostomy is created, a cuffed tube is used initially to protect the airway from secretions or bleeding. This may be changed after 3–4 days to a non-cuffed tube. The pressure within the tube cuff should be carefully monitored and should be low enough so as not to occlude circulation in the mucosal capillaries, which promotes scar tissue formation and subglottic stenosis. When in position, the tube should be retained by double tapes threaded through the flanges and passed around the patient's neck. It is important that the patient's head is flexed when the tapes are tied, otherwise they may become slack when the patient is moved from the position of extension, thereby resulting in a possible displacement of the tube if the patient coughs. Alternatively, the flanges of the plastic tube may be stitched directly to the underlying neck skin. A removable inner tube, which is easily cleaned, should

Figure 52.46 Modern plastic tracheostomy tube with the introducer, low-pressure cuff and inner cannula.

always be used to prevent lumen occlusion by thickened, dried secretions from the trachea.

All forms of tracheostomy and cricothyroidotomy bypass the upper airway and have the following advantages:

- the anatomical dead space is reduced by approximately 50%;
- the work of breathing is reduced;
- alveolar ventilation is increased;
- the level of sedation needed for patient comfort is decreased and, unlike endotracheal intubation, the patient may be able to talk and eat with a tube in place.

However, there are several disadvantages:

- loss of heat and moisture exchange in the upper respiratory tract;
- desiccation of tracheal epithelium, loss of ciliated cells and metaplasia;
- the presence of a foreign body in the trachea stimulates production of mucus; where no cilia are present, the mucociliary stream is therefore impeded;
- the increased mucus is more viscid and thick crusts may form and block the tube;
- although many patients with a tracheostomy can feed satisfactorily, there is some splinting of the larynx, which may prevent normal swallowing and lead to aspiration; this aspiration may be silent.

Postoperative treatment is designed to counteract these effects and frequent suction and humidification are most important. A trolley must be placed by the bed containing a tracheal dilator, duplicate tubes and introducers, retractors and dressings. Oxygen is at hand and, in the initial period, a nurse must be in constant attendance. Humidification will render the secretions less viscid and a sucker with a catheter attached should be on hand to keep the tracheobronchial tree free from secretions.

Summary box 52.11

Tracheostomy: postoperative management

- Suction – efficient, sterile and as often as required
- Humidification (with or without oxygen)
- A warm, well-ventilated room
- Position of the tube and patient
- Spare tube, introducer, tapes, tracheal dilator
- Change of tube, inner tube, possible speaking valve
- Physiotherapy
- Initiation of local decannulation protocols where indicated

Complications of tracheostomy

The intraoperative, early and late postoperative complications of tracheostomy are listed in ***Table 52.2***.

TABLE 52.2 Tracheostomy: complications.

Intraoperative complications	• Haemorrhage • Injury to paratracheal structures, particularly the carotid artery, recurrent laryngeal nerve and oesophagus • Damage to the trachea
Early postoperative complications	• Apnoea caused by a fall in the PCO_2 • Haemorrhage • Subcutaneous emphysema, pneumomediastinum and pneumothorax • Accidental extubation, anterior displacement of the tube, obstruction of the tube lumen and tip occlusion against the tracheal wall • Infection • Swallowing dysfunction
Late postoperative complications	• Difficult decannulation • Tracheocutaneous fistula • Tracheo-oesophageal fistula, tracheoinnominate artery fistula with severe haemorrhage • Tracheal stenosis

PCO_2, partial pressure of carbon dioxide.

OTHER EMERGENCY AIRWAY PROCEDURES

Fibreoptic endotracheal intubation

In most emergency situations, endotracheal intubation is the most direct and satisfactory method of securing the airway. Nasotracheal 'awake' intubation in expert hands is also a well-established technique and is particularly useful if the patient has trismus, severe mandibular injuries, cervical spine rigidity or an obstructing mass within the oral cavity or lower down in the upper aerodigestive tract. This is facilitated by passing a fibreoptic endoscope through the centre of an endotracheal tube, hence guiding it into the larynx and trachea under direct vision.

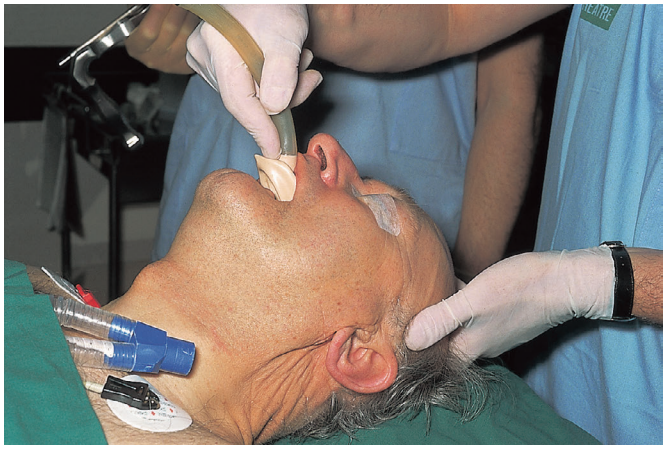

Figure 52.47 A laryngeal mask airway being inserted.

Laryngeal mask airway

The laryngeal mask airway (LMA) is a wide-bore airway with an inflatable cuff at the distal end, which forms a seal in the pharynx around the laryngeal inlet. Provided the laryngotracheal airway is clear, the LMA provides a clear and secure airway. The technique can easily be learnt by non-anaesthetists and secures an airway in most cases. It comes in a range of sizes covering infants to large adults. It is particularly useful in cases of difficult intubation where mouth opening is unimpeded (***Figure 52.47***). A newer variation of this is the i-gel® device, which replaces the inflatable cuff with a rim that conforms to the anatomical shape around the laryngeal inlet.

Transtracheal ventilation

This technique is simple and effective and allows ventilation for periods in excess of 1 hour, providing time to allow for more elective intubation. The cricothyroid membrane is located as discussed above, and a 14- or 16-gauge plastic sheathed intravascular needle attached to a 10-mL syringe containing a few millilitres of lidocaine is introduced in the midline and directed downwards and backwards into the tracheal lumen. The needle is advanced steadily and negative pressure is placed on the syringe until bubbles of air are clearly seen (***Figure 52.48***). The tissues of the neck may be infiltrated with the anaesthetic if desired and the tracheal mucosa likewise partly anaesthetised by the introduction of 1–2 mL of lidocaine after gaining the lumen. The needle is removed and the plastic sheath cannula left in the tracheal lumen; it must be carefully held and fixed in place by the operator so that it does not come out of the lumen into the soft tissues of the neck. It is attached by means of a Luer connection to the high-pressure oxygen supply. Ventilation may be undertaken in a controlled manner with a jetting device, with the chest being observed for appropriate movements.

If there is severe obstruction of the laryngopharynx by the foreign body or tumour, the exhaled outflow of gases can be aided by the placement of one or two further cannulae as exhalation ports. This procedure gains extremely rapid control of ventilation and requires a minimum of technical expertise. Its only notable complication is surgical emphysema of the neck tissues if the cannula dislodges from the tracheal lumen.

Cricothyroidotomy

Cricothyroidotomy has the advantages of speed and ease, requiring minimal equipment and surgical expertise, and has great value in the emergency setting when conditions are not optimal to perform a tracheostomy.

Cricothyroidotomy is performed through the cricothyroid membrane, which is a fibroelastic condensation connecting the thyroid cartilage to the cricoid cartilage. The cricothyroid artery and vein, the pyramidal lobe of the thyroid gland and lymph nodes may overlie the membrane. The membrane should be identified precisely before undertaking the procedure to avoid injury to adjacent structures; the patient's neck is extended and the area between the prominence of the thyroid cartilage and the cricoid cartilage below is palpated with the index finger of the free hand and, if necessary, the 'laryngeal handshake technique' can be used to define the membrane (***Figure 52.49***).

Cricothyroidotomy can be performed using the scalpel or cannulae. The scalpel–bougie tube technique is the fastest and most reliable method of securing the airway; a number 10 blade, a bougie and a 6-mm cuffed endotracheal tube are needed to perform this, with the patient receiving 100% oxygen and full neuromuscular blockade. A vertical skin incision is recommended with dissection rapidly carried down to the cricothyroid membrane. A 1-cm transverse incision is made through the membrane immediately above the cricoid cartilage and the scalpel twisted through a right angle to gain access to the airway. If available, an artery forceps, bougie, dilator or tracheal hook will improve the aperture and insertion of an

Laryngeal handshake technique in locating the cricothyroid membrane: a non-randomised comparative study. *Br J Anaesth* 2018; **121**(5): P1173–8.)

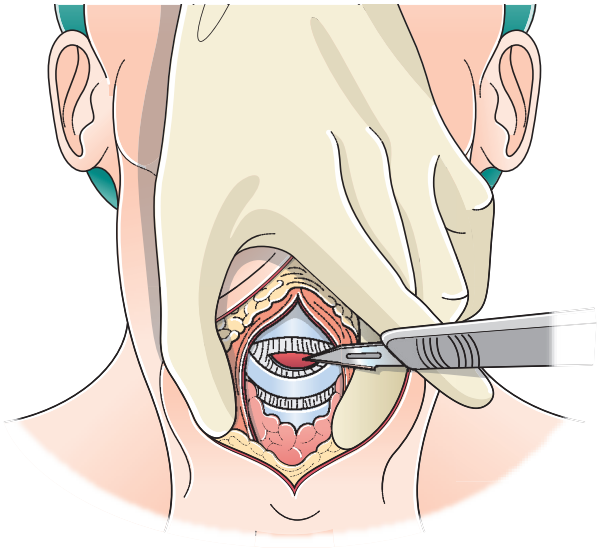

Figure 52.50 Incision in a cricothyroidotomy.

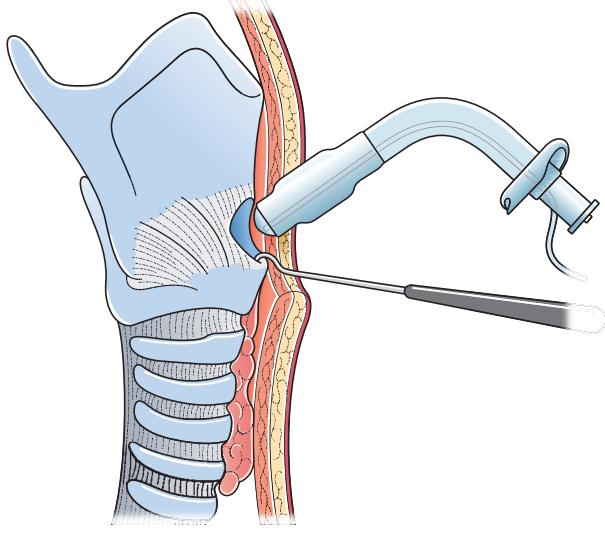

Figure 52.51 Insertion of a tube after cricothyroidotomy.

available tube (***Figures 52.50 and 52.51***). The endotracheal tube allows ventilation using conventional low-pressure equipment. Cannula cricothyroidotomy can be performed with a narrow-bore (internal diameter ≤2 mm) or wide-bore (internal diameter ≥4 mm) cannula to facilitate oxygenation. Specialist equipment is available for this, but both techniques are associated with kinking of the cannula and complications, such as device displacement and barotrauma.

As soon as practicably possible, the cricothyroidotomy should be converted to a tracheostomy. Although there is debate about the frequency of subglottic stenosis following this procedure, there is general agreement that it is much increased if any long-term ventilation is undertaken via even a modestly size tracheostomy tube through the cricothyroid membrane.

LARYNGEAL DISEASE CAUSING VOICE DISORDERS

Vocal nodules

These are fibrous thickenings of the vocal folds at the junction of the middle and anterior thirds (***Figure 52.52***) and result from vocal abuse; they are known as singers' nodules in adults and screamers' nodules in children. Speech therapy is therefore the preferred treatment and the lesions will resolve spontaneously in most cases. Occasionally, the nodules will need to be surgically removed using modern microlaryngoscopic dissection or laser techniques, but speech therapy will still be required for postoperative voice rehabilitation.

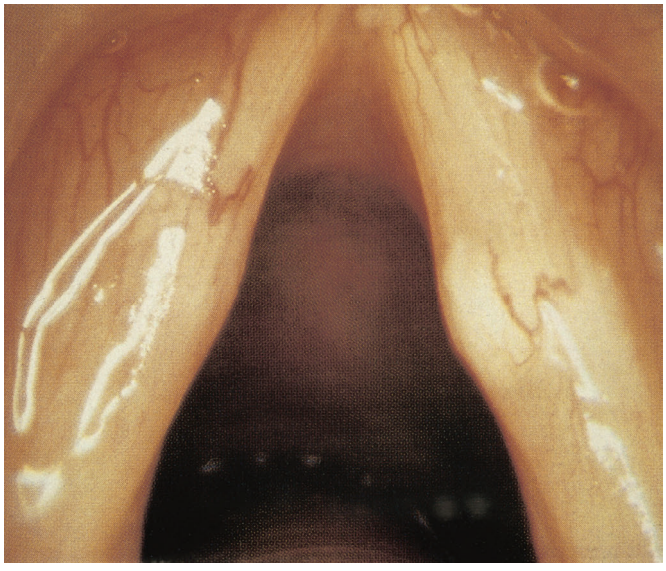

Figure 52.52 Vocal fold nodules.

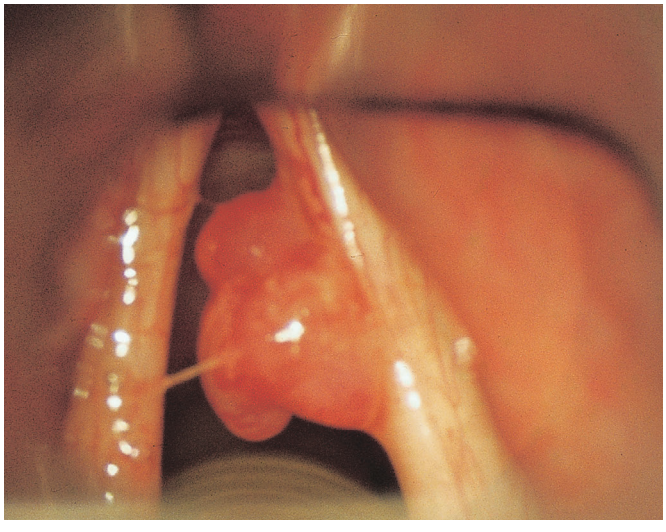

Figure 52.53 A vocal fold polyp.

Vocal fold polyps

These are usually unilateral and may be associated with an acute infective episode, cigarette smoking or vocal abuse (***Figure 52.53***). Speech therapy is again indicated, but they do usually require removal by microdissection or laser surgery.

Summary box 52.12

Causes of hoarseness

- Mucosal disease (e.g. vocal nodule, polyps or laryngeal papillomatosis, acute or chronic laryngitis)
- Neurological disease (e.g. vocal fold palsy)
- Neoplasia (e.g. laryngeal tumours)
- Non-specific voice disorders, functional dysphonia

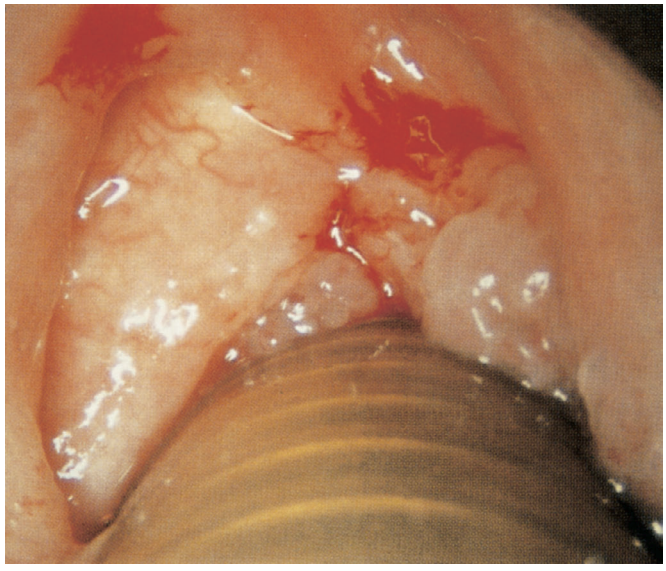

Figure 52.54 Laryngeal papillomas.

Laryngeal papillomata

These are rare benign tumours occurring mainly in children but can also present in adults. They are most commonly found on the vocal folds but may spread throughout the larynx and tracheobronchial airway (although this is less likely in adults) (***Figure 52.54***). They are caused by papillomaviruses (most frequently HPV 6 and 11) and need repeated removal usually by laser microsurgery or microdebrider to maintain a reasonable voice and airway. These patients are best managed in specialist centres, with the appropriate expertise. The evidence to date is mixed with regard to antiviral use, and existing data are insufficient to support the regular use of antiviral agents such as cidofovir in the management of laryngeal papillomatosis. Vaccination against papilloma has shown some therapeutic benefit in reducing the recurrence of the disease. There is a greater appreciation of the role that gastro-oesophageal reflux may play in this setting and many centres opt to place patients on proton pump inhibitors or H_2 blockers.

Acute laryngitis

This often occurs as part of an upper respiratory tract infection in association with a cough and pharyngitis. Usually viral, it may be localised to the larynx and it settles quickly if the voice is rested during the acute inflammation. Steam inhalations are soothing along with mild analgesia, but antibiotics are unnecessary.

Summary box 52.13

Warning

- Hoarseness lasting for 3–4 weeks should always be referred for an ENT opinion

Chronic laryngitis

Chronic laryngitis may be specific and can be caused by mycobacteria, syphilis and fungi. Treatment is directed towards the causative organism. Non-specific laryngitis is common, the main predisposing factors being smoking, chronic upper and lower respiratory sepsis and voice abuse. Gastro-oesophageal reflux has been implicated as a factor in laryngitis, vocal fold nodules and polyps, but the evidence is controversial. However, antireflux medication and proton pump inhibitors are commonly prescribed. Diagnosis of chronic laryngitis should not be made unless the larynx has been fully evaluated by a laryngologist.

Vocal fold palsy

This may be unilateral or bilateral (***Figure 52.55***). Unilateral cord palsy is most commonly idiopathic. In non-idiopathic cases, left vocal fold palsy is most common because of the long intrathoracic course of the left recurrent laryngeal nerve, which arches around the aorta and may be commonly involved in inflammatory and neoplastic conditions involving the left hilum or lung apex. Lung cancer should be considered the cause of a left vocal fold palsy until proved otherwise.

Tumours of the nasopharynx, larynx, thyroid gland or oesophagus may also cause vocal fold palsy. Bilateral vocal fold paralysis is uncommon and tends to occur after thyroid surgery or head injuries.

Summary box 52.14

Causes of vocal fold palsy

Congenital (infants)

Acquired

- Traumatic
  - Direct to neck
  - Post surgery (e.g. thyroidectomy)
- Infective
  - Viral (rare)
- Neoplastic
  - Carcinoma of the lung involving the left hilum
  - Carcinoma of the nasopharynx, larynx, thyroid and oesophagus
- Vascular
  - Aortic aneurysm
- Neurological
  - Lower motor neurone disease

Clinical features

Unilateral recurrent laryngeal nerve palsy of sudden onset produces hoarseness, difficulty in swallowing liquids and a weakened cough. These symptoms may be short-lived and the voice may return to normal within a few weeks as the muscles in the opposite vocal fold compensate and move it across the midline to meet the paralysed vocal fold, which usually lies in the paramedian position. Bilateral recurrent laryngeal nerve palsy is an occasional and serious complication of total thyroidectomy. On anaesthetic reversal, acute dyspnoea occurs as a result of the paramedian position of both vocal folds, which reduce the airway to 2–3 mm and which tend to get sucked together on inspiration. This can be temporarily relieved by positive pressure mask ventilation, but, in severe cases, tracheostomy or intubation is necessary immediately, otherwise death occurs from asphyxia.

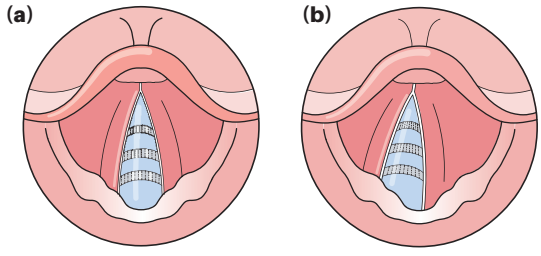

Figure 52.55 Vocal fold positions: **(a)** normal; **(b)** unilateral vocal fold palsy.

Investigation of vocal fold paralysis is by a CT scan from the skull base (including posterior fossa) to the diaphragm. Approximately 20–25% of vocal fold paralysis occurs without known pathology and spontaneous recovery may occur. When compensation does not occur, a unilateral paralysed fold may be medialised by injection or external thyroplasty.

In bilateral vocal fold palsy, surgery may be carried out to divide the posterior aspect of one vocal fold (cordotomy) or a portion of one arytenoid cartilage (arytenoidectomy). These procedures are most easily performed endoscopically with a carbon dioxide laser. They increase the size of the posterior glottic airway, allowing the patient to be decannulated or even avoid an initial tracheostomy.

Tumours of the larynx

Benign tumours of the larynx are extremely rare. Squamous cell carcinoma is the most common malignant tumour, being responsible for more than 90% of tumours within the larynx. It is the second most common head and neck cancer (oral cavity is more common) and previously usually occurred in elderly male smokers. However, over the past decades, the incidence among women has risen because of increased smoking. The incidence of laryngeal cancer in the three subsites – supraglottis, glottis and subglottis – varies around the world.

Clinical features

Patients typically present with voice change. Other symptoms include dysphagia, odynophagia and neck lumps. Advanced tumours can present with airway compromise, usually as inspiratory stridor (***Figure 52.56***).

Investigations

Direct laryngoscopy, followed by a general anaesthetic assessment, together with angled (30° and 70°) Hopkins' rod examination, allows precise determination of the extent of the tumour and biopsy confirms the histology. CT and MRI give further details of the extent of larger tumours, demonstrating

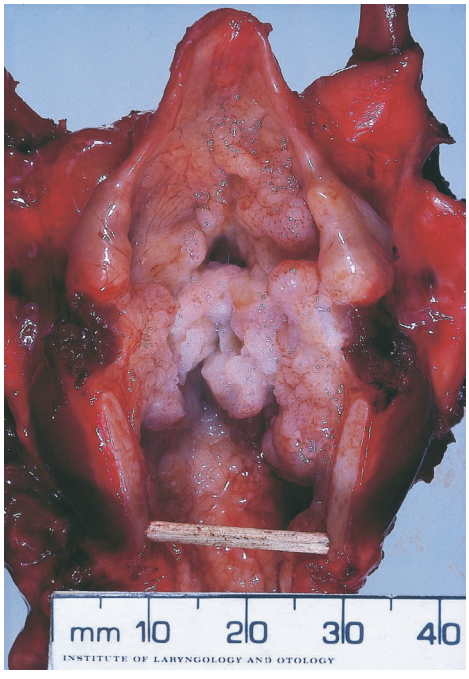

Figure 52.56 A total laryngectomy specimen with a transglottic tumour.

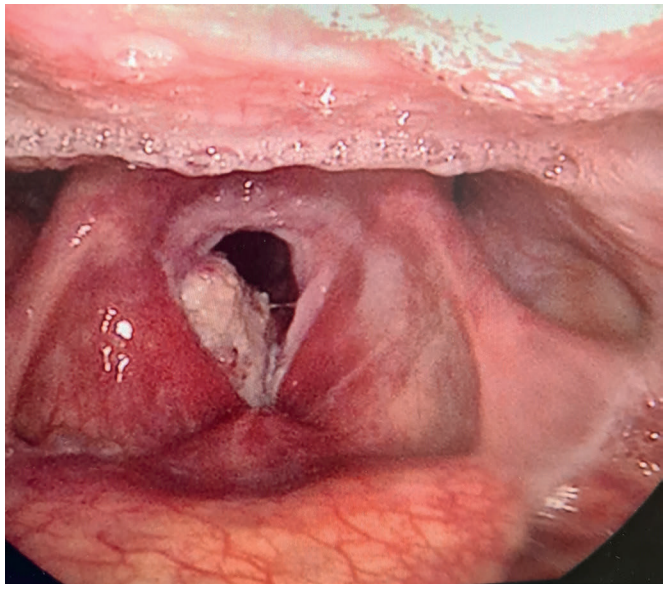

Figure 52.57 Flexible nasendoscopy demonstrating a laryngeal tumour seen involving the entire length of the right vocal fold.

spread outside the larynx and suspicious nodal involvement within the neck, which may not be obvious clinically.

Treatment

Early laryngeal cancer (T1 and T2)

Early-stage supraglottic and glottic tumours can be treated with a single modality: radiotherapy or endoscopic surgical resection, with the aim of preservation of function. Although both modalities are associated with similar survival rates (approximately 95% local control), transoral laser resection is commonly used as it usually involves day case surgery and more therapeutic options are available for the small number of patients who have local recurrence (***Figure 52.57***).

Advanced laryngeal cancer (T3 and T4)

Organ preservation should be a priority when treating locally advanced cancer without extralaryngeal spread and/or laryngeal dysfunction. The non-surgical standard of care is concurrent chemoradiotherapy; while a variety of open partial laryngectomy procedures are also available, these are best undertaken in specialist centres.

Laryngeal cancer with gross extralaryngeal extension is usually best treated with total laryngectomy and adjuvant post-operative radiotherapy or chemoradiotherapy (***Figure 52.56***).

After the larynx has been removed, the remaining trachea is brought out onto the lower neck as a permanent tracheal stoma and the hypopharynx, which is opened at the time of the operation, is closed to restore continuity for swallowing (***Figure 52.58***). Thus, the upper aero- and digestive tracts are permanently disconnected. Part or all of the thyroid gland and associated parathyroid glands may also be removed, depending on the extent of the disease.

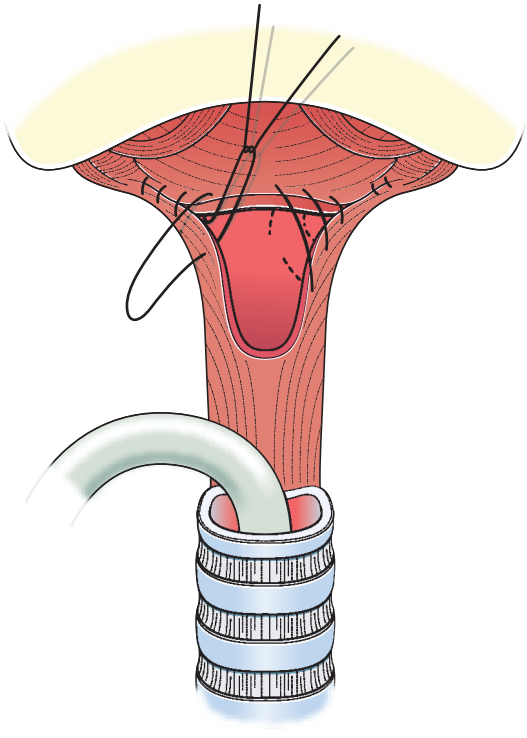

Figure 52.58 Transverse closure of the pharynx with an endotracheal tube in the end tracheostome.

Voice rehabilitation

The loss of the larynx as a generator of sound does not prevent patients speaking as long as an alternative source of sound can be created by vibration in the pharynx. This can be achieved in one of three ways:

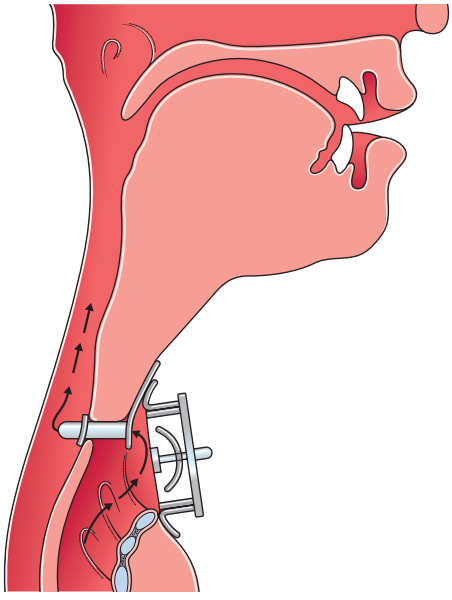

Figure 52.59 A Blom–Singer valve within a surgically fashioned tracheo-oesophageal fistula and an outer stoma valve.

Figure 52.61 Electrolarynx.

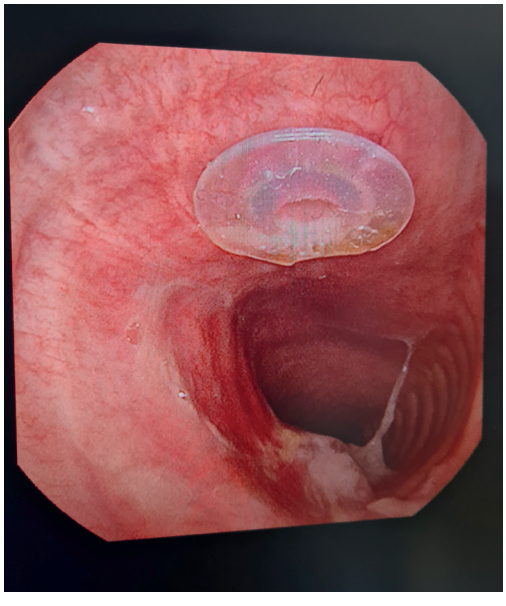

Figure 52.60 Provox voice valve prosthesis viewed in rear wall of trachea.

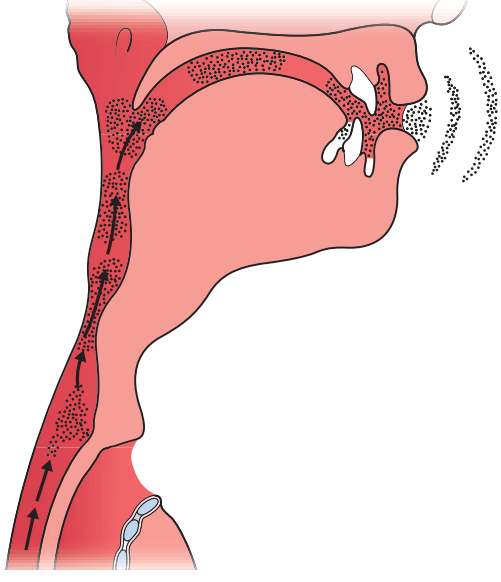

Figure 52.62 Production of oesophageal speech.

1 A small one-way valve may be inserted through the back wall of the tracheal stoma into the pharynx (***Figure 52.59***). This allows air from the trachea to pass into the pharynx, but does not allow food and liquid to pass into the airway. These valves must not be confused with tracheostomy tubes. Like all foreign bodies, the speaking valves are associated with minor complications, such as the formation of granulations, bleeding or leakage of pharyngeal contents, and have an ongoing financial cost because of the need for regular replacement (***Figure 52.60***).

2 An external battery-powered vibrating device that when applied to the soft tissues of the neck produces sound, which is turned into speech by the vocal tract comprising the tongue, pharynx, oral cavity, lips, teeth and nasal sinuses (***Figure 52.61***).

3 Oesophageal speech, when air is swallowed into the pharynx and upper oesophagus. On regurgitating the air, a segment of the pharyngo-oesophageal mucosa vibrates to produce sound, which is modified by the vocal tract into speech (***Figure 52.62***).

DISEASES OF THE NECK

LUMP IN THE NECK

On presentation, a careful history and examination are essential. The clinical signs of size, site, shape, consistency, fixation to skin or deep structures, pulsation, compressibility, transillumination or the presence of a bruit must be established and recorded.

Branchial cyst

A branchial cyst (***Figure 52.63***) develops from the vestigial remnants of the second branchial cleft, is lined by squamous epithelium and contains thick, turbid fluid. The cyst usually presents in the upper neck in early or middle adulthood and is found at the junction of the upper third and middle third of the sternomastoid muscle at its anterior border. It is a fluctuant swelling that may transilluminate and is often soft in its early stages so that it may be difficult to palpate.

Summary box 52.15

Diagnosis of a lump in the neck

- History
- Physical signs
  - Size
  - Site
  - Shape
  - Surface
  - Consistency
  - Fixation: deep/superficial
  - Pulsatility
  - Compressibility
  - Transillumination
  - Bruit

If the cyst becomes infected, it becomes erythematous and tender and the differential diagnosis is broadened. Ultrasound and fine-needle aspiration both aid diagnosis and treatment is by complete excision, which is best undertaken when the lesion is quiescent. It passes superficial to the hypoglossal and glossopharyngeal nerves, but deep to the posterior belly of the digastric. These structures and the spinal accessory nerve must be positively identified to avoid damage. In patients over 35 years of age, a high index of suspicion for a necrotic metastatic lymph node should exist and malignancy should be excluded before excision.

Branchial fistula

A branchial fistula (***Figure 52.64***) may be unilateral or bilateral and is thought to represent a persistent second branchial cleft. The external orifice is nearly always situated in the lower third of the neck near the anterior border of the sternocleidomastoid muscle, while the internal orifice is located on the anterior aspect of the posterior faucial pillar just behind the tonsil. Although the anterior aspect of the tract is easy to dissect, it may pass backwards and upwards through the bifurcation of the common carotid artery as far as the pharyngeal constrictors. The internal aspect of the tract may, however, end blindly at or close to the lateral pharyngeal wall, constituting a sinus rather than a fistula. The tract is lined by ciliated columnar epithelium and, as such, there may be a small amount of recurrent mucopurulent discharge onto the neck. The tract follows the same path as a branchial cyst and requires complete excision to avoid recurrence.

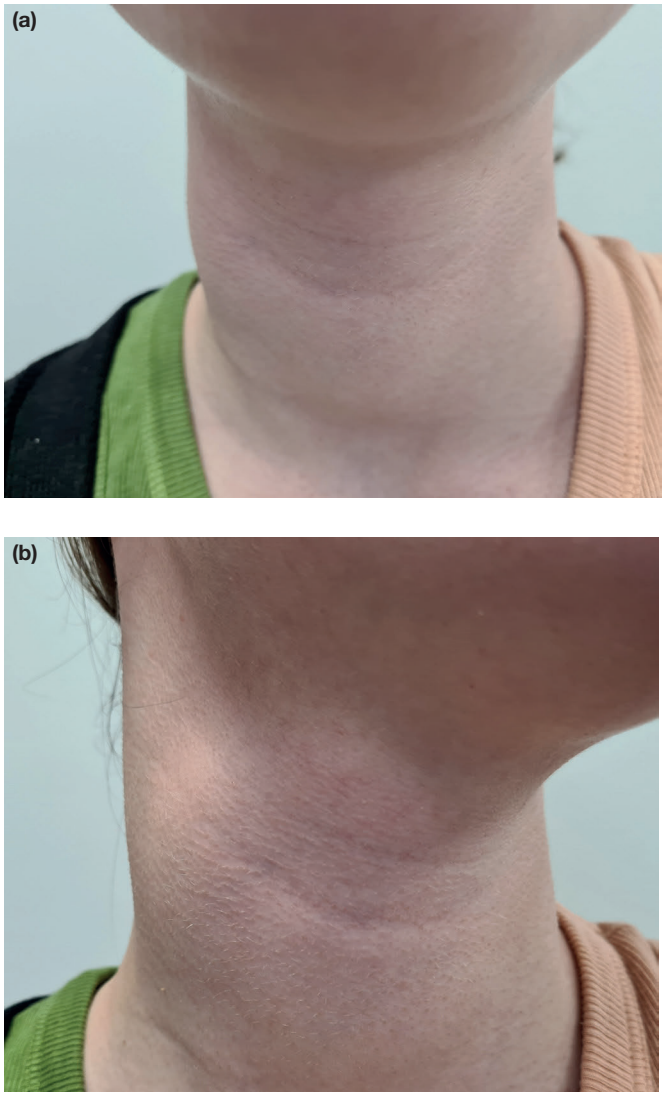

Figure 52.63 Right branchial cyst: anterior **(a)** and oblique **(b)** views.

Cystic hygroma

Cystic hygromas (***Figure 52.65***) usually present in the neonate or in early infancy, and occasionally may present at birth and be so large as to obstruct labour. The cysts are filled with clear lymph and lined by a single layer of epithelium with a mosaic appearance. Swelling usually occurs in the neck and may involve the face, submandibular region, tongue and floor of the mouth. The swelling may be bilateral and is soft and partially compressible, visibly increasing in size when the child coughs or cries. The characteristic that distinguishes it from all other neck swellings is that it is brilliantly transilluminant. The cheek, axilla, groin and mediastinum are other less frequent sites for a cystic hygroma.

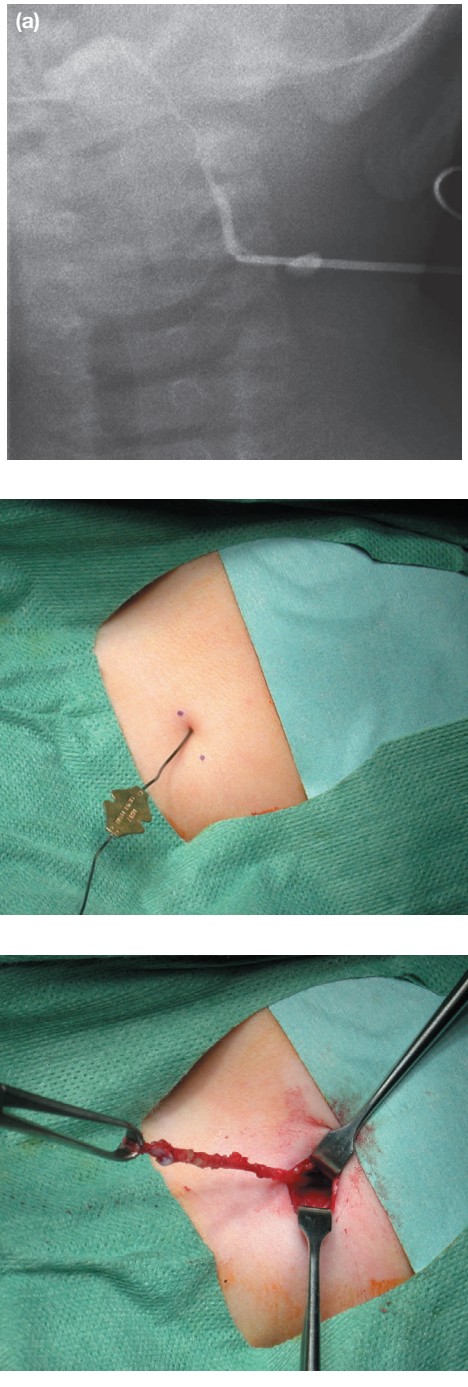

Figure 52.64 (a) Plain radiograph with radio-opaque dye in the fistula tract. **(b)** Probing of the fistula tract. **(c)** Excision of the fistula tract.

The behaviour of cystic hygromas during infancy is unpredictable. Sometimes the cyst expands rapidly and occasionally respiratory difficulty ensues, requiring immediate aspiration and even occasionally a tracheostomy. The cyst may become infected.

Definitive treatment involving complete excision of the cyst at an early stage is best if possible. Injection of a sclerosing agent is an alternative strategy and may reduce the size of the cyst; however, they are commonly multicystic and therefore complete resolution is a challenge.

Figure 52.65 Cystic hygroma.

Thyroglossal duct cysts

Embryology

The thyroid gland descends early in fetal life from the base of the tongue towards its position in the lower neck with the isthmus lying over the second and third tracheal rings. At the time of its descent, the hyoid bone has not been formed and the track of the descent of the thyroid gland is variable, passing in front, through or behind the eventual position of the hyoid body. Thyroglossal duct cysts represent a persistence of this track and may therefore be found anywhere in or adjacent to the midline from the tongue base to the thyroid isthmus. Rarely, what appears to be a thyroglossal cyst is an incompletely migrated thyroid gland that contains the only functioning thyroid tissue in the body. Ultrasound neck imaging is used to confirm a cyst and the presence of a thyroid gland in the normal location.

Clinical features

The cysts almost always arise in the midline but, when they are adjacent to the thyroid cartilage, they may lie slightly to one side of the midline. Classically, the cyst moves upwards on swallowing and with tongue protrusion, but this can also occur with other midline cysts such as dermoid cysts, as it merely indicates attachment to the hyoid bone.

Thyroglossal cysts may become infected and rupture onto the skin of the neck, presenting as a discharging sinus. Although they often occur in children, they may also present in adults, even as late as the sixth or seventh decade of life (***Figure 52.66***).

Treatment

Treatment must include excision of the whole thyroglossal tract, which involves removal of the body of the hyoid bone and

Figure 52.66 A patient with a thyroglossal fistula from a cyst in the midline of the neck.

the suprahyoid tract through the tongue base to the vallecula at the site of the primitive foramen caecum, together with a core of tissue on either side. This operation is known as Sistrunk's operation and minimises recurrence, most notably from small side branches of the thyroglossal tract.

TRAUMA TO THE NECK

The management of penetrating neck trauma depends on the structures that have been injured. The neck is classified into three zones for this purpose (***Table 52.3***). (Note: this is different from the levels used to describe cervical lymphadenopathy.) The majority of injuries occur commonly in zone 2. Critical clinical assessment coupled with appropriate imaging such as a CT scan or CT angiogram is crucial in managing these patients.

Wounds above the hyoid bone

The cavity of the mouth or pharynx may have been entered and the epiglottis may be transected. These wounds require repair with absorbable sutures under a general anaesthetic. If there is any degree of associated oedema or bleeding, particularly in relation to the tongue base or laryngeal inlet, it is advisable to perform a tracheostomy to avoid any subsequent airway compromise.

Wounds of the thyroid and cricoid cartilage

Blunt crushing injuries or severe laceration injuries to the laryngeal skeleton can cause marked haematoma formation or swelling and rapid loss of the airway. There may be significant disruption of the laryngeal skeleton. These patients should not have an endotracheal intubation for any length of time, even if this is the initial emergency way of protecting the airway. The larynx is a delicate three-tiered sphincter and the presence of a foreign body in its lumen after severe disruption gives rise to major fibrosis and loss of laryngeal function. These injuries frequently require a low tracheostomy, following which the larynx can be carefully explored, damaged cartilages repositioned and sutured or plated and the paraglottic space drained.

An indwelling stent of soft sponge shaped to fit the laryngeal lumen and held by a nylon retaining suture through the neck may be left in place for 5–10 days to minimise webbing. This stent can be removed endoscopically after cutting the retaining suture and, as the laryngeal damage heals, the patient may then be decannulated.

TABLE 52.3 The zones of the neck and structures contained within.

Zone	Boundary	Structures within
1	From clavicle/sternal notch to cricoid cartilage	Trachea, oesophagus, innominate artery, arch of aorta, brachial plexus, thoracic duct, carotid artery
2	From cricoid cartilage to angle of mandible	Larynx, hypopharynx, carotid artery (common/internal/external), internal jugular vein, sympathetic plexus, recurrent laryngeal nerve
3	From angle of mandible to skull base	Facial nerve, carotid artery (internal/branches of external), jugular vein

Division of the trachea

Wounds of the trachea are rare. They should all be formally explored and, to obtain adequate exposure, it is usually necessary to divide and ligate the thyroid isthmus. A small tracheostomy below the wound followed by repair of the trachea with a limited number of submucosal sutures is appropriate. In self-inflicted wounds, the recurrent laryngeal nerves, which lie protected in the tracheo-oesophageal grooves, are rarely injured. Primary repair of the nerve is rarely possible but may be undertaken at the time of formal exploration of a major neck wound.

Neurovascular injury

Penetrating wounds of the neck may involve the common carotid or the external or internal carotid arteries. Major haemorrhagic shock may occur. Venous air embolism may occur because of damage to one of the major veins, most commonly the internal jugular. Compression, resuscitation and exploration under general anaesthetic, with control of vessels above and below the injury and primary repair, should be undertaken. All cervical nerves are vulnerable to injury, particularly the vagus and recurrent laryngeal nerves and cervical sympathetic chain.

Thoracic duct injury

Wounds to the thoracic duct are usually iatrogenic and usually left sided, occurring when lymph node level IV is dissected during a neck dissection. When damage to the duct is not

Walter Ellis Sistrunk Jr, 1880–1933, Professor of Clinical Surgery, Baylor University College of Medicine, Dallas, TX, USA.

recognised at the time of operation, chyle may subsequently leak from the wound in amounts up to 2 L/day with profound effects on nutrition.

Should the damage be recognised during an operation, the proximal end of the duct must be ligated. Ligation of the duct is not harmful because there are a number of anastomotic channels between the lymphatic and venous systems in the lower neck. If undetected, chyle usually starts to discharge from the neck wound within 24 hours of the operation. Low-flow chyle leaks (less than 500 mL/day) can be managed conservatively with a low-fat diet and systemic octreotide. The patient's fluid and electrolyte balance must be closely monitored. Total parenteral nutrition and surgical re-exploration may be warranted in high-output leaks.

INFLAMMATORY CONDITIONS OF THE NECK

Ludwig's angina

Ludwig described a clinical entity characterised by a brawny swelling of the submandibular region combined with inflammatory oedema of the mouth. These clinical features, as well as accompanying putrid halitosis, define the condition.

The infection is often caused by a virulent streptococcal infection associated with anaerobic organisms. There may also be an underlying oral cavity cancer. The infection tracks deep to the mylohyoid muscle, causing oedema and inflammation such that the tongue is displaced upwards and backwards, giving rise to dysphagia and subsequently to painful obstruction of the airway. Unless treated, cellulitis may extend beneath the deep fascial layers of the neck to involve the larynx, causing glottic oedema and further airway compromise.

Antibiotic therapy should be instituted as soon as possible using intravenous broad-spectrum antibiotics, with anaerobic cover. If the swelling does not subside rapidly with such treatment, or in advanced cases where pus is evident, a curved submental incision may be used to drain both submandibular triangles. The mylohyoid muscle may be incised to decompress the floor of the mouth and corrugated drains placed in the wound, which is then lightly sutured. Although this operation may be conducted under local anaesthetic, a general anaesthetic approach is preferred as it provides a more controlled setting, allowing for optimal exposure and drainage without undue stress to the patient. Rarely, a tracheostomy may be necessary.

Cervical lymphadenitis

Cervical lymphadenitis is common owing to infection or inflammation in the oral and nasal cavities, pharynx, larynx, ear, scalp and face.

Acute lymphadenitis

The affected lymph nodes are enlarged and tender, and there may be varying degrees of general constitutional disturbance such as pyrexia, anorexia and general malaise. The treatment in the first instance is directed to the primary focus of infection, for example tonsillitis or a dental abscess.

Chronic lymphadenitis

Chronic, painless lymphadenopathy may be caused by TB in young children or adults or be secondary to malignant disease, most commonly from a squamous cell carcinoma in older individuals. Lymphoma and/or HIV infection may also be present in the cervical nodes.

Summary box 52.16

Causes of cervical lymphadenopathy

Inflammatory
- Reactive hyperplasia

Infective
- Viral
  - For example, infectious mononucleosis, HIV
- Bacterial
  - *Streptococcus, Staphylococcus*
  - Actinomycosis
  - TB
  - Brucellosis
- Protozoan
  - Toxoplasmosis

Neoplastic
- Malignant
  - Primary (e.g. lymphoma)
  - Secondary (e.g. squamous cell carcinoma)
    - Known primary
    - Occult primary

Tuberculous adenitis

This condition most commonly affects children or young adults but can occur at any age. The deep upper cervical nodes are most commonly affected, but there may be a widespread cervical lymphadenitis with matted nodes. In most cases, the tubercular bacilli gain entrance through the ipsilateral tonsil. In approximately 80% of patients, the tuberculous process is limited to the clinically affected group of lymph nodes, but a primary focus in the lungs must always be suspected.

Rarely, the patient may develop a natural resistance to the infection and the nodes may be detected at a later date, as evidenced by calcification on radiography. This can also be seen after appropriate general treatment of TB adenitis. If treatment is not instituted, the caseated node may liquefy and break down with the formation of a cold abscess in the neck. The pus is initially confined by the deep cervical fascia, but after weeks or months this may become eroded at one point and the pus flows through the small opening into the space beneath the superficial fascia. The process has now reached the well-known stage of a 'collar-stud' abscess. The superficial abscess enlarges steadily and, unless suitably treated, a discharging sinus results.

Wilhelm Friedrich von Ludwig, 1790–1865, Professor of Surgery and Midwifery, Tübingen, Germany.

Investigation

Fine-needle aspirate taken from neck nodes with a suspicion of TB should be tested for the presence of acid-fast bacilli. Systemic investigation should not be neglected, with a chest radiograph and tuberculin skin test (Mantoux) useful as first-line investigations. The drawback of the Mantoux test is the poor sensitivity in immunocompromised patients and low specificity in patients with prior bacille Calmette–Guérin (BCG) vaccination.

The interferon-γ release assay (QuantiFERON®-TB Gold In-Tube; QFT-GIT; Cellestis, Carnegie, Australia) with T-SPOT®.*TB* (Oxford Immunotec, Abingdon, UK), in contrast, is more specific than a Mantoux test as the results are not confounded by previous BCG vaccination. This blood test measures the cellular immune response to antigens derived from *Mycobacterium tuberculosis*. Although active or latent infection cannot be specifically differentiated with this test, a positive test in a patient with negative clinical and radiological evidence of TB indicates latent TB infection. Depending on the country of origin, where TB is diagnosed or suspected, the coexistence of other infectious diseases such as HIV and malaria should not be overlooked.

Treatment

The patient should be treated using appropriate chemotherapy, dependent on the sensitivities derived from the abscess contents. If an abscess fails to resolve despite appropriate chemotherapy and general measures, occasionally excision of the abscess and its surrounding fibrous capsule is necessary, together with the relevant lymph nodes. If there is active TB of another system, for example pulmonary TB, then removal of tuberculous lymph nodes in the neck is inappropriate. The matted nodes are associated with significant fibrosis, making surgery difficult to the extent that the sacrifice of adjacent structures such as the internal jugular vein or sternocleidomastoid muscle may be necessary. The resected nodes should be sent for both histology and microbiology.

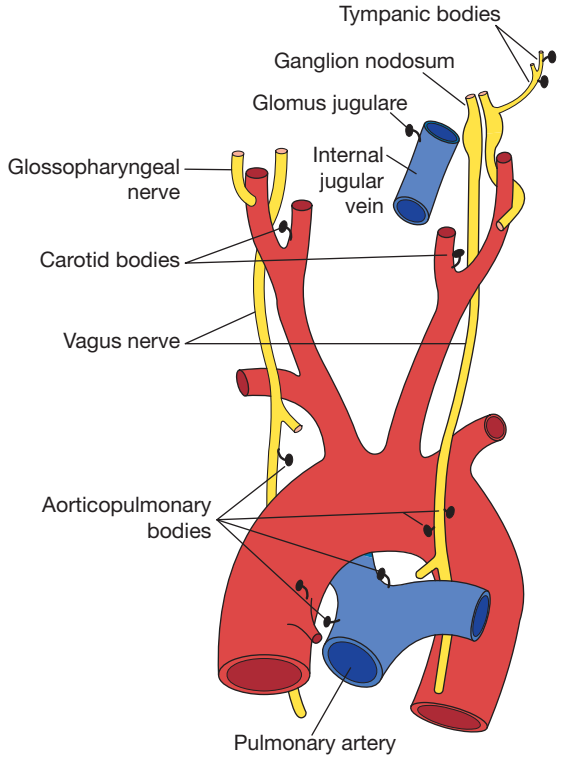

Figure 52.67 Sites for chemodectomas.

PRIMARY TUMOURS OF THE NECK

Neurogenic tumours

Paraganglioma (carotid body tumour)

This is a rare tumour that has a higher incidence in areas where people live at high altitudes because of chronic hypoxia leading to carotid body hyperplasia. The tumours most commonly present in the fifth decade. Approximately 10% of patients have a family history, with familial cases caused by mutations in the genes for succinate dehydrogenase (SDH) enzyme. There is an association with phaeochromocytoma in familial cases, and thus appropriate tests should be undertaken to rule out synchronous catecholamine-secreting tumours during the work-up. The tumours arise from the chemoreceptor cells on the medial side of the carotid bulb and, at this point, the tumour is adherent to the carotid wall. These tumours are usually benign with only a small number of cases producing proven metastases (***Figures 52.67 and 52.68***).

Clinical features

There is often a long history of a slowly enlarging, painless lump at the carotid bifurcation. About one-third of patients present with a pharyngeal mass that pushes the tonsil medially and anteriorly. The mass is firm, rubbery, pulsatile, mobile from side to side but not up and down and can sometimes be emptied by firm pressure, after which it slowly refills in a pulsatile manner. A bruit may also be present. Swellings in the parapharyngeal space, which often displace the tonsil medially, should not be biopsied from within the mouth.

Investigations

When a paraganglioma is suspected, a carotid angiogram can be carried out to demonstrate the carotid bifurcation, which is usually splayed, and a blush, which outlines the tumour vessels. MRI scanning also provides excellent detail in most cases. This tumour must not be biopsied and fine-needle aspiration is also contraindicated.

Charles Mantoux, 1877–1947, physician, Le Cannet, Alpes Maritimes, France, described the intradermal tuberculin skin test in 1908.
Albert Leon Charles Calmette, 1863–1933, and **Jean-Marie Camille Guérin**, 1872–1961, microbiologists at the Institute Pasteur, Lille, France, introduced the bacille Calmette–Guérin in 1908.

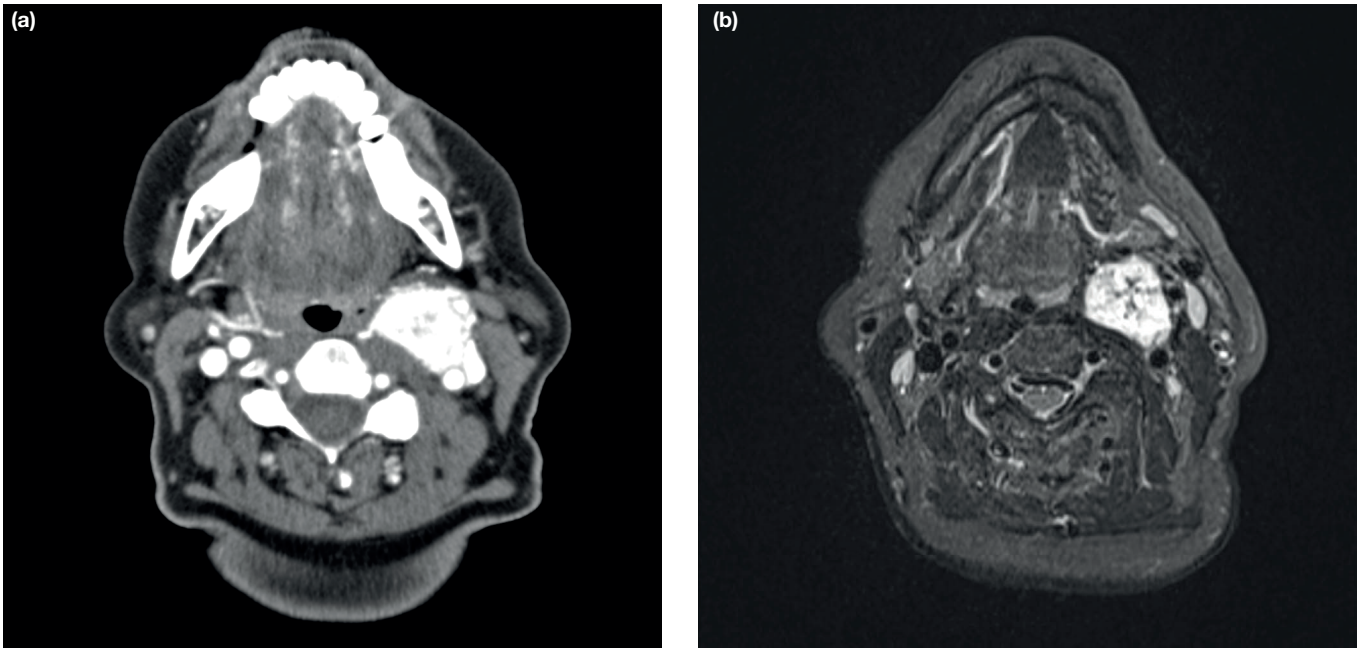

Figure 52.68 Axial view computed tomography angiogram **(a)** and magnetic resonance imaging **(b)** demonstrating a left carotid body tumour.

Treatment

The Shamblin classification is used to determine the surgical resectability of these tumours. Type I tumours are localised and do not involve more than 180° of the carotid vessels; type II tumours surround the vessel by over 180°; and type III tumours completely encase the vessels and are more challenging to resect with higher complications and a possible need for vessel reconstruction.

Because these tumours rarely metastasise and their overall rate of growth is slow, the need for surgical removal must be considered carefully as complications of surgery are potentially serious. The operation is best avoided in elderly patients. Radiotherapy will not cure the tumour but can prevent further growth. In some cases it may be possible to dissect the tumour away from the carotid bifurcation but, at times, when the tumour is large, it may not be separable from the vessels and resection will be necessary, such that all appropriate facilities should be available to establish a bypass while a vein autograft is inserted to restore arterial continuity in the carotid system.

Vagal body tumours

Vagal paragangliomas arise from nests of paraganglionic tissue of the vagus nerve just below the base of the skull near the jugular foramen. They may also be found at various sites along the nerve down to the level of the carotid artery bifurcation. They also present as slowly growing and painless masses in the anterolateral aspect of the neck, and may also have a long history, commonly of 2–3 years, before diagnosis. They may spread into the cranial cavity. Diagnosis is confirmed by CT and MRI scanning and additional MRA or arteriography if necessary. Treatment is surgical excision following appropriate consent of resulting hoarseness.

Peripheral nerve tumours

Schwannomas are solitary and encapsulated tumours attached to or surrounded by nerve, although paralysis of the associated nerve is unusual. The vagus nerve is the most common site. Neurofibromas also arise from the Schwann cell and may be part of von Recklinghausen's syndrome of multiple neurofibromatosis. Multiple neurofibromatosis is an autosomal dominant, hereditary disease; the neurofibromas may be present at birth and are often multiple.

Diagnosis requires CT or MRI scanning to differentiate them from other parapharyngeal tumours but, on occasions, the diagnosis must wait until excision (***Figure 52.69***).

Secondary carcinoma

Metastatic spread of squamous cell carcinoma to the cervical lymph nodes is a common occurrence from head and neck primary cancers; occasionally, this may be the sole presenting feature of the disease (***Figure 52.70***). The upper aerodigestive tract mucosa must be carefully examined for a primary site before considering surgery to the neck nodes. When a primary site is not seen on clinical examination, they are most often found in the oropharynx. Appropriate radiological

William R Shamblin, Mayo Graduate School of Medicine (University of Minnesota), Rochester, MN, USA, described this classification in 1971.
Friedrich Theodor Schwann, 1810–1882, Professor of Anatomy and Physiology, successively at Louvain (1839–1848) and Liège (1848–1880), Belgium, described the neurilemma in 1839.
Friedrich Daniel von Recklinghausen, 1833–1910, Professor of Pathology, Strasbourg, France, described generalised neurofibromatosis in 1882.

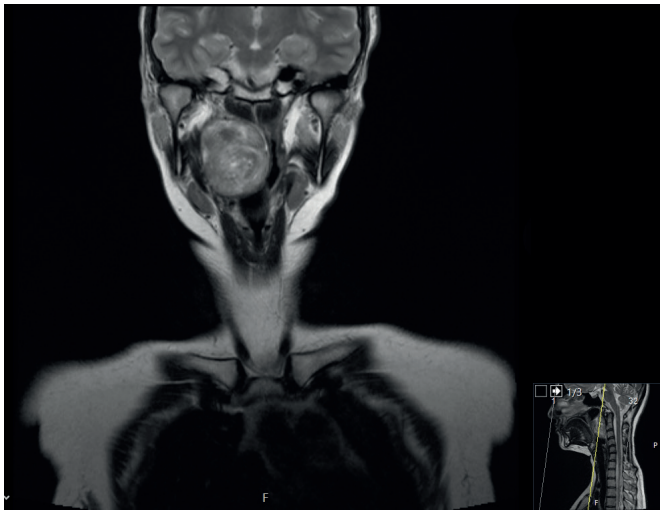

Figure 52.69 Magnetic resonance imaging scan demonstrating a large parapharyngeal tumour. The imaging characteristics of the tumour suggested a paraganglioma or a schwannoma. Resection confirmed the latter.

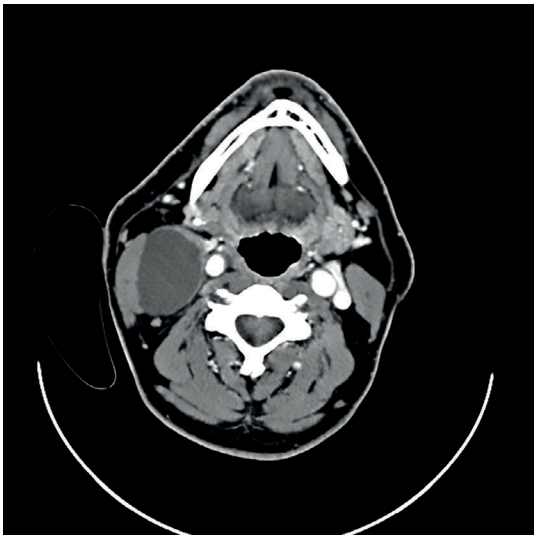

Figure 52.70 Axial computed tomography scan demonstrating a large cystic metastatic node from an unknown primary. Core biopsy confirmed a squamous cell cancer.

investigations (MRI, PET-CT) must be undertaken to define subclinical primaries, as management will be dictated by this. If radiological assessment shows no primaries, tonsillectomy and robot-assisted tongue base mucosectomy are performed as a diagnostic procedure because the oropharynx is the most common site for a clinically and radiologically unknown primary cancer.

Management

The management of malignant cervical lymph nodes depends on the overall treatment regime:

- if surgery is being used to treat the primary disease and the cervical nodes are palpable and <3 cm, they may be excised with the primary lesion as part of a neck dissection;
- if radiotherapy or chemoradiotherapy is used initially with resolution of the primary tumour, but there is subsequent residual or recurrent nodal disease, then this situation will require cervical lymph node dissection.

Type of neck dissection

Classical radical neck dissection (Crile)

The classic operation involves resection of the cervical lymph nodes (levels I–V) and those structures closely associated: the internal jugular vein, the accessory nerve, the submandibular gland and the sternocleidomastoid muscle. These structures are all removed en bloc and in continuity with the primary disease if possible. The main disability that follows the operation is weakness and drooping of the shoulder due to paralysis of the trapezius muscle as a consequence of excision of the accessory nerve. Bulky nodal disease may dictate the need for a radical neck dissection, but this operation is less commonly performed owing to a better understanding of the lymphatic drainage of the primary sites and as most patients with advanced disease need adjuvant radiation.

Modified radical neck dissection

This term denotes a procedure in which one or more of the non-lymphatic structures are preserved (the accessory nerve, the sternocleidomastoid muscle or the internal jugular vein) with clearance of all nodal levels (I–V).

Selective neck dissection

In this type of dissection, one or more of the major lymph node groups is preserved along with the sternocleidomastoid muscle, accessory nerve and internal jugular vein. In these circumstances, the exact groups of nodes excised must be documented.

It must be noted that, when neck dissections are performed for residual disease after (chemo)radiation therapy, the neck is often fibrotic and scarred and the operation may not fall into any of the above categories. For instance, lymph nodes in levels II and III may be removed, along with the sternomastoid muscle for access; thus, meticulous annotation of the procedure is more important than ascribing a name to the operation.

SUMMARY

The anatomical and physiological performance of the pharyngolarynx is involved in the important mechanisms of breathing, coughing, voice production and swallowing. A variety of congenital, traumatic, infectious and neoplastic conditions disturb these functions, giving rise to the common symptoms of pain, swelling, hoarseness, dyspnoea and dysphagia.

Squamous cell carcinomas are the most common malignancies, accounting for approximately 80% of all head and

George Washington Crile, 1864–1943, Professor of Surgery, The Western Reserve University, and one of the founders of the Cleveland Clinic, Cleveland, OH, USA.

neck tumours. Their incidence and anatomical site vary around the world, but they are mainly caused by the preventable aetiological agents of smoking and alcohol, although nasopharyngeal and oropharyngeal squamous cell carcinomas have additional genetic and environmental factors. All head and neck cancers have a high morbidity and mortality and require expert treatment.

PART 7 | Head and neck

CHAPTER 53

Oral cavity cancer

Learning objectives

To understand:

- The epidemiology and aetiology of oral cancer
- The cardinal features of malignant lesions of the oral cavity (signs and symptoms)
- Broad steps necessary for investigation and management of oral cavity cancers

INTRODUCTION

The oral cavity (***Figure 53.1***) extends from the mucosal surface of the lips to the junction of the hard and soft palate. It does not include the soft palate, uvula or tonsils, which form part of the oropharynx. Oral cavity cancer is the eighth most common cancer worldwide, with an estimated 350 000 cases arising annually. While there have been significant advances in the understanding and management of oral cavity cancer, the morbidity and prognosis associated with it have remained largely unchanged. In this chapter, we will outline the aetiology and epidemiology of oral cavity cancer, as well as risk factors for this disease, and highlight important geographical variations. Additionally, we will explore the investigation and management of oral cavity cancer. Lastly, we will outline emerging techniques and technologies utilised in oral cavity cancer treatment.

EPIDEMIOLOGY

There is considerable geographical variation in the incidence of oral cancers worldwide, reflecting differing lifestyles and risk factor exposure.

For clarity, and in keeping with the 11th revision of the *International Classification of Diseases* (ICD-11), we will include cancers of the lip, gum, tongue, palate and floor of the mouth as well as the rest of the mouth in oral cavity cancer. Cancers of the nasopharynx, hypopharynx and major salivary glands are excluded. The oropharynx includes the base of the tongue, the soft palate/uvula, the pharyngeal walls and the tonsils. Cancers arising in the oropharynx are discussed separately in ***Chapter 52***.

Incidence

There are approximately 350 000 new cases of oral cavity cancer per year worldwide. The vast majority of these are squamous cell carcinomas (SCCs). In 2015, the estimated age-standardised ratio of oral cavity cancer was 5.8 in men and 2.3 in women per 100 000. This 2:1 ratio has narrowed recently but still probably reflects the higher consumption of alcohol and tobacco by men worldwide. Two-thirds of all oral cancers occur in low-income countries, with half of those in South Asia. India, for example, has 100 000 new cases per annum.

Rates of oral cancer vary significantly worldwide. High-incidence areas include South East Asia, Papua New Guinea, parts of western Europe (e.g. Portugal and France), parts of eastern Europe (e.g. Slovakia and Hungary), as well as areas in Latin America (e.g. Brazil).

The incidence of oral cancer increases with age, with most cases occurring in those over 50 years. The mean age at presentation is 62 years, with a strong correlation between lower socioeconomic class and disease incidence. However, there is an increasing trend for cases affecting younger patients (45 years or younger), many of whom lack exposure to traditional risk factors.

The 5-year survival rate for early-stage cancers is 80%. Despite recent advances, the overall 5-year survival for oral cancer has not markedly improved and remains at 50%. In South Asia, this figure is often below 50%, with a reported 5-year survival of 35% in India.

Regional variations

Oral cancer is one of the most common cancers in India, with an age-adjusted incidence rate of 20 per 100 000.[1] The disease accounts for over one-third of all cancers in India. In contrast to western populations, cancers of the buccogingival/retromolar area account for over 40% of cancers in India and South East Asia, reflecting the commonplace use of the known carcinogens betel quid/gutka, along with smokeless tobacco.

In Europe, there is significant variation reflecting the varying cultures and lifestyles, especially between eastern and western Europe. Eastern Europe has one of the highest age-standardised incidence rates of oral cancer worldwide, with Hungary recording the highest rates. In these populations,

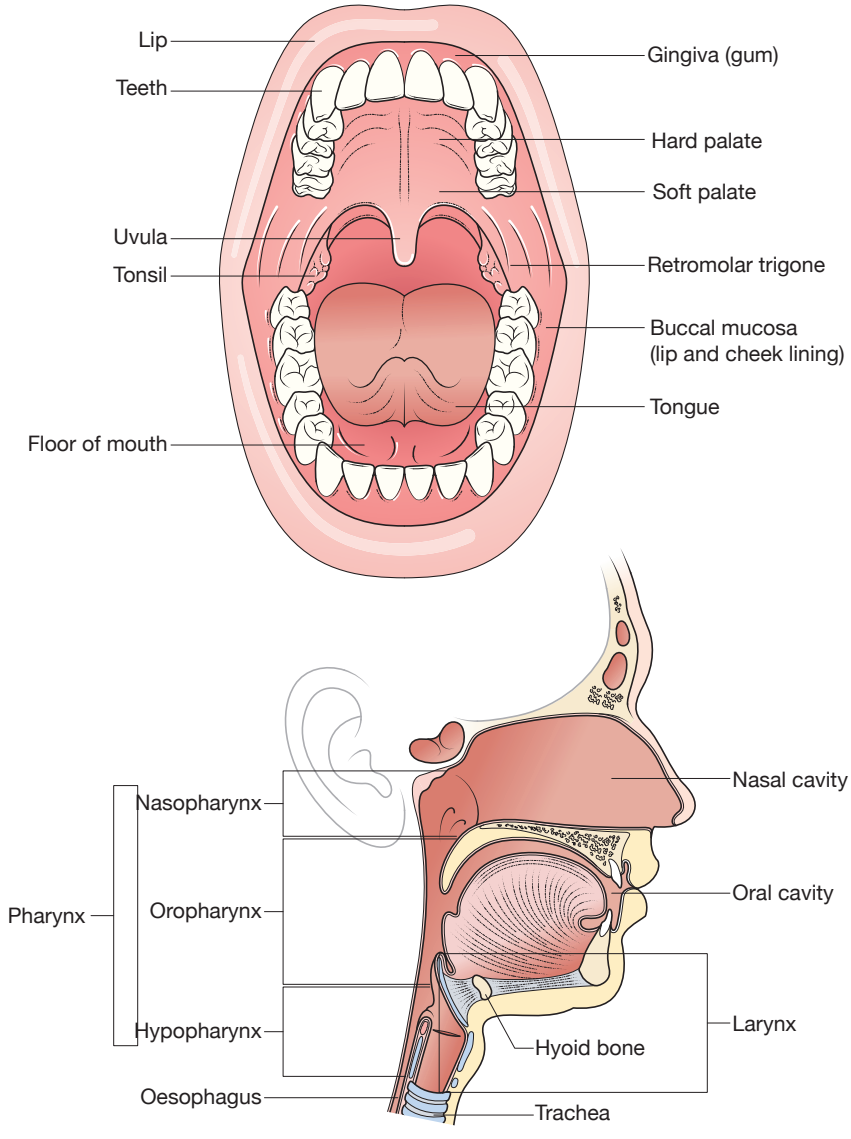

Figure 53.1 The oral cavity.

the lateral border of the tongue and the floor of the mouth constitute particularly high-risk sites.

In the USA, Surveillance, Epidemiology, and End Results (SEER) Program statistics indicate that the age-adjusted rate for oral cancer is 11.2 per 100 000 per year, while the number of deaths is 2.5 per 100 000 per year.

Risk factors

Tobacco, alcohol and betel quid (areca nut, catechu, slaked lime wrapped in a piper betel leaf) are long-established risk factors for oral cavity squamous cell carcinoma (OCSCC). There is a dose–response relationship between the use of tobacco, alcohol and betel quid and the development of oral cancer.

Transcriptionally active human papillomavirus (HPV) accounts for only a small percentage (approximately 5%) of OCSCCs, which is in stark contrast to oropharyngeal squamous cell cancers (OPSCCs), where 50–70% are caused by HPV. Although HPV-positive SCC has prognostic significance in the oropharynx (see ***Chapter 52***), this survival advantage does not appear to be conferred within the oral cavity.

Other risk factors include previous exposure to radiation, chronic infection, immunosuppression and hereditary conditions such as Fanconi anaemia and Li–Fraumeni syndrome.

Guido Fanconi, 1892–1979, Swiss paediatrician, named several conditions, including Fanconi anaemia, a rare genetic disorder of DNA repair leading to bone marrow failure and the development of haematological and solid malignancies typically within early life.

Frederick Pei Li, 1940–2015, Boston, MA, USA, and **Joseph F Fraumeni Jr**, b. 1933, National Institutes of Health, Bethesda, MD, USA, described a familial syndrome of soft-tissue sarcomas, breast cancer and other malignancies in 1969.

Summary box 53.1

Risk factors for oral cavity malignancy

- Smoking
- Alcohol
- Betel quid
- HPV
- Hereditary conditions
- Immunosuppression
- Chronic infection
- Potentially/premalignant lesions

Premalignant lesions

The majority of oral cancers do not originate from a pre-existing lesion. However, there are a group of oral premalignant lesions, or more accurately described potentially malignant lesions, that are mucosal abnormalities from which oral cancer can arise. These lesions include leukoplakia, erythroplakia, erythroleukoplakia, proliferative verrucous leukoplakia (PVL), oral submucous fibrosis, oral lichen planus and lupus erythematosus, as well as inherited conditions such as epidermolysis bullosa and dyskeratosis congenita. A leukoplakia is a white patch or plaque that cannot be rubbed off, while an erythroplakia is a bright red velvety plaque, neither of which can be characterised clinically or pathologically as any other recognisable condition. A speckled leukoplakia or erythroleukoplakia is essentially a combination of both; it carries the greatest risk for malignant change.

The management of premalignant lesions is challenging, not least because of an inconsistency with nomenclature internationally but also because the natural history of these lesions remains unclear.

The reported rates of malignant transformation vary widely between studies and countries. A systematic review of observational studies in 2016 reported that malignant transformation in oral leukoplakia could vary from 0.13% to 34.0%.[2]

Risk assessment forms the cornerstone of the management of these lesions. Among these lesions, erythroleukoplakia, PVL and dyskeratosis congenita carry the highest risk for malignant transformation. Clinical factors to be considered include size, location and lifestyle exposure to known carcinogens. Biopsy of lesions is advocated for accurate pathological diagnosis as well as to ascertain the degree of dysplasia (mild, moderate, severe), or indeed the presence of malignancy in a lesion.

Summary box 53.2

Factors associated with increased risk for malignant change in pre-existing (dysplastic) lesions

- Female sex
- Size >200 mm^2
- Non-homogeneous lesion
- Non-smoker
- Presence of multiple lesions
- Location (e.g. lateral border of tongue/floor of mouth)

It should be pointed out that surgical removal of a premalignant or dysplastic lesion does not completely remove the risk of transformation and as such appropriate surveillance regimes are necessary.

Molecular biology

According to The Cancer Genome Atlas (TCGA), alterations in *p53* (83%) and *CDKN2A* (57%) are the two most frequent genomic mutations noted in HPV-negative cancers of the head and neck (of which oral cancer is an example). This contrasts with HPV-positive tumours, found most frequently in the oropharynx, which have a considerably lower mutational burden and consistently retain *p53* 'wild-type' status. It is, however, important to note that, as yet, the current standard of care in head and neck squamous cell carcinoma (HNSCC), including oral cavity cancers, is not based on or influenced by genetic profiling or molecular biology.

STAGING

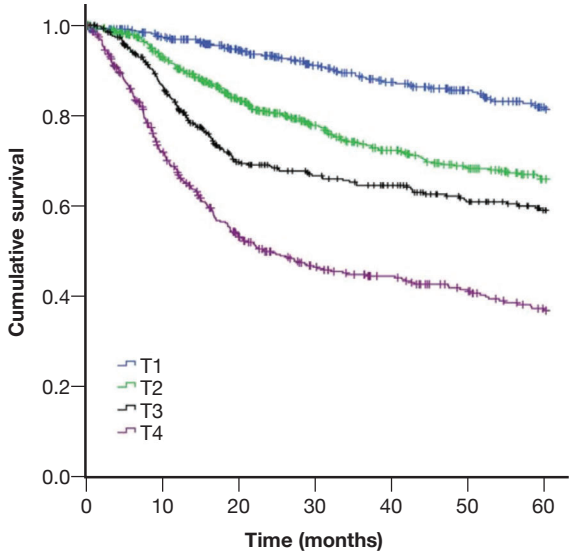
Staging is required to document tumour size, location and disease extent, as well as to formulate a treatment plan and facilitate discussion of prognosis with the patient. Additionally, it is an important tool for comparative outcome reporting. The eighth edition of the Union for International Cancer Control (UICC)/American Joint Committee on Cancer (AJCC) tumour–node–metastasis (TNM) staging manual (***Table 53.1***) has introduced changes in how oral cavity cancers are staged. The most significant updates for oral cancer are: (i) the inclusion of depth of invasion (DOI) as an element for determining the T stage of primary tumours and (ii) recognition of extranodal extension (ENE) as a feature necessitating upstaging of nodal disease. This recognition of additional negative prognostic factors in the eighth edition should allow improved stratification of outcomes for patients.

T stage

The size and extent of tumours are typically determined by thorough clinical examination (supported by examination under anaesthesia [EUA] where necessary) and by radiographic assessment with cross-sectional imaging (e.g. computed tomography [CT], magnetic resonance imaging [MRI]). While the DOI can be estimated radiologically, it remains a pathologically determined feature from a surgically resected specimen. ***Figure 53.2*** illustrates the influence that T stage, and therefore depth of invasion, has on overall survival.

N stage

The system for describing the anatomy of regional lymph node metastases has been well described previously and is outlined in ***Figure 53.3***. It divides the lateral neck nodes into five separate levels, based on their relationship to certain anatomical structures.



SCC in the oral cavity and lips tends to metastasise to lymph nodes at levels I, II and III. However, with SCC of the

TABLE 53.1 Outline of the T category from the American Joint Committee on Cancer (AJCC) tumour–node–metastasis (TNM) staging manual, 8th edition.

T category	T criteria
TX	Primary tumour cannot be assessed
Tis	Carcinoma *in situ*
T1	Tumour ≤2 cm, ≤5 mm DOI
T2	Tumour ≤2 cm, DOI >5 mm and ≤10 mm *or* tumour >2 cm but ≤4 cm, and ≤10 mm DOI
T3	Tumour >4 cm *or* any tumour >10 mm DOI
T4	Moderately advanced or very advanced local disease
T4a	Moderately advanced local disease: (lip) tumour invades through cortical bone or involves the inferior alveolar nerve, floor of mouth or skin of face (i.e. chin or nose); (oral cavity) tumour invades adjacent structures only (e.g. through cortical bone of the mandible or maxilla, or involves the maxillary sinus or skin of the face); note that superficial erosion of bone/tooth socket (alone) by a gingival primary is not sufficient to classify a tumour as T4
T4b	Very advanced local disease; tumour invades masticator space, pterygoid plates or skull base and/or encases the internal carotid artery

oral tongue there is a risk of skip metastasis directly to lymph node levels III or IV, without the involvement of higher level lymph node groups. By contrast, tumours arising in the oropharynx commonly metastasise to lymph node levels II–IV, as well as retropharyngeal and contralateral nodal groups. In addition to the number, size and location of involved nodes, ENE has now been included as a contributor to nodal staging (***Table 53.2***). ENE has been reliably shown to be an adverse prognosticator in all oral cavity tumours.

M stage

Routine assessment of the chest (as a minimum) for evidence of distant metastasis and/or synchronous lung primary tumours is the norm as part of staging prior to treatment. M0 denotes no distant metastases, whereas M1 signifies distant metastases present. The presence of any distant metastases automatically places a patient in the stage 4C group, currently without curative therapeutic options.

Prognostic stage groupings

The eighth edition AJCC stage groupings are outlined in ***Table 53.3***.

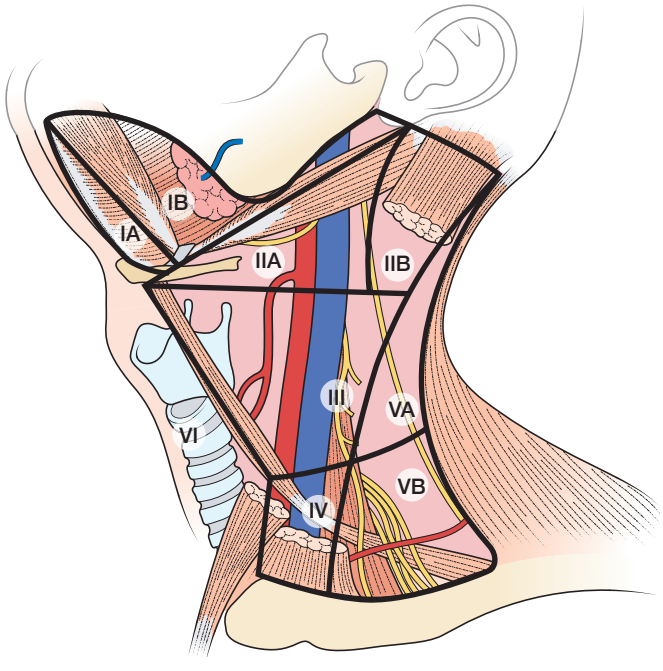

Figure 53.3 Cervical lymph node levels.

TABLE 53.2 Outline of the pathological N category from the American Joint Committee on Cancer (AJCC) tumour–node–metastasis (TNM) staging manual, 8th edition.

N category	N criteria[a]
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension and ENE-negative
N2	Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension and ENE-positive; *or* more than 3 cm but not more than 6 cm in greatest dimension and ENE-negative; *or* metastases in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension and ENE-negative; *or* metastases in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension and ENE-negative
N2a	Metastasis in a single ipsilateral or contralateral lymph node 3 cm or less in greatest dimension and ENE-positive; *or* metastasis in a single ipsilateral lymph node more than 3 cm but not more than 6 cm in greatest dimension and ENE-negative
N2b	Metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension and ENE-negative
N2c	Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension and ENE-negative
N3	Metastasis in a lymph node more than 6 cm in greatest dimension and ENE-negative; *or* metastasis in a single ipsilateral lymph node more than 3 cm in greatest dimension and ENE-positive; *or* metastasis in multiple ipsilateral, contralateral or bilateral lymph nodes, with any ENE-positive
N3a	Metastasis in a lymph node more than 6 cm in greatest dimension and ENE-negative
N3b	Metastasis in a single ipsilateral lymph node more than 3 cm in greatest dimension and ENE-positive; *or* metastasis in multiple ipsilateral, contralateral or bilateral lymph nodes, with any ENE-positive

ENE, extranodal extension.

[a]Note that a designation of 'U' or 'L' may be used for any N stage to indicate metastasis above the lower border of the cricoid ('U') or below the lower border of the cricoid ('L'). Similarly, clinical and pathological ENE should be recorded as ENE-negative or ENE-positive.

PATHOLOGY OF ORAL CANCERS

The vast majority (>95%) of oral cavity cancers are squamous cell carcinomas (OCSCCs). The World Health Organization (WHO) tumour grading system, based on cellular differentiation, is routinely used in pathological analysis and diagnosis of OCSCC. The histological parameters routinely described in OCSCC include:

- histological type;
- tumour grade/differentiation;
- pattern of invasion;
- tumour thickness and DOI;
- perineural invasion (PNI);
- lymphovascular invasion (LVI);
- bone involvement;
- nodal metastases.

Histological type

The vast majority of OCSCCs are conventional squamous-type carcinomas, reflecting their cell of origin. Other less commonly encountered variants include papillary, adenosquamous, acantholytic, basaloid, spindle cell and verrucous carcinomas, along with carcinoma cuniculatum.

Tumour grade (differentiation)

Often cited as an important prognosticator, the 'WHO grade' is based on Broders' original classification and includes well (G1), moderate (G2) or poorly differentiated (G3) grading. The grade is essentially based on how similar the tumour tissue appears relative to the normal tissue from which it originated.

In general, well-differentiated OCSCCs are less aggressive than their poorly differentiated counterparts, which infiltrate

Albert Compton Broders, 1885–1964, American pathologist, Minnesota, USA, and Chairman of the Department of Surgical Pathology, The Mayo Clinic, Rochester, MN, USA; for 1 year in 1935 Professor of Surgical Pathology and Director of Cancer Research, University of Virginia, VA, USA.

and metastasise more readily. Poorly differentiated tumours carry a worse prognosis.

Pattern of invasion

The pattern of invasion refers to the shape of the advancing front or border of the tumour. Like tumour grade/differentiation, it is of important prognostic value. The UK Royal College of Pathologists recommends the grading of pattern of invasion into two broad categories: cohesive and non-cohesive.

Tumour thickness and depth of invasion

Tumour thickness is measured as the maximum vertical dimension between the tumour surface and the deepest point of invasion. Although frequently used interchangeably with DOI, it is the latter that carries greater importance from a prognostic viewpoint as well as the propensity for metastases. DOI is the distance from the level of the basement membrane of the closest adjacent normal mucosa to the deepest point of the tumour invasion.

Perineural invasion

While there is no clear consensus on the criteria for diagnosing PNI, it is generally described as being present if at least one-third of the circumference of a nerve is surrounded by tumour cells and/or if deposits of tumour are found in any of the three layers of the nerve sheath.

PNI is a marker for the biological aggressiveness of a tumour and an independent risk factor for cervical metastases, local recurrence and therefore poorer prognosis.

Lymphovascular invasion

LVI represents the presence of tumour cells within an endothelium-lined space, irrespective of whether it is a vein or lymph channel.

Bone invasion

Three patterns of bone invasion, namely infiltrative, erosive or mixed, have been described. There is strong evidence that most tumours enter the bone at the point of contact in an erosive fashion, and not via foramina or the periodontal membrane. It is important to point out that cortical erosion as opposed to medullary invasion does not equate to a T4 tumour.

Metastases

As outlined previously, HPV-negative cervical node metastases are associated with decreased overall and disease-specific survival. While skip metastases have been described, most OCSCC metastases occur in levels I and II of the neck. ENE occurs when the capsule is breached and this is now accounted for in the UICC/AJCC eighth edition TNM staging system.

Distant metastases are rare in OCSCCs, with reported rates of 2–9%, and are associated most commonly with ENE and bilateral neck disease.

EXAMINATION, INVESTIGATION, DIAGNOSIS AND WORK-UP

These can be summarised as follows:

- history and examination;
- biopsy;
- clinical and radiographic staging investigations;
- comorbidity and functional status;
- multidisciplinary team (MDT)/tumour board discussion and treatment plan formulation;
- pathological staging;
- adjunctive treatments if appropriate.

When a lesion is suspicious for malignancy, a histopathological diagnosis is essential. Prior to this a thorough history and examination of the oral cavity, oropharynx and neck should be completed.

Radiographic assessment, in the form of a CT and MRI, is also mandatory. In some centres sentinel lymph node biopsy (SLNB) has become an established technique used for investigation and staging of early oral cancers that have no clinical or radiographic evidence for cervical metastases. A positive SLNB necessitates subsequent management of the neck (typically with completion neck dissection).

EUA is often used to further assess a tumour, especially in cases where a biopsy is not possible in the outpatient setting or where the extent of the tumour cannot be properly assessed via clinical examination in an awake patient. An EUA can support treatment planning and decision making with regards to access, extent of resection and reconstructive plans.

Oral cavity

All sites in the oral cavity are examined under direct visualisation. ***Table 53.4*** details the signs and symptoms that are suggestive of a neoplastic process. ***Figure 53.4*** demonstrates the wide clinical presentation of OCSCCs, which range from small areas of (erythro)leukoplakia to larger erosive and cavitated lesions that invade surrounding tissues. Reduced tongue movement, sensory nerve deficit, trismus, otalgia and dysphagia are all in keeping with late-stage disease. Fibreoptic examination is not routinely performed in oral cavity assessment but may support assessment of the posterior extent of the tumour. The incidence of synchronous primary tumours of the upper digestive tract is 2.4–4.5%.

TABLE 53.4 Signs and symptoms of oral cavity neoplasm.

Signs	Symptoms
• Non-healing ulcer (>2 weeks) • Persistent neck mass/ lymphadenopathy • Lesion, pigmentation with progressive increase in size • Lesion with associated induration • Persistent red or white lesion • Non-resolving 'inflammatory' lesion • Soft-tissue lesion with associated radiographic changes • Unexplained tooth mobility	• Sensory nerve deficit • Chronic otalgia • Trismus of unknown aetiology • Dysphagia

Figure 53.4 Clinical presentations of oral cavity squamous cell carcinoma (SCC). Note the cardinal features consistent with malignancy; namely speckled appearance, raised rolled edges, contact bleeding and variable ulceration. **(a)** Right ventral tongue SCC. **(b)** Right soft palate SCC. **(c)** Left posterolateral tongue SCC. **(d)** Right lateral tongue SCC.

The neck

All levels of the neck must be palpated thoroughly, to assess for lymphadenopathy. However, it is important to note that, along with clinical examination, cross-sectional imaging of the neck is also required. Clinical examination without imaging has a 74% sensitivity for detecting lymphadenopathy. The presence of a neck metastasis decreases a patient's prognosis by approximately 50%.

Biopsy

Primary tumour

Histopathological diagnosis via a formal biopsy is the gold standard prior to further investigation and treatment. An incisional biopsy is preferred. It is important to avoid necrotic areas, and a narrow deep biopsy is more useful than a shallow broad one. Other biopsy techniques such as exfoliative cytology and brush biopsy lack sensitivity and are therefore not commonly employed.

Neck lump

Fine-needle aspiration cytology (FNAC) is the first-line biopsy for the investigation of neck lymphadenopathy. This technique carries a sensitivity of 89–98%. It will help in differentiating between thyroid malignancy, oropharyngeal and oral cavity lesions (utilising HPV diagnostic tests) and lymphoma.

Imaging

Contemporary cross-sectional imaging techniques are essential in the management of head and neck cancer. They inform treatment decisions and prognosis. CT and/or MRI are the gold standard imaging modalities to stage a tumour of the oral cavity. Plain film radiography and ultrasonography, along with positron emission tomography–computed tomography (PET-CT) are useful adjuncts. The aims of imaging are as follows:

- outline the anatomical extent of the primary tumour (T stage), as well as the 'resectability' of the tumour based on its relationship to vital structures;

- detection of locoregional metastases;
- detection of metastatic disease precluding cure;
- detection of synchronous primary tumours of the lung and upper aerodigestive tract;
- monitoring of disease response following non-surgical treatment and for detection of disease recurrence.

Computed tomography

Contrast-enhanced CT (CECT), typically modern multi-detector slice computed tomography (MDCT), is a commonly available staging tool. This offers the advantage of rapidly acquired spatially accurate cross-sectional images. Hard-tissue detail is a particular advantage of CT, relative to MRI; this is particularly important when assessing bony involvement (mandible/maxilla) in oral SCC. CT is also the usual imaging modality for thoracic staging.

Magnetic resonance imaging

By comparison with CT, MRI has improved soft-tissue contrast resolution and, depending upon specialist radiologist preference, it is frequently the imaging modality of choice for defining the primary extent of oral cavity cancers. Additionally, it offers more information on perineural spread and bone marrow invasion. T1-weighted 'anatomical' images have good spatial resolution, while T2-weighted images preferentially highlight oedema and therefore pathology.

MRI has a sensitivity of 82% and specificity of 66.7% for the detection of bone/bone marrow invasion in the mandible. The ability of MRI to detect neck metastases is comparable to that of CT.

Positron emission tomography combined with computed tomography

PET-CT is not a first-line imaging investigation for head and neck cancer and its use is usually restricted to detection of distant metastases or synchronous tumours, investigation of tumours of unknown primary and post-treatment surveillance.

Plain film and panoramic radiographs

Plain film or panoramic radiographs can be helpful in defining gross bony involvement during tumour staging; however, their main utility is for evaluation of the dentition to plan essential prophylactic dental treatment and highlight infection or inflammation.

Ultrasound

Ultrasonography is a non-invasive, chair-side investigation that is now most commonly used to guide FNAC sampling of suspicious lymph nodes. It is operator dependent but in experienced hands is very useful in the detection of lymphadenopathy. It is of limited value in investigation of oral cavity tumours. It has 85% sensitivity and 78.9% specificity for cervical lymphadenopathy.

Sentinel lymph node biopsy

Sentinel lymph node biopsy (SLNB) has become a recognised technique to support staging of the neck in patients who do not have clinical or radiological evidence of lymph node metastases (cN0). The sentinel node is the first node to which cancer cells are most likely to spread. SLNB seeks to determine the presence of nodal metastasis within the first draining node(s) and guides the necessity (or otherwise) for further treatment of the neck.

There is robust evidence that, in patients with a T1/2 oral cavity SCC, performing a prophylactic elective neck dissection as opposed to adopting a 'watch and wait' policy leads to superior overall and disease-free survival.[3] However, not all patients will have nodal metastases and as such provision of a neck dissection for all will inevitably result in overtreatment of a significant proportion. SLNB can be utilised to highlight those patients with occult metastases and who can then proceed to formal neck dissection. Additionally, SLNB may demonstrate unexpected contralateral lymph node drainage that would not otherwise have been identified or treated. Despite its potential benefits, the SLNB technique has a false-negative rate of 14%.[4] To date, evidence providing a comparative analysis of elective neck dissection versus SLNB (where survival is the primary end point) is still lacking.

SURGICAL MANAGEMENT

Surgery, with adjuvant radiotherapy (or chemoradiotherapy) if indicated, remains the mainstay for management of oral cavity cancer. Over time, surgical techniques have evolved to become more refined with a greater emphasis on function-sparing techniques and a move away from more radical procedures. Reconstruction of postablative defects with an associated improvement in quality of life is a cornerstone of the surgical management of oral cavity cancer. This evolution in surgical management has been influenced by an improved understanding of tumour biology, more accurate staging investigations and microvascular free tissue transfer reconstruction. Overall and disease-specific survival is largely dictated by tumour biology, with features such as nodal metastases with ENE of greatest importance. Notwithstanding this, surgeons can optimise the outcome for patients by considering the following principles:

- patient selection;
- key surgical decisions;
- reconstruction;
- multidisciplinary care.

Patient selection

As outlined previously, patients' comorbidities and functional status as well as their social circumstances play a significant role in their ability to tolerate surgery and rehabilitation. The early involvement of an MDT including physicians, anaesthetists, physiotherapists and dieticians is important particularly in high-risk patients in order to optimise their performance status preoperatively.

The 'operability' of a tumour is determined largely by its size and relationship to important anatomical structures of the head and neck. In the AJCC eighth edition TNM staging system T4b tumours are those that may be unresectable owing to involvement of or proximity to the skull base, masticator space, pterygoid plates and/or the internal carotid artery.

Key surgical decisions

Once the decision has been made that surgery is appropriate, a few key decisions are to be made. These are as follows:

- airway management;
- access to the tumour;
- tumour resection;
- management of the neck;
- reconstruction.

Airway management

Airway management in patients undergoing surgery for OCSCC is largely centred on protecting the airway against acute embarrassment in the perioperative period. The available options are immediate postoperative extubation, overnight intubation/delayed extubation, submental intubation and tracheostomy. The choice of airway is a joint decision made between the anaesthetist and surgeon, and is influenced heavily by the ability to re-establish a patient's airway quickly should a life-threatening event occur. Immediate postoperative extubation is generally reserved for smaller well-lateralised tumours in uncomplicated patients who may not require reconstruction. In selected patients, overnight intubation is considered when tracheostomy is unlikely yet can still be sited on postoperative day 1 if warranted; this approach is burdensome on resources given the higher level of care for the first night, but it reduces length of stay via a quicker restoration of speech and swallow.

A low threshold for placing a tracheostomy is appropriate in patients having a bilateral neck dissection or previous neck dissection; large resection with reconstruction; and in patients with a difficult airway. Consideration should also be given to placing a tracheostomy in patients having a segmental mandibular resection; lateralised resections involving the floor of mouth and reconstruction; as well as previously irradiated patients.

Access surgery

The goal in surgical management of OCSCC is to remove the tumour with an adequate margin circumferentially. While most tumours can be removed via a transoral approach, some cannot be resected safely without an access procedure. These might include large maxillary tumours, posteriorly located tumours and tongue base tumours, or patients who have previously had surgery and/or radiotherapy. The most commonly used access procedures include the lip-split mandibulotomy (LSM) (***Figure 53.5***), the mandibular lingual release, the visor flap and the Weber–Fergusson approach (***Figure 53.6***), which provides excellent access to the maxilla and, if extended infraorbitally, to the periorbital area.

Lip-split mandibulotomy

This is the most commonly used access procedure and provides excellent access to the posterior oral cavity, tongue base and oropharynx. It involves making an osteotomy in the mandible in order to 'swing' it laterally, thereby facilitating access. Care must be taken to ensure that the lingual mucosa does not tear in an uncontrolled fashion towards the tumour resection margin.

Tumour resection

The gold standard in OCSCC is resection with a 1-cm clinical margin circumferentially, vital structures permitting.

Mandibular resection

Decisions regarding management of the mandible when tumour lies close to, abuts or invades the bone are critical. If there is evidence of infiltrative bone invasion, either segmental or rim resection of the involved mandible is required.

Segmental resection involves removing the full height of the invaded section of the mandible such that there is loss of continuity of the lower border. Rim resection or 'marginal mandibulectomy' involves removing a partial thickness of mandible such that continuity of the lower border remains. A rim resection is sometimes performed when a tumour lies close to but does not definitively invade the mandible, in order to achieve a satisfactory soft-tissue margin.

Maxillary resection

Owing to anatomical differences such as thinner bone, the presence of sinuses, tightly adherent palatal mucosa and proximity to the orbit and skull base, maxillary resection considerations differ from those in the mandible. Small tumours of the maxillary alveolus can be managed by transoral partial maxillectomy. More extensive tumours involving the floor of the maxillary sinus require wider access by a Weber–Fergusson incision (***Figure 53.6***). If the preoperative investigations demonstrate extension of the disease into the pterygoid space or the infratemporal fossa, the prognosis is poor as surgical clearance is difficult or not possible. Tumour extending into the orbit requires simultaneous orbital exenteration or, in some instances, a combined neurosurgical resection. The various methods of maxillary reconstruction can be guided by the extent of resection and tissues involved. Reconstruction seeks to provide an oral seal and restore facial profile and tissue loss, while facilitating a means to achieve dental rehabilitation.

Management of the neck

In surgical terms, 'management of the neck' refers to a neck dissection – elective or therapeutic. In patients with clinical and/or radiographic evidence of cervical metastases, treatment of the neck in the form of a therapeutic neck dissection is indicated (primary radiotherapy is less common). In patients with early-stage disease and in whom there is no clinical or radiographic evidence for cervical metastases, there is now strong evidence showing that patients who have an up-front or elective neck dissection have better overall and disease-specific survival relative to patients who have a 'watch-and-wait' policy and a therapeutic neck dissection only when a metastasis becomes apparent.[5] SLNB can be utilised as a staging investigation to better guide the indications for a neck dissection in the setting of a small tumour where occult metastases may still be present.

Over the last 100 years, neck dissections have evolved to achieve a less radical extent as evidence emerged for the oncological safety of more selective or nuanced procedures.[6] For elective neck dissections, a selective neck dissection involving

Sir William Fergusson, 1808–1877, Scottish surgeon, described and published a modification of the original Weber incision to access the midface.

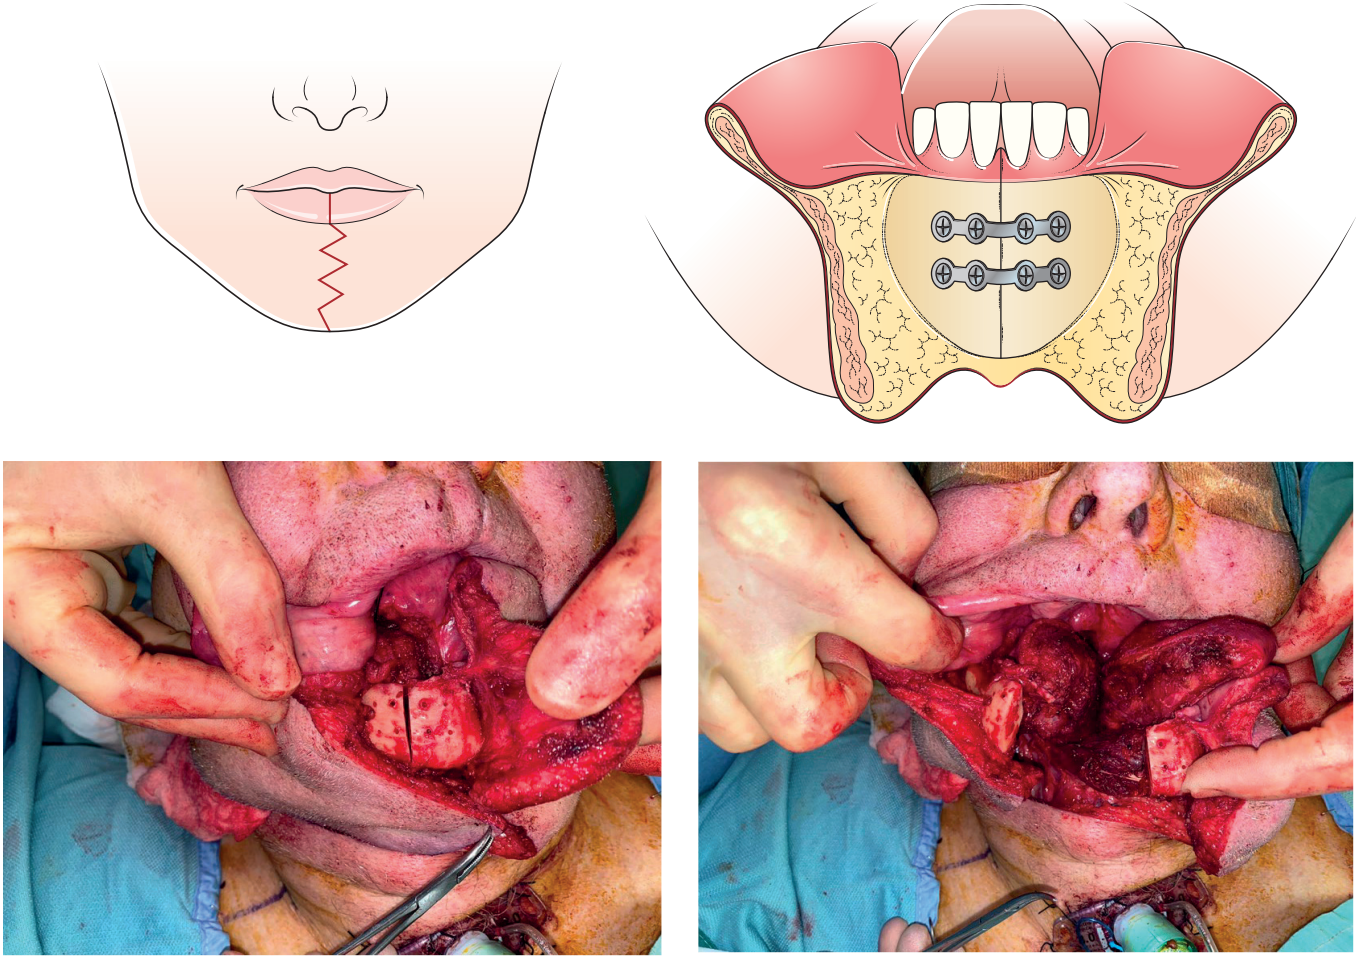

Figure 53.5 Lip-split mandibulotomy.

levels I–III of the neck is indicated for the management of OCSCC.[7]

A neck dissection is performed not only to stage a disease and aid prognosis, but also for therapeutic purposes as well as informing the need for adjuvant therapy. Additionally, it provides access to recipient vessels within the neck, which may be used in microvascular free tissue reconstruction.

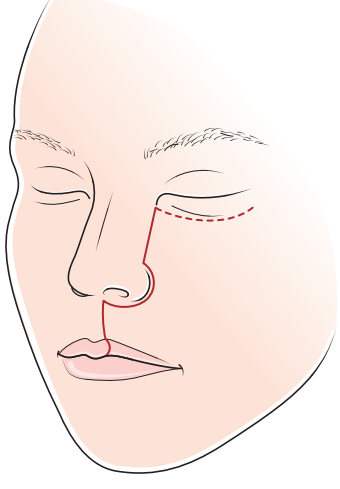

Figure 53.6 Weber–Fergusson approach.

Reconstruction

Reconstruction following tumour ablation is a key component in the management of OCSCC. Decision making with regards to reconstruction should not influence the ablative procedure. Notwithstanding the importance of facial aesthetics, preservation or restoration of speech, chewing, swallow and oral continence are of paramount importance. The oral cavity is a unique site. It contains hard and soft tissues, including the dentition, is bathed in saliva and is anatomically complex. It is the opening to the aerodigestive tract and has a multitude of motor and sensory nerves. Like any defect, reconstruction of the oral cavity should aim to replace resected tissue with similar tissue. The reconstruction ladder (***Figure 53.7***) is a useful algorithm and can be applied to the oral cavity.

Additionally, general reconstruction principles apply: namely, use the simplest method that will meet reconstruction aims, replace lost tissue with similar tissue, consider vascularised tissue in a previously irradiated recipient site and always have an alternative should your primary reconstruction fail.

- Healing by secondary intention
- Primary closure
- Skin grafting
- Local flaps
- Regional flaps
- Microvascular free tissue transfer

Figure 53.7 The reconstruction ladder.

While free tissue transfer ('free flaps') has revolutionised reconstruction following ablation of an OCSCC, there are instances, for example owing to patient comorbidities, where a local or regional flap is appropriate.

Owing to the extensive and consistent blood supply in the head and neck, local flaps in this region are safe and predictable. Smaller defects not requiring substantial soft tissue or bone for reconstruction can be reliably reconstructed with flaps such as, but not limited to, the facial artery myomucosal (FAMM), nasolabial, buccal fat pad, tongue and palatal flaps. Regional and pedicled flaps include tissue(s) from other parts of the head and neck, such as the temporalis and platysma flaps, as well as those from more distant sites such as the latissimus dorsi, deltopectoral and pectoralis major flaps.

Free flaps

A free flap is a portion of vascularised tissue harvested from a distant donor site and transferred to an area requiring reconstruction where its artery and vein are anastomosed locally, thereby providing an independent blood supply. Most tissue types, including skin, fascia, muscle, tendon and bone, can be harvested. Therefore, within the oral cavity both bone and soft tissue can be replaced with similar tissue(s).

Soft-tissue reconstruction

In oral cavity reconstruction, common soft-tissue flaps used include the radial forearm free flap (RFFF; ***Figure 53.8***) and anterolateral thigh (ALT) flap. Alternative soft-tissue free flaps include rectus abdominis, latissimus dorsi, medial sural artery perforator and lateral arm flaps. The relative merits of these flaps are outlined in ***Table 53.5***.

Composite reconstruction

The fibula is the most commonly used bone-containing (composite) flap globally, while the iliac crest (DCIA), scapula (including tip of scapula) and composite RFFFs are also used, each carrying specific pros and cons. Chimeric flaps, where osseous and soft-tissue components are independently mobile (e.g. the thoracodorsal system of free flaps), are advocated for certain complex reconstructions. The relative merits of the more common composite flap donor sites are outlined in ***Table 53.6***.

Reconstruction by anatomical subsite

Soft-tissue reconstruction

Intraorally this includes the tongue, floor of the mouth, buccal and retromolar mucosa as well as the soft palate. As outlined previously the most commonly used soft-tissue flaps are the RFFF and ALT. The RFFF provides a thin, non-hirsute and pliable flap with a long vascular pedicle and so can be useful where significant bulk is not required. The ALT (***Figure 53.9***), however, owing to its increased bulk, is far more suited to tongue reconstruction where bulkiness is crucial in creating a seal between the oral cavity and soft palate during speech and swallowing. The ALT also facilitates multiple skin paddles and/or muscle components, where necessary.

TABLE 53.5 Relative merits of common soft-tissue flaps.

Donor site	RFFF	ALT	MSAP	TDAP	Lateral arm	Rectus	LD
Donor site morbidity	+++	++	++	++	++	+++	++
Pedicle length	++++ 18 cm	+++ 12 cm	++ 10 cm	++++ 15 cm	+ 6 cm; increased with ELAF	+ 7 cm	++ 8.5 cm
Quality of vessels	++++	+++	+++	++++	++	++++	++++
Diameter	Artery: 3 mm Vein: 1.5 (3 mm if cephalic) No atherosclerosis	Artery: 2.1 mm Vein: 2.3 mm	Artery: 1.25 mm Vein: 2 mm	Artery: 2.7 mm Vein: 3.4 mm No atherosclerosis	Artery: 1.5 mm Vein: 2.5 mm	Artery: 3.5 mm Vein: 4 mm	Artery: 2.7 mm Vein: 3.4 mm No atherosclerosis

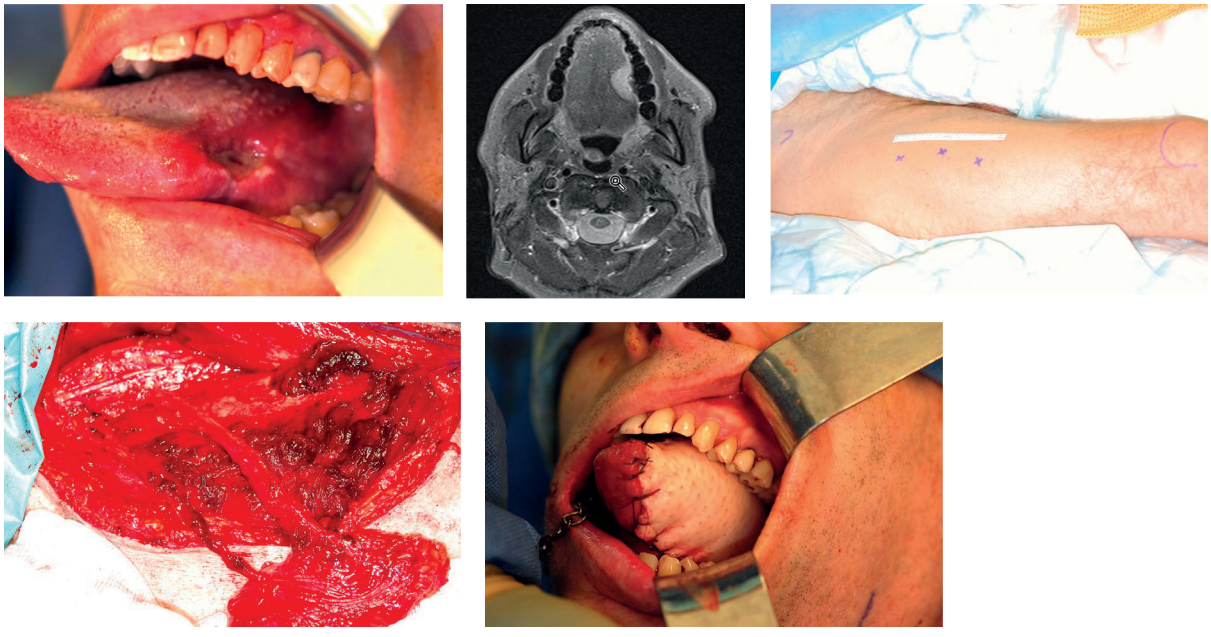

Figure 53.9 The use of an anterolateral thigh flap to reconstruct a left partial glossectomy/floor of the mouth ablative defect.

Mandible reconstruction

Reconstruction with composite free flaps is now the gold standard for segmental mandibular defects (***Figures 53.10 and 53.11***). The choice of flap is varied and depends on factors including the site, size and complexity of the defect, patient comorbidities and indeed surgeon training and preference.

While it is possible to leave small posterior sites unreconstructed, reconstruction of an anterior defect is particularly important, and challenging, in order to achieve satisfactory function for the patient.

The following general principles may help to plan mandibular reconstruction:

- reconstruction of the anterior mandible is always more challenging;
- although the lengths of the bone and pedicle are often cited as factors in choosing the donor site, the average defect is 6–10 cm and usually immediately adjacent vessels for microvascular anastomosis mean that these are not usually an impediment;
- use the curvature of the chosen bony flap to follow the natural shape of the mandible, thereby reducing the number of potential osteotomies;
- in an edentulous case, it may be helpful to slightly reduce the span of the mandibular segment to avoid a resultant class III appearance, where the mandible protrudes beyond the opposing maxilla, giving a very prominent chin position;
- free bone can become a nidus for persistent infection, particularly following radiotherapy.

Maxillary reconstruction

The main aims of maxillary reconstruction are as follows:

- restore facial contours and aesthetics;
- separate sinonasal cavities from the mouth;
- restore soft palate competence to facilitate speech and swallowing;
- restore/provide for replacement of dentition.

A classification system for maxillary defects is useful for both treatment planning and discussion with colleagues. The most widely adopted classification is that proposed by Brown and Shaw; this classification considers both the vertical and horizontal extent of the defect. Classes I–VI (***Figure 53.12***) describe the increasing size in a vertical dimension, while the horizontal extent is described by the letters a–c. Although not absolute, one of the advantages of this classification system is that it implies management.

Class I defects are easy to repair with the only reconstructive requirement being to separate the oral and nasal/antral cavities. Local flaps are often satisfactory, and the RFFF is the most commonly used free flap. Class II defects can be restored in a similar fashion to class I, especially when more posteriorly located. However, composite (bone-containing) free flaps are usually required for anterior defects, and class IIc defects, as well as situations where the existing dentition is not adequate to retain a prosthesis.

In classes III and IV, support for the contents of the orbit is lost, as well as support for the anterior cheek and alveolus. A prosthesis alone will provide a suboptimal result. The reconstructive goals are to support the orbital contents and facial skin, ensure bony continuity between the remaining alveolus and zygomatic buttress (ideally sufficient to facilitate endo-osseous implant placement), as well as seal the oral and nasal cavities. Therefore, a composite free flap (e.g. the thoracodorsal free flap) is suitable for fulfilling these requirements.

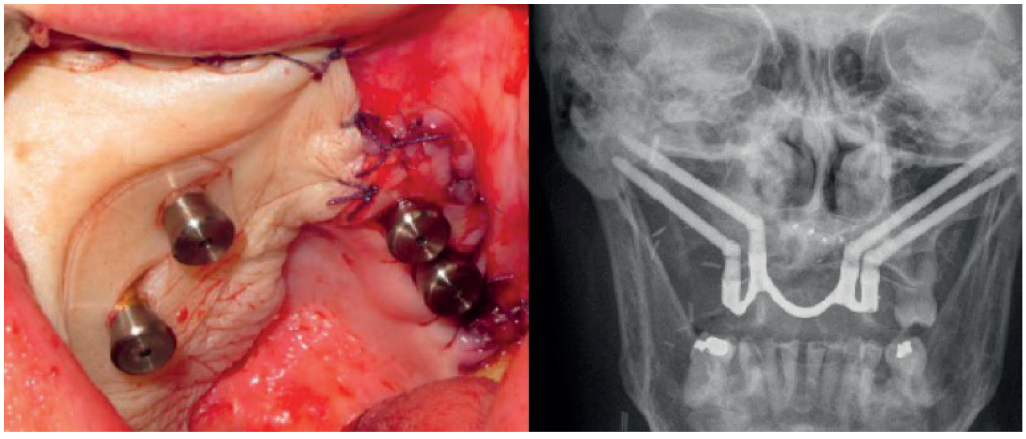

Figure 53.13 A zygomatic implant perforator used to reconstruct a left hemi-maxillectomy defect (courtesy of Prof. C Butterworth).

Evolution in zygomatic implant technology can support prosthetic rehabilitation and restoration of low-level maxillectomy defects in combination with soft-tissue flaps. In select cases, this can remove the necessity for composite free flaps.

It should be pointed out that prosthetic reconstruction, using an obturator denture, of a maxillary defect remains a reasonable and sometimes appropriate alternative to free tissue reconstruction. However, studies have shown that free flap reconstruction results in improved functional and aesthetic outcomes when compared with prosthetic obturation.

Zygomatic implants and zygomatic implant perforator (ZIP) flaps

Zygomatic as well as oncological or co-axis implants, used in conjunction with a fixed or removable prosthesis, or indeed with a free flap, have improved our ability to quickly restore dentition post maxillectomy. Recently, the use of zygomatic implants that perforate a soft-tissue free flap (used to close an oroantral/oronasal communication) and placed immediately after tumour ablation has been described (***Figure 53.13***).

Virtual surgical planning

The use of virtual surgical planning (VSP) in oral cavity reconstruction is increasing. Potential benefits include reduced operating time, greater accuracy and improved aesthetic/functional outcomes.

Patient-specific surgical stents and cutting guides for both the tumour and donor sites are made preoperatively, based on CT scans and software (***Figure 53.14***). The surgeon performs the surgery virtually; based on the resection and therefore the size and shape of reconstruction required, cutting guides are provided for both the oral resection and donor site harvesting (***Figure 53.15***). Prefabricated reconstruction plates can also be made.

ADJUVANT THERAPY FOR THE MANAGEMENT OF ORAL CAVITY CANCER

While primary chemoradiotherapy can be offered to patients who are unsuitable for or refuse surgery, primary surgery, with/without adjuvant (chemo)radiotherapy, is the standard

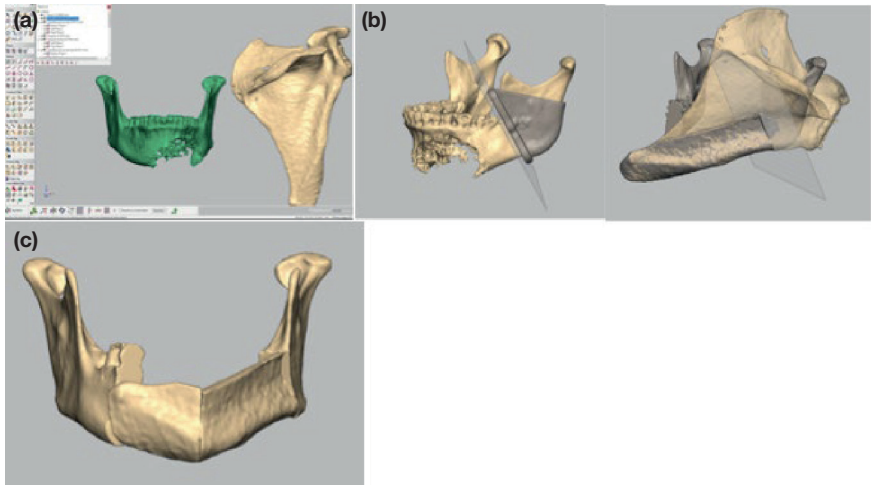

Figure 53.14 Virtual surgical planning. **(a)** A virtual mandible (green) with an obvious bony defect. **(b)** The resection cutting plane with the scapula overlaid. **(c)** The final reconstruction plan with a two-part (osteotomised) scapula osseous component.

treatment for oral cavity cancer. Adjuvant therapy is given based on pathological features of the tumour. Radiotherapy is administered typically via external beam radiotherapy. In high-risk cases, chemotherapy (usually cisplatin-based) is included as a radiosensitiser within the adjuvant regime for suitably fit patients.

As outlined in previous sections, the adverse pathological features associated with locoregional recurrence and decreased overall and disease-specific survival include ENE, close/involved margins, LVI and PNI. It is these, among other, adverse features that inform the decision to administer adjuvant therapy.

While there is no absolute international agreement regarding the criteria for radiotherapy, the current consensus is that one major criterion (ENE and/or involved margin [<1 mm]) or two minor criteria (close margin [1–4.9 mm], multiple involved nodes, largest node >3 cm, LVI/PNI, T3/4) would indicate the need for adjuvant radiotherapy.[8]

Adjuvant chemoradiotherapy

The landmark RTOG 9501 and EORTC 22931 randomised trials form the basis for the contemporary role of adjuvant chemotherapy (CRT) in high-risk OCSCC (although only 25%

of recruited patients had OCSCC). These studies looked at the benefit conferred by adding high-dose cisplatin to conventional postoperative radiotherapy (RT), with primary end points of locoregional control and progression-free survival, respectively. Positive surgical margins and extracapsular extension (ECE; now ENE) were used to classify patients as high risk in both studies, while several other criteria unique to each were also investigated. Ultimately, and following several associated long-term, subgroup and pooled analyses, these trials provided strong evidence for the use of concurrent cisplatin-based CRT in high-risk patients.

Immunotherapy

Antitumour immunotherapy is based on the principle that tumours can sometimes escape immune response/checkpoints owing to adaptations in immune surveillance and the tumour microenvironment. Immunotherapy represents a change in the treatment paradigm.

The pathway of the programmed death receptor-1 (PD-1) and its ligand (PD-L1) has become an increasingly important target for immunotherapy in HNSCC. The receptor–ligand interaction is a major mechanism used by tumours to evade the immune system. Multiple randomised phase III trials have demonstrated that exposure to a PD-1 inhibitor prolongs survival in recurrent or metastatic HNSCC.

These results, among others, highlight the potential for research assessing the role of checkpoint inhibition in the management of HNSCC.

MANAGEMENT OF RECURRENT AND/OR METASTATIC DISEASE

Patients with a low burden of disease or oligometastatic deposit(s) and a satisfactory performance status can be offered salvage surgery and/or radiotherapy with curative intent. Patients with a recurrence not amenable to surgery and/or radiotherapy are eligible for systemic treatment. Current standard of care options depend on previous exposure to platinum-containing chemotherapy, but include both immunotherapy and palliative chemotherapy regimens. Nonetheless, the poor prognosis for these patients remains.

CHAPTER
54 Disorders of the salivary glands

Learning objectives

To understand:

- The surgical anatomy of the salivary glands
- The presentation, pathology and investigation of salivary gland disease
- The medical and surgical treatment of various pathologies affecting the salivary glands

INTRODUCTION

The parotid, submandibular and sublingual glands are the three paired major salivary glands; the minor salivary glands are multiple and situated mainly in the lips, buccal mucosa, tongue and palate, but they can be present anywhere along the aerodigestive tract. Obstructive and inflammatory conditions, tumours and autoimmune-mediated conditions affect these glands.

Saliva is an important secretion that performs a number of essential functions, such as clearing substances from the mouth, maintaining pH and tooth mineralisation and influencing the oral microbiome, which protects the body and helps with wound healing. Moreover, saliva not only neutralises some harmful dietary components but also lubricates and hydrates oral mucosal surfaces. This has been the topic of study for centuries, with the oldest reference to salivary glands, and more specifically to saliva, found in clay tablets at the Akka Library, which was created by the Assyrian King Assurbanipal from old Mesopotamia around 2500 BCE. It even referred to the use of the plant belladonna for curing excessive salivary flow.

CLINICAL ANATOMY AND EMBRYOLOGY

The parotid, submandibular and sublingual glands are three paired glands whereas there are innumerable minor salivary glands (***Figure 54.1***). The glandular architecture is essentially a series of ducts that open into the oral cavity and are surrounded by acini, which produce the saliva. The extracellular matrix includes the myoepithelial cells, myofibroblasts, immune cells, endothelial cells, stromal cells and nerve fibres. The parotid is ectodermal in origin, while the submandibular and sublingual glands are endodermal. The parotid represents the largest of the salivary glands and is situated in front of the external acoustic meatus between the ramus of the mandible and the sternocleidomastoid muscle. Each gland is encapsulated and is composed of fat and cells that secrete mainly serous fluids. The major duct of the parotid gland is called Stensen's duct, which opens into the vestibule of the mouth opposite the crown of the upper second molar tooth, while the submandibular duct is Wharton's duct, which opens into the floor of the mouth paramedian to the frenulum. The parotid gland, being primarily serous, secretes watery saliva while the rest are mixed serous and mucinous glands.

Summary box 54.1

Surgical anatomy of the salivary glands

- Three pairs of major salivary glands – parotid, submandibular and sublingual
- Approximately 800 minor salivary glands

Parotid gland

Understanding a gland's development gives us insight into the pathophysiology of the various disorders afflicting it. The parotid gland is ectodermal in origin and develops in the sixth week of gestation, when the epithelial buds invaginate from the oral mucosa into the surrounding mesenchyme. A tunnel develops from this groove and the gland is formed at its blind end by proliferation, budding and extensive branching. The secretory acini develop from the epithelial tissue, whereas the capsule of the gland and the connective tissue develop from the mesenchyme. The parotid, unlike other glands in the body, does not become encapsulated early to form a regular gland. The other structures in the vicinity, including the vessels, nerves and lymphatics, develop before encapsulation. The gland goes on to

Niels Stensen, 1638–1686, Danish anatomist, natural scientist and theologist.
Thomas Wharton, 1616–1673, physician, St Thomas' Hospital, London, UK, described the submandibular duct in 1656.

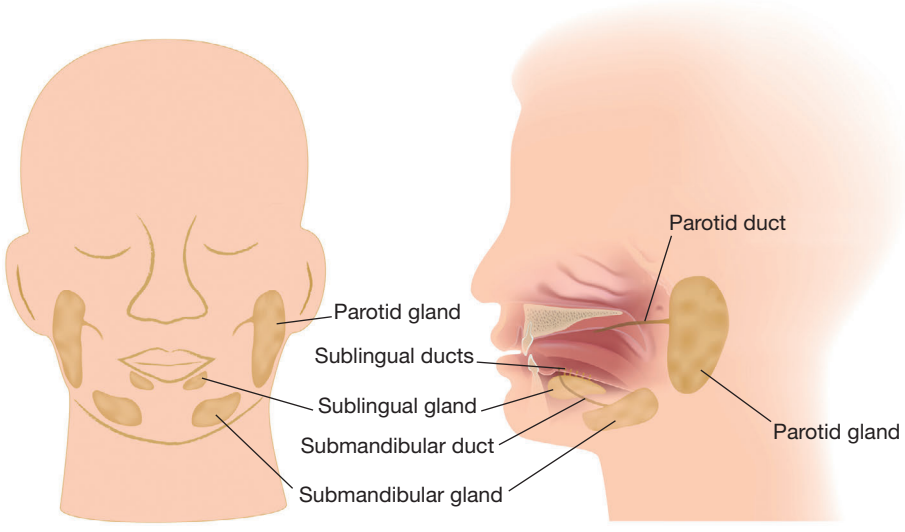

Figure 54.1 Anatomical position of the three major salivary glands.

envelop the facial nerve, the terminal branches of the external carotid artery, the retromandibular and superficial temporal vein and the lymph nodes. The capsule thus merges with the investing fascia from the zygoma, over the temporomandibular joint and the masseter and reaches the styloid base, posterior digastric belly and the sternocleidomastoid muscle. The superficial musculoaponeurotic system is closely approximated to this capsule. The parotid gland is, thus, irregular in shape and wedged in a recess between the ramus of the mandible, the base of the skull and the mastoid process.

The parotid (Stensen's) duct passes over the masseter muscle and enters the buccal mucosa through the buccinator muscle at the level of the upper second molar tooth. In some cases, an accessory gland is found along the course of the duct. Salivary tissue that is separated from the main parotid gland is referred to as an accessory parotid gland. These lie on the masseter muscle in front of Stensen's duct and have a secondary duct joining Stensen's duct. According to autopsy studies, the incidence of an accessory parotid gland is 21–61%. Embryologically, the growing, budding salivary glands originate from the oral cavity epithelium outwards into the mesenchyme as it differentiates into the various facial structures. The late completion of parotid gland encapsulation needs to be considered when planning surgery for accessory gland pathology that might also require removal of a superficial parotid gland. Following superficial parotid gland removal, the remnant unencapsulated acinar system in the glandular structure may also account for sialocele formation (a localised cavity or cyst containing saliva). Also after parotid gland surgery the acinar system with its ductules can be exposed to the wound, resulting in breakdown and leakage of saliva with fistula formation.

The facial nerve gets enveloped within the substance of the gland as it grows laterally, dividing the parotid gland into the superficial and deep lobes. Generally, the major functional component (80%) is superficial whereas the deep lobe is usually the retromandibular component with minimal functional gland tissue.

The lymphatic system develops within the parotid glandular tissue after encapsulation of the submandibular and sublingual glands. This results in the majority of the lymphatic structures, including the lymph nodes, being embedded within the parotid. The retromandibular vein, which drains these lymphatics, generally lies deep to the facial nerve and is a constant landmark that is useful during the retrograde method of identification of the main trunk of the facial nerve. Most of the lymph nodes lie in the superficial (preauricular) lobe of the parotid gland lateral to the masseter while very few lie in the deep (retromandibular) lobe of the parotid.

Summary box 54.2

Parotid gland

- Parotid gland and minor salivary glands are ectodermal in origin whereas the submandibular and sublingual glands are endodermal
- Parotid gland develops in the sixth week but has delayed encapsulation
- Facial vessels, facial nerve and lymphatic tissue are embedded in the substance of the parotid gland before the capsule fuses

Parotid innervation and Frey's syndrome

The glossopharyngeal nerve (cranial nerve IX) carries preganglionic parasympathetic fibres from the inferior salivatory nucleus. The Jacobson nerve, a branch of cranial

Lucja Frey, 1896–1944, physician, The Neurological Clinic, Warsaw, Poland.
Ludwig Levin Jacobson, 1783–1843, Danish anatomist.

nerve IX, enters via the inferior tympanic canaliculus to form the tympanic plexus in the middle ear. The lesser petrosal nerve carrying the preganglionic fibres from here exits via the foramen ovale, where it synapses with the postganglionic secretomotor parasympathetic fibres in the otic ganglion. These fibres exit the otic ganglion and join the auriculotemporal nerve in the infratemporal fossa, which innervates the parotid gland for the secretion of saliva.

Within the gland, acetylcholine (ACh) stimulates both acinar activity and ductal transport, leading to vasodilatation of the glands and contraction of the myoepithelial cells. Atropine decreases salivation by competing with ACh for the salivary receptor site and is useful in reducing salivary secretion. Regeneration of parasympathetic fibres to the sweat glands leads to abnormal autonomic reinnervation. ACh can act as a neurotransmitter for both postganglionic sympathetic and parasympathetic fibres; this might contribute to 'gustatory sweating' (Frey syndrome), which involves sweating and flushing of the skin overlying the parotid region while eating in some patients following parotidectomy.

Submandibular gland

The submandibular glands originate from the junctional tissue between ectoderm and endoderm from the floor of the mouth. They grow from the 18th to the 25th embryonic week and acquire connective capsules.

They lie in the submandibular space between the digastric muscles and extend upwards deep to the mandible. They consist of a larger superficial and a smaller deep lobe that is continuous around the posterior border of the mylohyoid muscle. The deep part of the gland lies on the hyoglossus muscle in close relation to the lingual nerve. The submandibular ganglion innervates the submandibular gland by the postganglionic parasympathetic fibres from the superior salivatory nucleus of the pons, through the chorda tympani and lingual nerve. The ganglion connections are required to be separated to free the gland and preserve the lingual nerve during excision.

The gland is surrounded by a well-defined capsule derived from the deep cervical fascia, which splits to enclose it. Wharton's (submandibular) duct lies between the hyoglossus and mylohyoid muscle after arising from the deep part of the gland. It drains at the sublingual papilla into the anterior floor of the mouth. The facial vein lies superficial to the gland to reach the anterior border of the mandible. The facial artery enters deep to the posterior belly of the digastric and stylohyoid muscles and passes through or superficial to the gland to reach the anterior border of the mandible. The glandular branches need to be ligated when preserving the facial artery during submandibular gland removal. The facial artery is commonly used as the recipient artery in microvascular anastomosis in free tissue transfer in head and neck reconstruction. The marginal mandibular branch of the facial nerve lies in the superficial fascia, traversing over the facial vessels. Martin described the technique of ligating these vessels and flipping them above in order to preserve the mandibular division of the facial nerve during neck dissection.

Sublingual gland

The sublingual glands contribute around 5% of saliva production and are the smallest of the major salivary glands. They lie above the mylohyoid muscle and below the floor of mouth mucosa and are bordered by the mandible laterally and by the genioglossus muscle medially. Their secretions are drained by small ducts (Rivinus's ducts) that exit along the sublingual fold at the floor of the mouth. A few anterior ducts may join together to form a common duct called Bartholin's duct, which empties close to or into Wharton's duct near the sublingual caruncle.

The pathology of the sublingual glands mainly involves the formation of a mucous retention cyst (ranula). Tumours of sublingual glands are very rare.

Summary box 54.3

Sublingual gland

- Problems are rare
- Minor mucous retention cysts may need surgery
- A plunging ranula is a retention cyst that tunnels deep
- Nearly all tumours are malignant

Minor salivary glands

Minor salivary glands appear at about the 12th week of gestation, forming directly from upper respiratory ectoderm. They develop as individual units with simple tubuloacinar systems.

The minor salivary glands lack a distinct capsule and merge with the surrounding connective tissue in the submucosal region. They are widely distributed in the head and neck region and are mainly located (70–90%) in the oral cavity and oropharynx, including the palate, the tongue, the lips, the buccal mucosa and the retromolar trigone. The other sites are the nose, paranasal sinuses, pharynx and the larynx. They contribute 8–10% of the saliva and play a major role in saliva production during sleep.

COMMON DISORDERS

Mucoceles

Extravasation mucoceles and retention cysts are formed by mucous extravasation. Both have similar clinical features but variable distinct pathogenesis (***Figure 54.2***).

Hayes Martin, 1892–1977 Attending Surgeon, Memorial Hospital; Chief, Head and Neck Surgery, Memorial Sloan Kettering Cancer Centre; Professor of Surgery, Cornell University Medical College, New York, NY, USA.
Augustus Quirinus Rivinus, 1652–1723, German physician and botanist, studied the anatomy of salivary glands and also developed ways of classifying plants.
Thomas Bartholin, 1616–1680, Professor of Anatomy, Copenhagen University, Copenhagen, Denmark.

Figure 54.2 Mucous retention cyst. A translucent swelling on the lower lip is typical.

Extravasation mucocele

Trauma to the minor salivary gland duct causes accumulation of saliva in the surrounding connective tissue, followed by an inflammatory reaction. They occur commonly in children and adolescents and are mainly found on the lower lip. A ranula is a type of extravasation mucocele.

Ranula (little frog)

Ranulas, first described by Banister in his surgical compilation of 1585, are caused either by the rupture of the main duct or by the rupture of obstructed acini of the sublingual gland. They appear as a characteristic bluish swelling in the anterior floor of the mouth and resemble the belly or air sac of a frog. They can remain localised or insinuate through the mylohyoid muscle to present as a submental swelling called a 'plunging ranula'. They are usually soft, fluctuant and painless unless infected. Imaging corroborates the clinical diagnosis and aspiration yields the thick sticky saliva that distinguishes them from a lymphangioma (***Figures 54.3 and 54.4***).

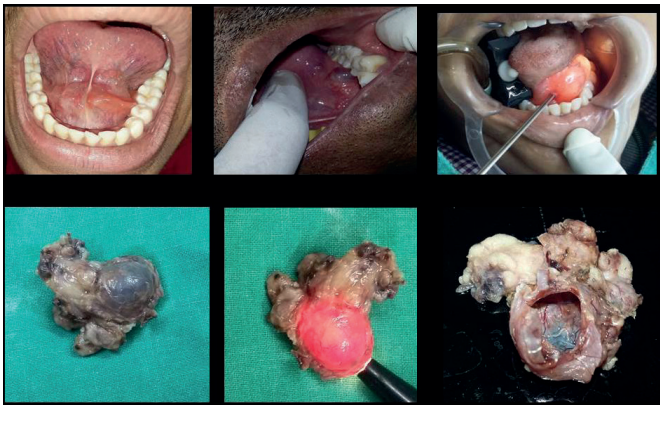

Figure 54.3 Ranulas in the floor of mouth, transillumination and specimen (courtesy of Dr Shirish Ghan, Nasik, India).

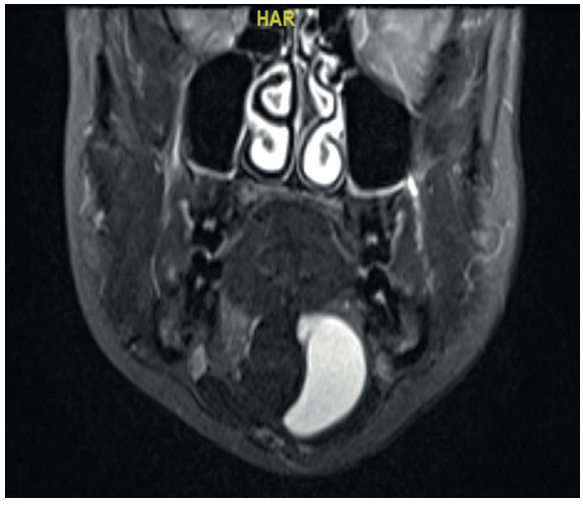

Figure 54.4 Magnetic resonance imaging scan showing a ranula in the floor of mouth.

Treatment should include removal of the sublingual gland as this gland has multiple ducts and ranulas can recur if the gland is left behind. Incision, drainage and marsupialisation have low success rates. Injecting OK-432 at the local site produces inflammation and fibrosis. Injection of botulinum toxin has shown a good success rate but needs further evaluation.

Retention cyst

These result from obstruction of the duct by periductal scars, sialolithiasis (salivary gland stone formation) or pressure from surrounding tissue. These cysts are mainly found in the ductal system of a minor salivary gland. The cyst cavity may contain fragments of a sialolith or mucous material. Some may regress spontaneously but are best treated by surgical excision.

Acute necrotising sialometaplasia

This usually occurs on the palate and primarily affects the minor salivary glands. It initially presents as a swelling that goes on to develop a central crater with rolled out margins, mimicking a malignant ulcer. Clinically it can be mistaken for a malignancy and the biopsy also raises doubt because of the presence of necrosis and hyperplasia. However, the lobular architecture of the glands is generally preserved and the lack of cellular atypia might help the pathologist to reach the right diagnosis. Ultimately, the lesion heals in a few weeks. The exact aetiology is unknown but is suspected to follow trauma or be caused by an injection to that area or by excessive vomiting.

Immunological conditions

Sjögren's syndrome

Sjögren's syndrome (SjS) is a chronic autoimmune disease with lymphocytic infiltration and autoimmune injury to the salivary and lacrimal glands, leading to dryness of the mouth

John Banister, 1533–1610, English anatomist, surgeon and teacher.
Henrik Samuel Conrad Sjögren, 1899–1986, Professor of Ophthalmology, Gothenburg, Sweden, described this condition in 1933.

(xerostomia) and eyes. The understanding of the pathophysiology of the disease is evolving and is a complex interaction among genetic elements, environmental factors and abnormal host immunity. It mainly affects women in the fourth to fifth decades, who present with enlargement of the salivary glands, especially the parotid. Typically there is a delay in the time taken to diagnosis of the disease. Studies have shown a delay of 2–6 months between the first consultation and diagnosis. SjS can be considered to have four stages: initiation stage, preclinical stage, asymptomatic SjS stage and overt SjS stage.

Primary SjS is not associated with any illness or disease, whereas secondary SjS is associated with other autoimmune disorders, including systemic lupus erythematosus, rheumatoid arthritis and scleroderma (***Table 54.1***).

With no diagnostic markers, the diagnosis is based on a set of five criteria proposed by the European Alliance of Associations for Rheumatology (EULAR). One of them is a biopsy of the sublabial salivary glands, which shows histological features of focal lymphocytic sialadenitis. The criteria required for diagnosis of SjS involve at least one focus score of more than 50 lymphocytes per 4 mm^2 of parenchymal tissue. Other tests for early diagnosis are evolving; these include testing for increasing levels of biomarkers such as complement C3 and neutrophil elastase in saliva and tears. In addition, identification of traditional antibodies such as anti-nuclear antibodies (anti-SSA/Ro or anti-SSB/La) and rheumatoid factor can also be used. However, a significant proportion of patients with SjS may be seronegative.

Treatment depends on disease activity and the organs involved. Tear substitutes can be used and xerostomia is treated by dental and oral surgeons. Randomised controlled trials have not shown any benefit with hydroxychloroquine or disease-modifying antirheumatic drugs (DMARDs). Treatment with glucocorticoids and/or immunosuppressant drugs should be considered in severe systemic manifestations.

TABLE 54.1 Degenerative disorders of the salivary glands.

Primary Sjögren's syndrome	• More severe xerostomia • Widespread exocrine gland dysfunction • No connective tissue disorder
Secondary Sjögren's syndrome	• Male-to-female ratio 1:10 • Middle age • Underlying connective tissue disorder
Benign lymphoepithelial lesion	• Diffuse parotid swelling 20% bilateral • 5% develop lymphoma

Scleroderma

This is an immunologically mediated disease with complex interactions between the vascular network, inflammatory markers and collagen tissue. It mainly affects adults with a female preponderance. Multiple organs may be affected by excessive deposition of collagen in various organs. While skin is more commonly affected, it can also involve the heart, lungs, kidneys and gastrointestinal tract. Salivary gland parenchyma may be replaced by collagen tissue, leading to clinical xerostomia. Biopsy of a minor salivary gland may be useful for diagnosis.

Sarcoidosis

This is an inflammatory disorder characterised by multiple non-caseating granulomas in multiple systems. A dry cough, fatigue and shortness of breath are its main symptoms. The chest radiograph typically shows bilateral hilar lymphadenopathy and reticular opacities in the lungs. Skin, heart, kidney, eyes, joints, exocrine glands and the central nervous system may be involved. The aetiology is unclear but one proposed mechanism is where an individual with a susceptible genotype is exposed to one or more potential antigens, resulting in a sustained inflammatory response. The disease most commonly occurs in those aged 20–60, in people of African or northern European descent and in those with a family history of the disease. Triggers are thought to include infection (mycobacteria, propionic bacteria and viruses) or exposure to certain chemicals or dust. The function of an organ can begin to be affected as granulomas form and enlarge.

For the salivary glands, the patient can present with a localised tumour-like swelling, usually in the parotid – the so-called sarcoid pseudotumour along with xerostomia. In the absence of other disease, the diagnosis is usually made following surgical excision for a presumed neoplasm. Heerfordt's syndrome is a rare manifestation of sarcoidosis that involves parotid swelling, anterior uveitis, facial palsy and fever.

Ectopic/aberrant salivary gland tissue

The presence of ectopic salivary tissue in the mandible can manifest as circumscribed unilocular osteolytic radiolucency of the jaw, known as a Stafne bone cyst. They are possibly caused by either congenital entrapment of salivary tissue during mandibular development or pressure resorption from the adjacent ectopic salivary gland and facial artery. On orthopantomogram, the size ranges from 0.5 to 2 cm, with a median of 1.2 cm. They are mainly located in the posterior region of the mandible, especially between the first molar and the angle of the mandible. The other sites of ectopic salivary tissue include the cervical lymph nodes, middle ear, parathyroid glands, thyroid gland, pituitary gland, cerebellopontine angle and soft tissue medial to the sternocleidomastoid muscle.

Sialadenitis

Inflammation of a salivary gland can be acute or chronic (***Table 54.2***). Acute causes include viral and bacterial infection. It mainly affects the young adolescent population. Parotid glands are more commonly involved than submandibular glands.

Christian Frederick Heerfordt, 1871–1953, Danish ophthalmologist, described this syndrome in 1909.
Edward C Stafne, 1894–1981, dental surgeon, The Mayo Clinic, Rochester, MN, USA, described these cysts in 1942.

TABLE 54.2 Various causes of acute and chronic sialadenitis.

Acute sialadenitis	Chronic sialadenitis
• Viral: ◦ Mumps ◦ Coxsackie ◦ Cytomegalovirus ◦ Paramyxovirus • Bacterial: ◦ *Staphylococcus aureus* (acute suppurative parotitis)	• Granulomatous: ◦ TB ◦ Cat scratch disease ◦ Actinomycosis ◦ Sarcoidosis • HIV • Abscess (parotid and submandibular) • Recurrent subacute parotitis • Radiation sialadenitis

HIV, human immunodeficiency virus; TB, tuberculosis.

Viral infections are more common than bacterial infections. The causative organisms are most commonly paramyxovirus (mumps), followed by cytomegalovirus, coxsackie virus, human immunodeficiency virus (HIV), parainfluenza virus types I and II, influenza virus A and herpesvirus.

Among bacteria, *Staphylococcus aureus* is the most common organism and usually results in a retrograde spread of infection through the duct. Duct obstruction and xerostomia in the elderly population are predisposing factors. The patient will present with a painful red swelling over the gland region.

Viral sialadenitis is self-limiting in most cases, requiring symptomatic supportive care, while bacterial infection will require antibiotics.

Human immunodeficiency virus sialadenitis

This is mainly characterised by bilateral enlargement of the parotid glands. This may mimic SjS. HIV sialadenitis is usually seen in young individuals with an absence of any serological antibodies, whereas SjS is mainly seen in middle-aged women. The prevalence is between 5% and 10% and it has been postulated that it is more common in women on highly active antiretroviral therapy (HAART) (mainly protease inhibitors).

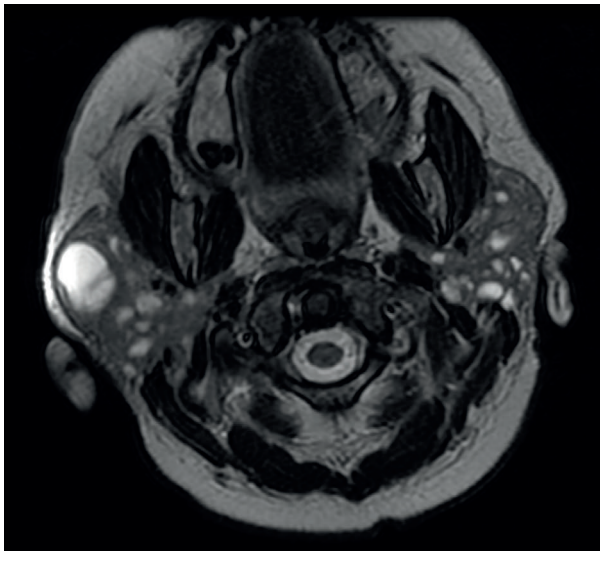

Figure 54.5 Lymphoepithelial cysts in a human immunodeficiency virus-infected patient.

Patients also complain of xerostomia, which may be due to HAART or parenchymal disease of the salivary gland as a result of HIV (***Figure 54.5***).

Biopsy reveals perivascular, periductal and periacinar areas predominantly infiltrated with CD8 cells. Abnormal deposition of fat seen in the parotid gland (parotid lipomatosis) as well as in the abdomen and dorsal cervical areas may be associated with the use of protease inhibitors.

Benign lymphoepithelial cysts are HIV-related reactive lymphoproliferation, which may occur in the intraparotid lymph nodes (***Table 54.1***). The parotid glandular epithelium may get trapped within the normal intraparotid lymph nodes, resulting in cystic enlargement or migration of HIV-infected cells into the parotid gland, which could trigger lymphoid proliferation, salivary duct dysplasia, ductal obstruction and cyst formation. Ultrasonography is usually diagnostic. There may be a rare conversion into lymphoma. Diffuse infiltrative lymphocytosis syndrome manifests with bilateral enlargement caused by constant infiltration of CD8 in the parotid glands.

Summary box 54.4

HIV sialadenitis
- Incidence 5–10%
- More common in women on HAART
- Mimic SjS, but absent antibody
- Infiltration of CD8 in the parotid glands

Recurrent parotitis of childhood

This is characterised by rapid swelling of one or both parotid glands that is aggravated by chewing and eating. Systemic upset with fever and malaise is variable. The symptoms usually last about a week and are followed by a quiescent period for weeks to several months. It is mainly seen between the ages of 3 and 6 years. It is postulated to be caused by an incompetent parotid duct punctum, leading to ductal contamination with oral fluids. The diagnosis is based on the characteristic history. In addition, sialography shows a characteristic punctate sialectasis (snowstorm). The condition is difficult to manage if it becomes established and the initial treatment is important. The treatment consists of long courses of antibiotics and endoscopic washouts.

Sialadenosis

This is a non-inflammatory bilateral enlargement of the parotid glands. The swelling is generally painless with reduced saliva and is associated with chronic malnutrition, obesity, alcoholism, liver disease, diabetes and drugs such as guanethidine, thioridazine or isoprenaline. It requires differentiation from any neoplastic disorder. Treatment mainly consists of management of the underlying systemic disorder.

Sialolithiasis

Salivary gland stones can form in the gland ducts. Patients between the ages of 30 and 60 with sialolithiasis typically present with cyclical postprandial swelling of the major salivary

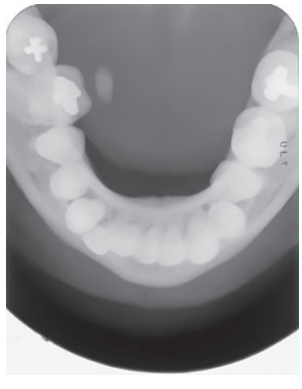

Figure 54.8 Occlusal view showing a stone in the submandibular gland.

glands and dryness possibly due to decreased salivary flow. Duct abnormality, inflammation and increased calcium content of the saliva may contribute to an increased risk of sialolithiasis. Chronic dehydration and pharmacological causes of decreased salivary flow are often implicated. The submandibular gland is most commonly affected (85%) owing to the ascending course of its duct, predisposing it to stagnation of the mucinous as well as the more viscous saliva it produces (***Figure 54.6***). The alkaline saliva precipitates calcium and phosphate and predisposes to stone formation. On examination, there is an asymmetrical enlargement of the gland and a large proximal stone may be palpated in certain cases. Submandibular gland duct stones are mainly proximal and parotid gland duct stones are mainly distal (***Figure 54.7***). Sialolithiasis complicated by a secondary bacterial infection may present with an abscess.

Conventional radiographs are considered as an initial diagnostic test (***Figure 54.8***). However, small stones may be missed and only 80% of stones are radio-opaque. In such cases, computed tomography (CT) scanning, ultrasonography and a magnetic resonance sialogram will be more sensitive for diagnosis and localisation. Sialography is the gold standard for diagnosis and involves injecting a dye into the duct of the salivary gland. It not only helps in diagnosis of sialolithiasis but also identifies any pathology in the duct. In addition, it may be therapeutic in certain cases. Sialendoscopy provides

direct visualisation of the duct and can be used for removal of stones. It is a safe procedure that can be performed under local anaesthesia with better outcomes than open surgery. The smaller (<5 mm) distal stones can be removed with endoscopy while the larger (>5 mm) distal stones may require duct slitting. For an impacted stone, the transoral route is used. Intraparenchymal stones between 5 and 7 mm can be extracted endoscopically while larger stones require transoral slitting. Stones that are not palpable and not visualised endoscopically can be removed using external shock wave lithotripsy (ESWL). However, ESWL is not suitable for stones larger than 7–10 mm. Hilar stones are removed using an endoscope. Excision of the submandibular gland should be considered as a last resort. Parotid stones (<7 mm) can be removed endoscopically and difficult cases might need a combined transcutaneous approach. ESWL can be considered for impacted stones. Again gland removal should be considered only as a final remedy.

Xerostomia

Normal salivary flow decreases with age. Typical complaints are of a dry mouth, difficulty swallowing and speaking, intolerance to spicy, acidic and crunchy food, a loss of taste and denture-wearing issues. Xerostomia is more common among postmenopausal women, who complain of a burning tongue or mouth. Common causes of xerostomia are chronic anxiety states and depression; dehydration; anticholinergic drugs, especially antidepressants; salivary gland disorders (e.g. SjS); and radiotherapy to the head and neck region. Xerostomia and salivary gland hypofunction diagnosis requires a thorough history and examination as well as documentation with one of the several questionnaires available. Treatments include proper hydration, humidification at night, avoiding harmful dentifrices and crunchy/hard foods and the use of sugar-free chewing gums and lozenges. Medications include lubricants, saliva substitutes or stimulants.

Sialorrhoea

Excess salivation is rarely symptomatic in healthy individuals as it is swallowed spontaneously. Certain drugs and oral infection produce a transient increase in salivary flow; however, uncontrolled drooling is usually seen in the presence of normal salivary production in children with mental and physical disability, most notably cerebral palsy. Sialorrhoea can be managed with antisialogogues or with intraparenchymal injection of botulinum toxin injection. Most resting salivary flow arises from the submandibular glands and surgery should focus on either bilateral excision or repositioning of the salivary duct to control sialorrhoea.

Trauma

Trauma to the salivary glands or ducts is uncommon and is usually associated with polytrauma due to penetrating injuries, blasts or vehicular accidents. This can result in injury to the salivary glandular tissue, the duct and the surrounding nerves, such as the facial and hypoglossal nerves. Often these injuries go unnoticed and manifest later with a salivary fistula, nerve palsy and/or sialoceles.

The basic principles of all wound care management apply to salivary gland injuries, including removal of foreign bodies, wound washout, debridement and tension-free closure of the wound. Besides this, the glandular tissue, the duct and the nerves in the vicinity require utmost attention to prevent late complications. These are often overlooked and missed.

Facial nerve

A cranial nerve examination guides the clinician towards the possibility of nerve injuries. The wound is examined for nerve injuries. If the branches are severed anteriorly to an imaginary line dropped vertically down from the lateral canthus of the eye, they are not repaired. If the injury is posterior to this line, a direct nerve repair or grafting is carried out depending on the wound status. If not feasible at that time the nerve endings are tagged for later.

Salivary duct

Within the first 72 hours a duct injury should be repaired with a direct end-to-end anastomosis over a cannula. If there is a loss of duct tissue of over 1 cm, the proximal portion is either cannulated for subsequent marsupialisation into the oral cavity or a duct rerouting is considered. In cases with significant parenchyma and duct injury a ductal ligation along with gland excision should be considered.

NEOPLASMS OF THE SALIVARY GLAND

Primary salivary gland neoplasms are extremely rare and form less than 3% of head and neck malignancies. The incidence is 0.4–13.5 cases per 100 000 for benign neoplasms and 0.4–2.6 per 100 000 for malignant tumours. These neoplasms present after the fourth decade and affect both sexes equally. Warthin's tumours are more common in older men, while pleomorphic adenomas are slightly more common in women.

With a varied spectrum of pathologies, salivary gland neoplasms present a diagnostic and therapeutic challenge. The World Health Organization (WHO) first classified these in 1972, and its last update was in 2017 (***Table 54.3***). Most salivary gland tumours (>80%) occur in the major salivary glands and the majority of them are benign. Minor salivary gland tumours, in contrast, are more likely to be malignant (>50%) (***Figure 54.9***). The commonest benign neoplasm is the pleomorphic adenoma (mostly seen in the parotid glands), while the commonest malignant tumour is the mucoepidermoid carcinoma.

Radiation exposure has been implicated in the development of both benign and malignant salivary gland tumours, while there is a strong association of smoking with Warthin's tumour. Viral infections, environmental factors and industrial exposure, such as rubber manufacturing, nickel compounds and hair dyes, have been reported to be associated with the development of salivary gland tumours.

Aldred Scott Warthin, 1866–1931, Professor of Pathology, University of Michigan, Ann Arbor, MI, USA.

TABLE 54.3 World Health Organization classification of salivary gland neoplasms (2017).

Malignant epithelial tumours

- Acinic cell carcinoma
- Mucoepidermoid carcinoma
- Adenoid cystic carcinoma
- Polymorphous low-grade adenocarcinoma
- Epithelial–myoepithelial carcinoma
- Clear cell carcinoma, not otherwise specified
- Basal cell adenocarcinoma
- Sebaceous carcinoma
- Sebaceous lymphadenocarcinoma
- Cystadenocarcinoma
- Low-grade cribriform cystadenocarcinoma
- Mucinous adenocarcinoma
- Oncocytic carcinoma
- Salivary duct carcinoma
- Adenocarcinoma, not otherwise specified
- Myoepithelial carcinoma
- Carcinoma ex pleomorphic adenoma
- Carcinosarcoma
- Metastasising pleomorphic adenoma
- Squamous cell carcinoma
- Small cell carcinoma
- Large cell carcinoma
- Lymphoepithelial carcinoma
- Sialoblastoma

Benign epithelial tumours

- Pleomorphic adenoma
- Myoepithelioma
- Basal cell adenoma
- Warthin's tumour
- Oncocytoma
- Canalicular adenoma
- Sebaceous adenoma
- Lymphadenoma
  - Sebaceous
  - Non-sebaceous
- Ductal papillomas
  - Inverted ductal papilloma
  - Intraductal papilloma
  - Sialadenoma papilliferum
- Cystadenoma

Soft-tissue tumours

- Haemangioma

Haematolymphoid tumours

- Hodgkin's lymphoma
- Diffuse large B-cell lymphoma
- Extranodal marginal zone B-cell lymphoma

Secondary tumours

Histological grades of salivary gland cancers

High grade

- High-grade mucoepidermoid carcinoma
- Salivary duct carcinoma
- Adenoid cystic carcinoma
- Carcinoma ex pleomorphic adenoma
- Squamous cell carcinoma
- Anaplastic or undifferentiated carcinoma
- Malignant mixed carcinoma

Low to intermediate grade

- Low-grade mucoepidermoid carcinoma
- Acinic cell carcinoma
- Polymorphous low-grade adenocarcinoma
- Epithelial–myoepithelial carcinoma

Figure 54.9 Mucoepidermoid carcinoma of the palate.

Benign tumours

Pleomorphic adenoma

These are the most common benign salivary gland tumours. They can occur at all ages, but are most commonly seen between the third and sixth decade. The average age of presentation is 45 years and they are more frequently seen in women. They occur most frequently in the parotid glands (>80%), but are also seen in the submandibular gland and hard palate. Pleomorphic adenoma presents as a painless, well-defined solitary mobile mass with gradual progression over many years and can reach enormous proportions (***Figure 54.10***). Occasionally they can present as metachronous and synchronous tumours. When they arise from the deep lobe of the parotid they may present as a paratonsillar bulge. A sudden increase in size or facial nerve palsy is associated with malignant transformation, which is rare. Treatment involves surgical excision with a cuff of surrounding normal tissue, where possible, to include the

Thomas Hodgkin, 1798–1866, curator of the museum and demonstrator of Morbid Anatomy, Guy's Hospital, London, UK, described lymphadenoma in 1832.

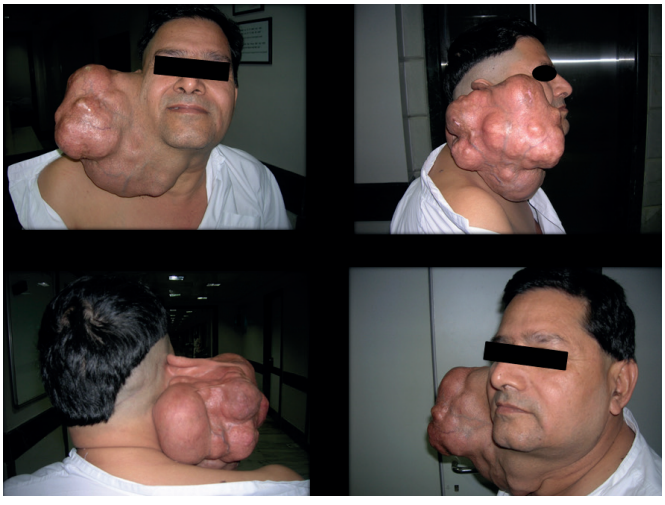

Figure 54.10 Double head: large pleomorphic adenoma grown over 15 years.

pseudopods from the tumour capsule. Enucleation may result in capsular breach and tumour spillage, increasing the possibility of local recurrence; it should be avoided.

Histopathology

On gross examination, pleomorphic adenoma presents as a well-circumscribed, nodular, firm mass with a white to tan cut surface, sometimes showing cartilaginous areas. Large tumours may show areas of degeneration and cystic changes. On microscopy, the tumour comprises mixed epithelial, myoepithelial and stromal components. A spectrum of architectural and cellular features is seen, including oval, epithelioid, spindle shaped, plasmacytoid and clear cells, in variable amounts of myxoid to chondroid and hyalinised stroma. The presence of ductal atypia, diffuse fibrosis and necrosis should be evaluated further to rule out malignancy. In immunohistochemistry, luminal cells express CK7 (strong and diffuse) and myoepithelial cells express p63, S-100, SOX10 and SMA.

Warthin's tumour

Warthin's tumour, also known as adenolymphoma or cystadenoma lymphomatosum, is a benign tumour composed of oncocytic epithelial cells lining ductal, papillary and cystic spaces in a reactive lymphoid tissue. They are the second most common benign salivary gland tumours (5–15%) and are mainly seen in older men, after the sixth decade of life. They have been associated with cigarette smoking as well as radiation exposure. They are almost exclusively seen in the parotid gland, especially in the inferior pole, and are rarely seen in the periparotid nodes. They can occur synchronously or metachronously in the same or bilateral glands. They are also known to occur with other salivary gland neoplasms such as pleomorphic adenoma and salivary duct carcinoma. Clinically, they present as painless, slow-growing swellings. Facial palsy is rare. Malignant transformation is extremely rare (<1%) and can occur in both the epithelial (Warthin's adenocarcinoma) and lymphoid (lymphoma) components. Complete surgical excision with an adequate margin is the treatment of choice. Recurrences are very rare and may be due to multifocal tumours.

Histopathology

On gross examination, they are well circumscribed and ovoid to spherical with a cut surface showing solid and cystic areas containing mucoid to brownish fluid and papillary projections. On microscopy, the tumours have papillary and cystic structures lined by bilayered oncocytic epithelial cells in a lymphoid stroma with germinal centres. The epithelium may show metaplastic changes, including squamous, sebaceous, ciliated and mucous cells.

Malignant tumours

Mucoepidermoid carcinoma

Mucoepidermoid carcinomas are malignancies consisting of mucinous, intermediate and squamoid tumour cells in variable proportions. They are the most common salivary gland malignancies in children and young adults, with a peak incidence in the second decade of life. They are known to occur following radiation or chemotherapy in childhood. They occur in both major and minor salivary glands, with the parotid being the most common site involved. They generally present as soft to firm, painless masses with a gradual increase in size. The tumours are classified as low, intermediate or high grade based on histology. High-grade mucoepidermoid carcinomas tend to be locally aggressive with bone and/or skin involvement and nodal metastases. Distant metastases are seen mainly to the lungs. Complete surgical excision with wide margins is advocated for mucoepidermoid carcinoma. Appropriate adjuvant radiotherapy is the treatment of choice for intermediate- to high-grade mucoepidermoid carcinomas.

On gross examination, the tumours are circumscribed or infiltrative and partially cystic. On histopathology, mucoepidermoid carcinomas have squamoid, mucin-producing and intermediate cells in variable proportions. There can be a cystic and solid growth pattern. Low-grade mucoepidermoid carcinomas are generally cystic, well circumscribed and rich in mucous cells. Intermediate-grade tumours are less circumscribed and more solid, usually with a predominant intermediate cell component. High-grade mucoepidermoid carcinomas are usually solid, infiltrative and show nuclear atypia, mitosis, necrosis, perineural invasion and lymphovascular emboli. Demonstration of at least focal intracellular mucin is essential for the diagnosis of high-grade mucoepidermoid carcinoma.

Summary box 54.5

Mucoepidermoid carcinoma

- Most common salivary gland malignancy
- Can occur in minor and major salivary glands
- Most common site: parotid

Adenoid cystic carcinoma

Adenoid cystic carcinoma is a slow-growing malignancy composed of both epithelial and myoepithelial cells and

characterised by a high predilection for perineural invasion. It has varying outcomes with good 5-year control but poor 10-year survival owing to the higher incidence of delayed distant metastases. They occur mainly in the fifth to sixth decades, with a slight female preponderance (1.5:1). Most of these malignancies occur in the major salivary glands, but they can also be seen in minor glands in the oral cavity, paranasal sinuses, tracheobronchial tree, etc. Most patients will present with slow-growing masses, with the presence of numbness, paraesthesia or pain. Facial and other neural palsies may be present depending on the site of the tumour. Nodal metastases are seen with high-grade lesions and asymptomatic distant metastases, especially lung metastases, are a frequent presentation. In addition, bone, liver and brain metastases are also seen. Radical surgical excision with or without adjuvant radiotherapy is the treatment of choice. Single-modality radiotherapy is associated with inferior control outcomes. There is an emerging role of proton ion and carbon ion therapy, especially in unresectable/metastatic disease. Factors influencing survival include the tumour site, stage, nodal disease, presence of perineural spread and grade of tumour.

Grossly, adenoid cystic carcinoma presents as a poorly circumscribed, firm, grey-white and solid mass. On histopathology, it is an unencapsulated, infiltrative biphasic neoplasm with variable proportions of epithelial and myoepithelial cells and shows cribriform tubular and solid patterns. The cells show small, angulated, hyperchromatic nuclei with scant cytoplasm. The cribriform pattern is characterised by neoplastic cells arranged around small, sharply punched out cylindromatous spaces containing basophilic matrix. The tubular pattern shows bilayered tubules with a true lumen. The solid pattern is less common and shows sheets and nests of tumour cells without lumen formation. Perineural invasion is widely seen in adenoid cystic carcinoma. High-grade transformation can occur. Immunohistochemically, the ductal cells are positive for c-KIT, and myoepithelial cells are positive for p63 and SMA.

Acinic cell carcinoma

Acinic cell carcinoma is composed of neoplastic acinar cells. It is a low- to intermediate-grade tumour occurring mostly (90%) in the parotid gland. They typically present in the fifth decade and have a slight female predilection (1.5:1). They are generally slow-growing, painless, mobile, solitary tumours and rarely present with facial palsy. A small proportion may be high grade and may metastasise to cervical nodes and lung. Complete excision with an adequate margin is the recommended treatment. Recurrences can occur in cases of incomplete resection, deep lobe involvement and larger size tumours. On histopathology, the tumours show characteristic serous acinar cells and variable proportions of other cell types, including clear, vacuolated, intercalated duct-type oncocytic and hobnail features. They can have solid (most common), follicular or microcystic patterns with a prominent lymphoid infiltrate. Mitoses, necroses and nuclear pleomorphism are rare. Immunohistochemically, the neoplastic cells are positive for DOG1 and SOX10, whereas they are immunonegative for mammaglobin, differentiating them from secretory carcinoma.

Carcinoma ex pleomorphic adenoma

Carcinoma ex pleomorphic adenoma (epithelial and/or myoepithelial) arises in association with primary or recurrent pleomorphic adenoma. The carcinoma component can be either purely epithelial or myoepithelial in presentation, with infiltration into the surrounding glandular and extraglandular tissue. It occurs mainly in the parotid gland, is more common in women and presents a decade later than pleomorphic adenoma (sixth decade). It often presents as a rapidly growing mass (within a longstanding swelling) associated with pain and facial palsy. Radical surgical excision with or without adjuvant radiotherapy is the treatment of choice. Local and distant metastases occur in 70% of cases with poor 5-year survival outcomes of 25–65%.

On histopathology, the tumour shows variable proportions of both pleomorphic adenoma and high-grade adenocarcinoma such as salivary duct carcinoma or myoepithelial carcinoma. It is subclassified as non-invasive or intracapsular (tumour is confined within pleomorphic adenoma), minimally invasive (tumour breaching the pleomorphic adenoma capsule) and widely invasive into adjacent salivary gland and soft tissue. TP53 mutations and amplification of HER2 (in salivary duct carcinoma) with a high degree of genetic instability and copy-number alterations are seen.

Salivary duct carcinoma

Also known as high-grade ductal carcinoma, salivary duct carcinoma is a high-grade adenocarcinoma, resembling high-grade mammary ductal carcinoma. The tumour may arise *de novo* or as a malignant component of carcinoma ex pleomorphic adenoma. It is relatively less common and mostly arises in the parotid. It is commonly seen in elderly men in their sixth or seventh decade. Salivary duct carcinoma is an aggressive tumour presenting as a rapidly growing mass, often with facial palsy, pain and cervical lymphadenopathy. Complete excision with wide margins (total parotidectomy) with neck dissection is the treatment of choice. On histopathology, it resembles high-grade invasive ductal breast cancer with a large duct-like configuration with comedo necrosis and cribriform and Roman bridge-like features. Vascular and perineural invasion is seen. Salivary duct carcinoma also shows androgen receptor and HER2 receptor positivity in a significant percentage of cases, making it a target for treatment, especially in the recurrent/metastatic setting. It has a high predilection for local recurrence and regional and distant metastases and a poor overall survival.

INVESTIGATIONS

Imaging

Various modalities, from plain radiography to ultrasonography, CT, MRI and sialography are available to clinicians. In most cases, CT scans are considered superior for differentiating neoplasms from inflammatory conditions, while MRI scans give better differentiation between benign and malignant neoplasms.

High-resolution ultrasonography

Ultrasonography is a very useful diagnostic tool, especially for lesions of major salivary glands. Acute inflammatory conditions may be picked up by enlarged glands with increased blood flow, compared with chronic inflammation, in which the glands may be smaller in size and hypoechoic. Sialolithiasis will present with distinct acoustic shadowing. Benign tumours such as pleomorphic adenoma are generally visualised as well-lobulated, hypoechoic lesions with some calcifications. Malignant tumours will have irregular shapes and a hypoechoic, inhomogeneous appearance with blurred margins. However, ultrasonography cannot adequately characterise lesions of the deep lobe of the parotid gland and when there is suspected involvement of the skull base; in these cases, cross-sectional imaging such as CT/MRI is preferred.

Computed tomography/magnetic resonance imaging scans

These are the best tools for almost complete imaging of the salivary glands. They detect both cystic and solid masses with good accuracy as well as help in diagnosing and localising sialolithiasis. CT scans are especially useful in determining the extent of the tumour, erosion of surrounding osseous structures, extraglandular involvement and the presence of metastatic nodes. MRI scans, especially diffusion-weighted (DW) and gadolinium-enhanced dynamic MRI, can differentiate benign and malignant neoplasms based on the apparent diffusion coefficient (ADC) values, peak enhancement and washout ratios.

Positron emission tomography with computed tomography (PET-CT) scans

These scans are used mainly in the detection of distant metastases in high-grade malignancies or if the salivary glands are involved as the site of metastasis with an unknown primary.

Cytology

Fine-needle aspiration cytology

Fine-needle aspiration cytology (FNAC) is a widely available, simple and relatively safe diagnostic tool. It is used in the clinical setting of mass-forming lesions, often performed under ultrasound guidance. It can differentiate between inflammatory conditions and neoplasms with a high sensitivity (96%) and specificity (98%). Systematic reviews have reported FNAC to have a high sensitivity (80%) and specificity (97%) in differentiating benign from malignant lesions. The Milan system (***Table 54.4***) for reporting salivary gland cytopathology is an effective tool to assess the adequacy of the cytopathology specimen and quantify the risk of malignancy.

Core needle biopsy

FNAC has a high specificity but a lower sensitivity in diagnosing malignancies. Being operator dependent, there is a high variability in practice. In addition, in lymphoma or high-grade malignancies, ancillary studies such as flow cytometry and immunohistochemistry are required to confirm the diagnosis. In these settings, core needle biopsy has greater diagnostic accuracy than FNAC. It provides more tissue for diagnosis and preserves the cellular architecture for further classification of malignancies. However, as it is a more invasive procedure, it is often reserved as a supplement to FNAC for problem solving.

TABLE 54.4 The Milan system for reporting salivary gland cytopathology.

Diagnostic criteria	Risk of malignancy	Usual management
I Non-diagnostic	25%	Clinical and radiological correlation/repeat FNAC
II Non-neoplastic	10%	Clinical follow-up and radiological correlation
III AUS	20%	Repeat FNAC or surgery
IV Neoplasm		
IVA Benign	<5%	Conservative surgery or clinical follow-up
IVB SUMP	35%	Conservative surgery[a]
V Suspicious for malignancy	60%	Surgery[a]
VI Malignant	>90%	Surgery[a] (extent depends on type and grade of malignancy)

AUS, atypia of undetermined significance; FNAC, fine-needle aspiration cytology; SUMP, salivary gland neoplasm of uncertain malignant potential.

[a]Intraoperative frozen section may be helpful to determine the extent of surgery.

STAGING OF SALIVARY GLAND MALIGNANCIES

Major salivary gland malignancies are staged using the eighth edition of the American Joint Committee on Cancer (AJCC) staging. However, minor salivary gland malignancies are staged as per their site of origin. The primary tumour (T) staging is as given in ***Table 54.5***. The nodal (N) and distant metastasis (M) staging is similar to that for head and neck squamous cell carcinomas.

TREATMENT OF SALIVARY GLAND MALIGNANCIES

The treatment guidelines are based on retrospective studies, with very little randomised evidence to guide treatment decisions. Surgery forms the mainstay of treatment with a goal to extirpate the tumour with microscopic margins of at least 0.5 cm. The extent of resection is determined not only by the size and stage of the malignancy but also by the grade of differentiation. The preservation of the facial nerve should be planned, but not at the cost of residual disease. Elective neck dissection should be offered for T3/T4 and high-grade tumours. In node-positive disease, comprehensive neck dissection is mandatory. Adjuvant radiotherapy is advocated for stage III and IV tumours, high grade of differentiation as

TABLE 54.5 T staging of salivary gland tumours as per the American Joint Committee on Cancer system.

T category	T criteria
TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
Tis	Carcinoma *in situ*
T1	Tumour 2 cm or smaller in greatest dimension without extraparenchymal extension[a]
T2	Tumour larger than 2 cm but not larger than 4 cm in greatest dimension without extraparenchymal extension[a]
T3	Tumour larger than 4 cm and/or tumour having extraparenchymal extension[a]
T4a	Moderately advanced disease Tumour invades skin, mandible, ear canal and/or facial nerve
T4b	Very advanced disease Tumour invades skull base and/or pterygoid plates and/or encases carotid artery

[a]Extraparenchymal extension is clinical or macroscopic evidence of invasion of soft tissues. Microscopic evidence alone does not constitute extraparenchymal extension for classification purposes.

well as the presence of high-risk features such as close/positive surgical margins, the presence of perineural or lymphovascular invasion and nodal metastases with extranodal extension. The role of chemoradiation in the adjuvant setting is still under investigation. In unresectable or metastatic tumours, palliative chemotherapy and/or targeted therapy is being explored.

SURGERY AND COMPLICATIONS

Submandibular gland resection

The submandibular gland is surrounded by important structures and its removal is fairly straightforward if planned well. The approaches to the submandibular gland are transcutaneous (such as lateral transcervical, submental and retroauricular) or transoral. Visualisation during the various approaches can be improved with endoscopic or robotic assistance, potentially reducing complications.

Summary box 54.6

Important anatomical relations to the submandibular gland

- Lingual nerve
- Hypoglossal nerve
- Marginal mandibular branch of the facial nerve
- Anterior facial vein
- Facial artery

Planning the surgery

Decision making is determined by the nature of the disease. In benign lesions only the gland is removed, preserving surrounding nerves. In malignant lesions, depending on the stage and histology, there may be a consideration for a supraomohyoid neck dissection involving levels I–III.

Anaesthesia

General anaesthesia is usually preferred unless there is any contraindication, in which case local anaesthesia may be considered.

Incision

The incision planned should ensure complete access to the tumour, be extendable to encompass intraoperative surprises and be safe and cosmetically acceptable. The standard incision is placed in a neck crease at least two finger breadths below the mandible. The horizontal incision is along the lines of relaxation, which results in a cosmetic scar (***Figure 54.11a***).

Flap elevation

After incising the skin the platysma is exposed and divided in the same plane. The skin is retracted with skin hooks and the flap is elevated in the avascular subplatysmal plane, taking care that the veins remain in the investing fascia. The flap is elevated up to the attachment of the platysma on the mandible, which helps in identification of the marginal mandibular nerve (***Figure 54.11b***).

Marginal mandibular nerve preservation

The fascia above the facial vessels is palpated in the midportion of the body of the mandible. The nerve is usually identified in the fascia above the vessels and is dissected along its path horizontally to expose it as it exits the parotid and traverses onto the muscles anteriorly.

Gland mobilisation

The facial vein and artery are ligated below the marginal nerve, exposing the lower edge of the body of the mandible. The submandibular gland is now retracted downwards and outwards to expose the mylohyoid muscle (***Figure 54.11c***); the fascia overlying the submandibular gland is dissected, exposing the submental artery and vein, which are secured and ligated. The lateral edge of the mylohyoid is delineated and retracted with a curved retractor. This exposes the deeper portion of the submandibular gland as well as Wharton's duct. The submandibular gland is then retracted downwards to expose the lingual nerve (***Figure 54.11d***) and the connecting submandibular ganglion, which is divided. The gland is then retracted superiorly and posteriorly, exposing the deep fascia alongside the ranine veins above the hypoglossal nerve (***Figure 54.11e***). Wharton's duct is then clamped, divided and ligated close to the floor of the mouth to prevent retention of debris or stones, reducing the chance of infection. The gland is retracted downwards and laterally, exposing the facial artery above the common tendon of the digastric muscle. The facial artery is clamped, divided and ligated, completing the gland excision.

Malignant submandibular tumours

Treatment for low-grade tumours that are less than 4 cm without extraparenchymal spread is submandibular gland removal with clearance of the perivascular group of lymph nodes around

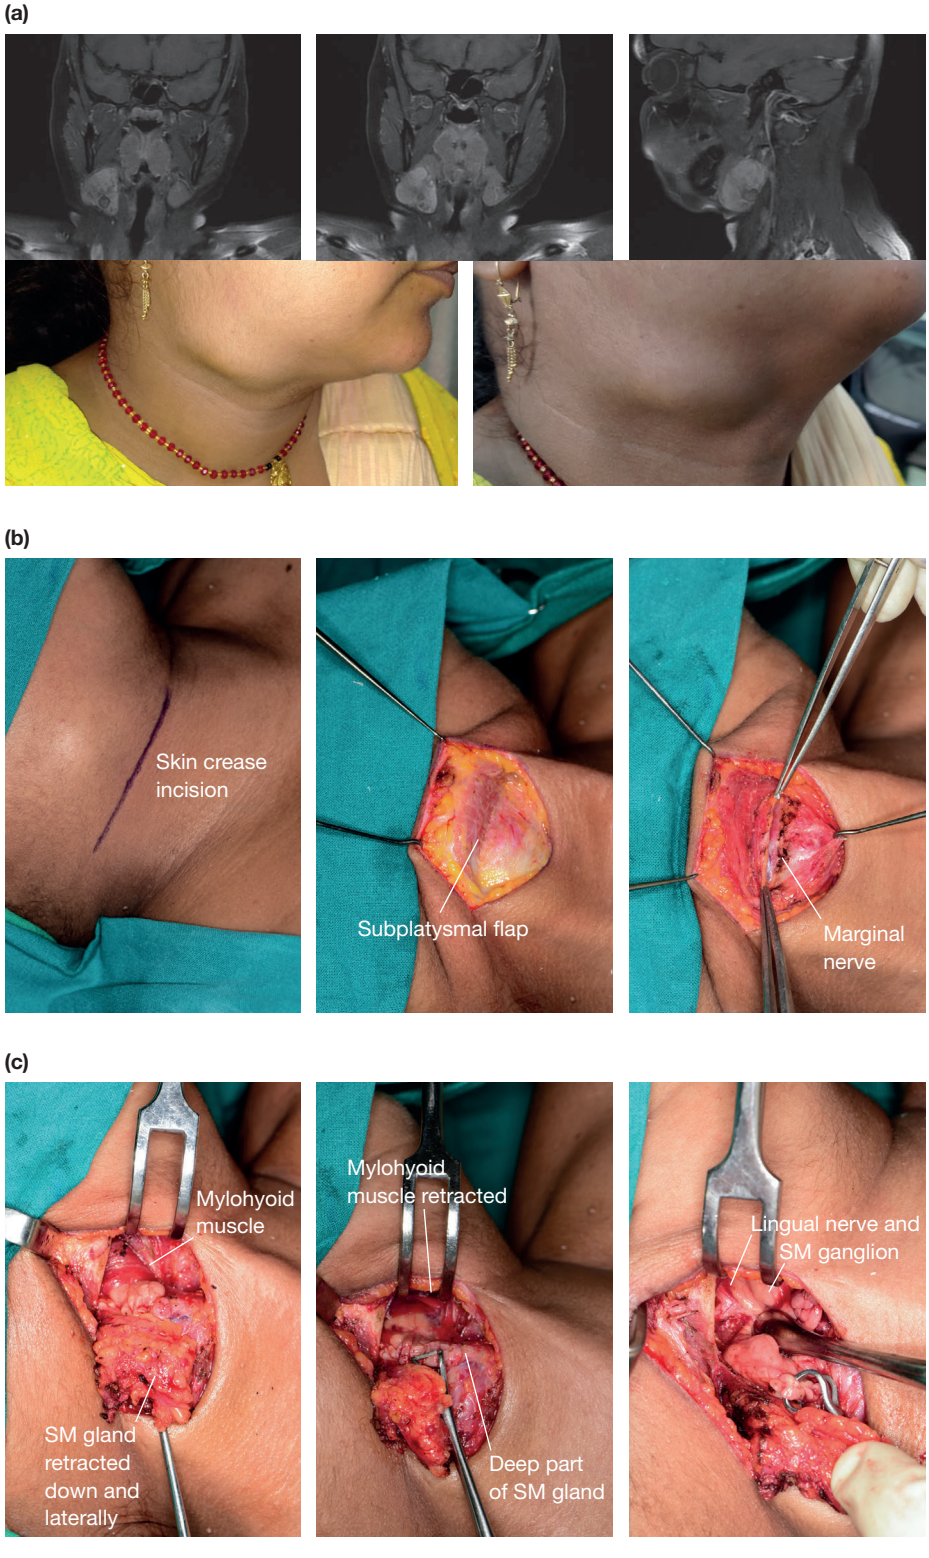

Figure 54.11 (a) Submandibular (SM) pleomorphic adenoma: clinical presentation and T1-weighted magnetic resonance imaging with contrast view showing the tumour. **(b)** A horizontal skin crease incision, subplatysmal flap elevation and identification of the marginal mandibular nerve. **(c)** The gland is retracted downwards and outwards to identify and retract the mylohyoid muscle to locate the lingual nerve.

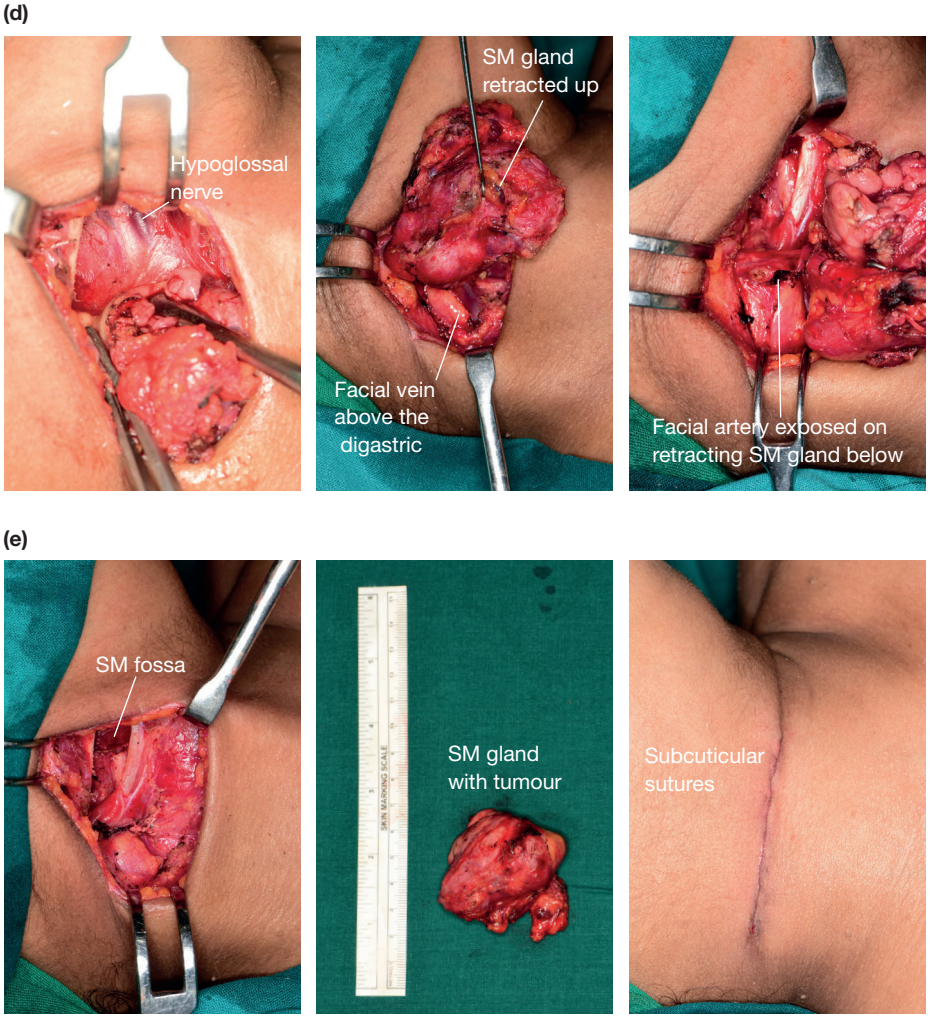

Figure 54.11 (d) The gland is retracted downwards and outwards to identify the hypoglossal nerve and the facial vein and artery before removing the gland. **(e)** The submandibular fossa after tumour-laden gland removal and closure with subcuticular sutures.

the facial vein. In high-grade tumours, supraomohyoid neck dissection (levels I–III) is recommended, whereas node-positive tumours require a comprehensive neck dissection (levels I–V).

For tumours with extraparenchymal spread, radical clearance of the involved structures along with a formal comprehensive neck dissection is required.

Closure

Haemostasis is achieved and an antiseptic wash is given. Intraoral communication is ruled out before placing a suction drain over the mylohyoid with the tip pointing laterally to prevent migration into the oral cavity. The wound is closed by approximating the platysma with absorbable sutures and the skin with absorbable or non-absorbable sutures.

Complications

Nerve palsy

The proximity of the three nerves (marginal division of the facial, lingual and hypoglossal) to the submandibular gland makes them susceptible to injury. Care should be taken, especially in recurrent sialadenitis, which causes dense adhesions, increasing the possibility of nerve injury.

Haemorrhage

The facial artery and the ranine veins along the hypoglossal are notorious for postoperative haemorrhage and should be double-checked prior to closure.

Parotidectomy

In parotidectomy, the tumour is removed with a cuff of normal surrounding tissue where possible. The embryological development of the parotid with its late encapsulation not only embeds vessels, nerves and lymph nodes within the capsule but also fuses widely with the investing fascia from the temporalis above to the digastric below and from the buccinator anteriorly to the mastoid posteriorly. The facial nerve traverses the parotid, making the removal of this gland difficult.

Summary box 54.7

Types of parotid surgery as per the extent of resection (conservative to radical)

- Extracapsular dissection
- Adequate parotidectomy
- Superficial parotidectomy
- Total conservative parotidectomy
- Radical parotidectomy

Planning the surgery

Decision making should take into consideration:

1. presumed tumour histology;
2. relation to the facial nerve plane (Patey's faciovenous plane);
3. location of the tumour (deep lobe of the parotid);
4. facial nerve function.

Traditionally, the type of parotidectomy is based on the location of the tumour either lateral to the plane of the facial nerve, necessitating a superficial parotidectomy, or deep to it, requiring a total parotidectomy. A total conservative parotidectomy usually preserves the facial nerve whereas a radical parotidectomy involves its sacrifice.

Today, with a focus towards reducing morbidity and preserving gland function, variations of parotidectomy have evolved in the management of benign tumours:

- Extracapsular tumour dissection does not require a formal facial nerve dissection; this reduces the incidence of temporary facial nerve palsy.
- Adequate parotidectomy involves removal of the tumour with a cuff of normal tissue in tail of parotid lesions, preserving function. It may not be possible to excise the tumour with a cuff of normal tissue in all the cases, especially when the lump is abutting the facial nerve.
- Deep lobe parotid tumours can be removed, preserving the entire superficial parotid gland, which is functional as well as cosmetic.

Anaesthesia

General anaesthesia is usually preferred unless there is any contraindication, in which case local anaesthesia may rarely be considered.

Incision

The planned incision should ensure complete access to the tumour, be extendable to encompass intraoperative surprises and be safe and cosmetically acceptable. The Blair incision is a straight preauricular incision curving slightly below the ear lobule. Bailey modified the inferior segment towards the mastoid and along the anterior border of the sternocleidomastoid.

The modern 'lazy S' incision gently curves downwards along the natural skin crease of the neck (***Figure 54.12a***) and has three components: (i) the horizontal part along the skin crease two finger breadths from the angle of the mandible, (ii) the vertical part close to the tragus in a skin crease if present, and (iii) the communicating part connecting the horizontal and vertical components in a gentle curve.

The facelift incision has two components: the anterior preauricular component is similar to the modified Blair incision while the posterior limb curves at right angles, reaching the hairline and avoiding any neck incision.

Flap elevation

The horizontal component of the modified Blair incision is incised first to identify the platysma, the external jugular vein and the greater auricular nerve. The vertical component is then incised and connected inferiorly. The platysma is divided and the subplatysmal flap is raised until the parotid gland is visualised and continued above, remaining below the superficial musculoaponeurotic fascia, which connects the temporalis fascia and the platysma. This allows a suitable flap to be raised with the entire subcutaneous fat lifted off the parotid gland. The flap is developed anteriorly with elevation over the parotid gland but not onto the masseteric fascia to prevent damage to the nerve branches as they exit the gland (***Figure 54.12b***).

Parotid gland mobilisation

The fascia between the sternocleidomastoid and the parotid is dissected in the avascular plane. The greater auricular nerve is dissected up to the ear lobule and its anterior branches are divided (***Figure 54.12c***). The gland is then dissected off the sternomastoid muscle and fibrofatty tissue overlying the internal jugular vein to identify the posterior belly of the digastric muscle, which is then traced to the mastoid process. The external jugular vein is preserved as it provides a good landmark for the facial nerve plane. The parotid is then mobilised from the tragal cartilage and the bony external auditory meatus, exposing its tip – the 'tragal pointer'. The two avascular planes are then connected by blunt and sharp dissection, identifying the tympanomastoid suture.

Facial nerve localisation

The facial nerve is usually identified by the antegrade technique using anatomical landmarks, which are fairly constant, and is delineated from the trunk to the peripheral branches (***Figure 54.12d***):

- tragal (Conley's) pointer: the facial nerve lies 1 cm deep and inferior to the tip of the tragal cartilage;
- digastric muscle: the facial nerve can be identified above the upper border of the posterior belly of the digastric muscle;
- tympanomastoid suture: the facial nerve lies inferior to this suture line as it overlies the stylomastoid foramen.

David Howard Patey, 1899–1976, surgeon, The Middlesex Hospital, London, UK.
Vilray Papin Blair, 1871–1955, described the incision that bears his name in 1912.
Henry Hamilton Bailey, 1894–1961, surgeon, The Royal Northern Hospital, London, UK.
John J Conley, 1912–1999, otolaryngologist, St. Vincent's Hospital and Medical Center, USA, made important contributions in the treatment of head and neck cancer.

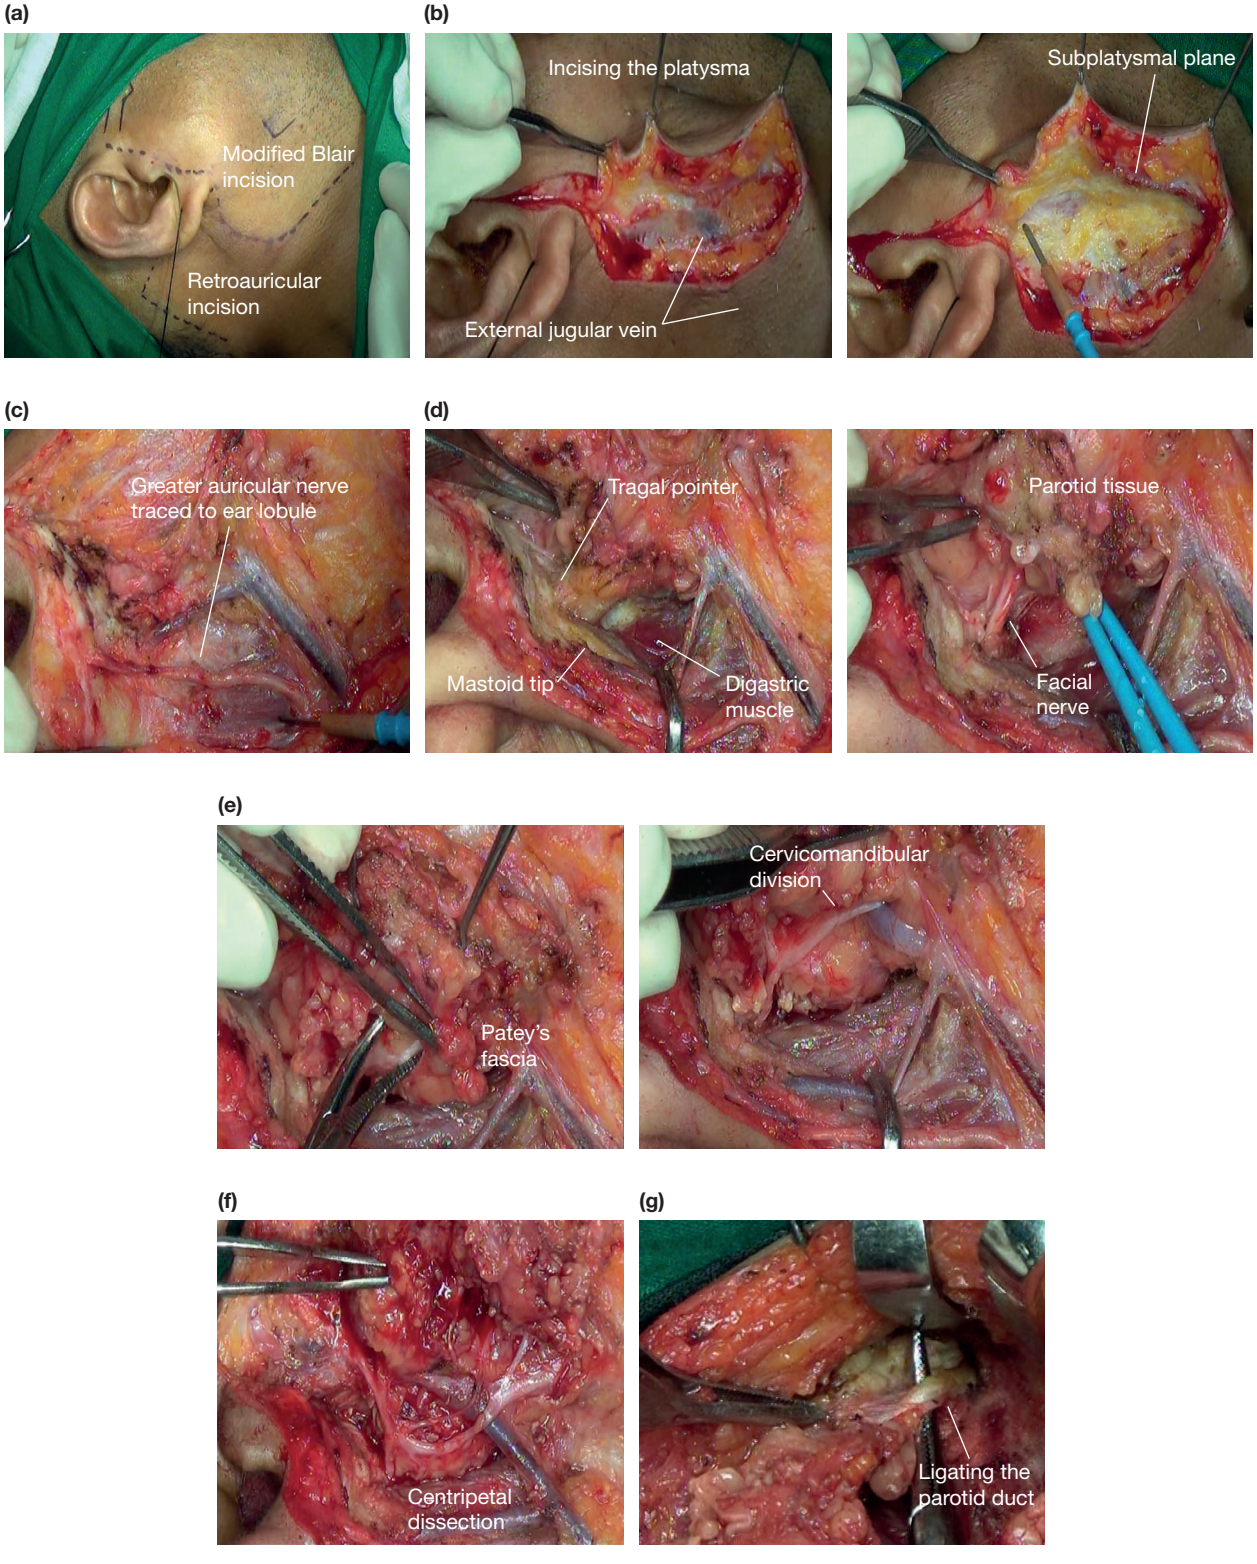

Figure 54.12 (a) Incision planning showing the modified Blair incision and the retroauricular incision. **(b)** Subplatysmal flap elevation to identify the superficial musculoaponeurotic system layer, preserving the external jugular vein. **(c)** Greater auricular nerve traced as far as the ear lobule, dividing the branches going on to the parotid gland. **(d)** Tragal pointer and the digastric muscle used in combination to identify the facial nerve exiting the stylomastoid foramen in the centre. **(e)** Dissection of the nerve in Patey's fascia: dissecting the nerves of the main trunk from the periphery to the centre. **(f)** Centripetal dissection of the parotid gland towards the parotid duct in the centre. **(g)** Ligation of the parotid duct.

At the stylomastoid foramen, the facial nerve is encircled by the parotid gland, fibrofatty tissue and the stylomastoid branch of the posterior auricular artery. Dissection of the glandular tissue and artery exposes the nerve. Bleeding can be brisk; this can be controlled with pressure, adrenaline (epinephrine) neuropatties and bipolar electrocautery.

Identification of the facial trunk by a retrograde dissection technique is useful in revision cases with altered anatomy and fibrosis. It relies on the identification of one of the main branches of the nerve (usually the buccal branch in relation to the parotid duct), which is then traced proximally to the main trunk.

Centripetal dissection

Once the main trunk is identified, a curved fine artery forceps is used to dissect in Patey's plane above the nerve, taking care to avoid stretching the nerve (***Figure 54.12e***). The glandular tissue is dissected off the nerve and divided laterally. Starting with the lower cervicomandibular division and its further divisions into the cervical, marginal mandibular and lower buccal branches, the entire course of each branch is identified until it exits the gland. Each of the branches is dissected in a sequential manner in a centripetal dissection working towards the parotid duct (***Figure 54.12f***). Thereafter, the upper temporozygomatic division is traced onto its temporal, zygomatic and upper buccal branches, similarly reaching the duct. Thus at the end of the dissection the entire superficial part of the gland remains attached to the parotid duct, which can be clamped and ligated to deliver the specimen (***Figure 54.12g***).

Total conservative parotidectomy

In a tumour straddling the superficial and deep lobes across Patey's plane, following removal of the superficial lobe, the deep lobe is dissected off the temporal veins and terminal branches of the external carotid artery. This results in complete removal of the suprafacial and subfacial parotid gland with preservation of the facial nerves – a total conservative parotidectomy.

Radical parotidectomy

In malignant tumours with extraparenchymal spread and facial nerve invasion, it is imperative to remove the involved structures. Radical parotidectomy involves removal of all parotid gland tissue and elective division of the involved facial nerve branches as well as the structures involved, most commonly the masseter muscle. It is imperative to repair the facial nerves when a segment has been removed. The branches supplying the orbicularis oculi and oris are prioritised in the reconstruction using cable grafts from either the greater auricular nerve or the sural nerve.

Extracapsular dissection

Extracapsular dissection for select benign parotid tumours is practised to avoid facial nerve dissection. It is reported to be as safe as parotidectomy. With a similar incision the subcutaneous flap is elevated above the platysma. At the site of the tumour the fascia is incised in a cruciate or curvilinear manner to expose the tumour. The tumour is dissected carefully in an extracapsular plane, visualising the facial nerve branches. Use of intraoperative nerve monitoring makes this safer. However, in the absence of monitoring, careful dissection and a high level of suspicion before cutting any tissue is critical for uneventful surgery. After excision the fascia is sutured with absorbable sutures, followed by skin closure.

Drain placement and closure

Sternomastoid muscle flaps or acellular dermal sheets may be used to cover the parotid bed. This attempts to prevent cross-innervation of the subcutaneous gland and overlying skin by the auriculotemporal nerve to avoid Frey's syndrome. A suction drain tube is placed and anchored beneath the posterior belly of the digastric muscle. The drain is brought out posterior to the suture line. The skin is sutured in layers.

Complications

Temporary facial palsy is commonly seen in the lower branches, especially the marginal mandibular nerve. Most patients tend to recover over time. When the zygomaticotemporal division is affected, eye care is essential to protect the cornea.

Parotidectomy is a clean operation and hence infection is rare. Postoperative management of the drains following aseptic precautions and timely removal decreases the risk of infection.

Haematoma is uncommon and is usually preventable with appropriate intraoperative haemostasis. Small haematomas usually resolve without intervention. Extreme collection causing discoloration suggests a possible bleeding diathesis that requires appropriate management and evacuation of the haematoma.

Sialocele is preventable by underrunning the capsule, where possible, to avoid exposure of the main acinar ductal system. Treatment includes the use of anticholinergics to reduce salivary secretion, aspiration and pressure dressings. Longstanding salivary fistulae may require low-dose radiation.

Hollowing of the retromandibular area can be reduced with autologous fat grafts, which can be placed at the time of primary surgery.

Frey's syndrome (gustatory sweating) results from cross-innervation of the dermal sweat glands by the regenerating postganglionic parasympathetic nerve fibres of the auriculotemporal nerve. It occurs in most patients but is often not significant; patients rarely mention it unless it is excessive. Common presentations are sweating and flushing in the preauricular region during meals. Minor's starch iodine test identifies the region affected. In it iodine is painted in the preauricular region, dried and covered with starch. Salivary stimulation causes sweating, which turns the starch blue. Frey's syndrome can be reduced either by raising a thick flap with all subcutaneous fat over the parotid or by interposition of tissue, such as a sternocleidomastoid flap, temporalis fascia, allodermal tissue or autologous fat between the skin and the surgical bed. Its incidence can be reduced by extracapsular

Victor Minor, Russian neurologist, described the starch iodine test in 1928.

dissection and careful closure of the superficial musculo-aponeurotic system. Treatment includes use of antiperspirants in mild cases; in more severe cases, tympanic neurectomy or botulinum toxin injection at the site of perspiration is used, which is very effective.

Summary box 54.8

Complications of parotid gland surgery

- Haematoma formation
- Infection
- Deformity: unsightly scar and retromandibular hollowing
- Temporary facial nerve weakness
- Transection of the facial nerve and permanent facial weakness
- Sialocele
- Facial numbness
- Permanent numbness of the ear lobe associated with great auricular nerve transection
- Frey's syndrome

Summary box 54.9

Management of established Frey's syndrome

- Antiperspirants, usually containing aluminium chlorohydrate
- Denervation by tympanic neurectomy
- The injection of botulinum toxin into the affected skin

CHAPTER

55 The thyroid gland

Learning objectives

- To understand the development and anatomy of the thyroid gland
- To know the physiology and investigation of thyroid function
- To be able to select appropriate investigations for thyroid swellings
- To know when to operate on a thyroid swelling
- To describe thyroidectomy
- To know the risks and complications of thyroid surgery

EMBRYOLOGY

The embryology of the thyroid and parathyroid glands underlies the anatomical position, anatomical variations and congenital conditions of these structures; it is therefore vital for surgery (***Figure 55.1***). The thyroglossal duct develops from the median bud of the pharynx. The foramen caecum at the junction of the anterior two-thirds and posterior one-third of the tongue is the vestigial remnant of the duct. This initially hollow structure migrates caudally and passes in close continuity with, and sometimes through, the developing hyoid cartilage. The parathyroid glands develop from the third and fourth pharyngeal pouches. The thymus also develops from the third pouch. As it descends, the thymus takes the associated parathyroid gland with it, which explains why the inferior parathyroid, which arises from the third pharyngeal pouch, normally lies inferior to the superior gland. However, the inferior parathyroid may be found anywhere along this line of descent (see also ***Chapter 56***). The developing thyroid lobes amalgamate with the structures that arise in the fourth pharyngeal pouch, i.e. the superior parathyroid gland and the ultimobranchial body. Parafollicular cells (C cells) from the neural crest reach the thyroid via the ultimobranchial body.

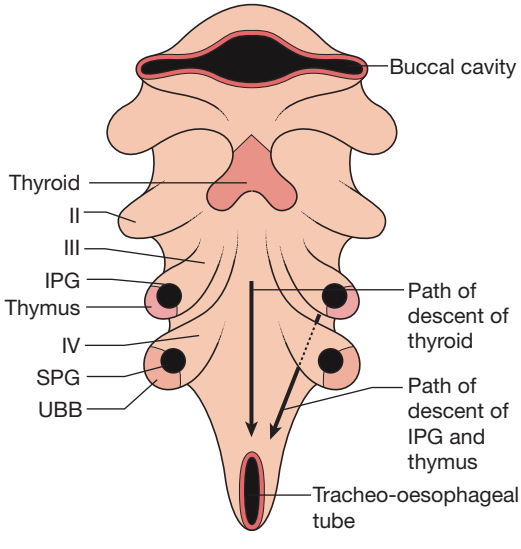

Figure 55.1 Embryology of the thyroid and parathyroid. Diagram of an anterior view of the pharynx in a 4-week embryo showing the relationship of the third and fourth pharyngeal pouches to the final position of the thyroid and parathyroid glands. IPG, inferior parathyroid; SPG, superior parathyroid; UBB, ultimobranchial body.

SURGICAL ANATOMY

The normal thyroid gland weighs 20–25 g. The functioning unit is the lobule supplied by a single arteriole and consists of 24–40 follicles lined with cuboidal epithelium. The follicle contains colloid in which thyroglobulin is stored (***Figure 55.2***). The arterial supply is rich, and extensive anastomoses occur between the main thyroid arteries and the branches of the tracheal and oesophageal arteries (***Figure 55.3***). There is an extensive lymphatic network within and around the gland. Although some lymph channels pass directly to the deep cervical nodes, the subcapsular plexus drains principally to the central compartment juxtathyroid – 'Delphian' and paratracheal nodes and nodes on the superior and inferior thyroid veins (level VI) – and from there to the deep cervical (levels II, III, IV and V) and mediastinal groups of nodes (level VII) (***Figure 55.4***).

The relationship between the recurrent laryngeal nerve (RLN) and the thyroid is of supreme importance to the

Delphi, a sacred site near the Gulf of Corinth in Greece, is the place where Pythia, the snake-woman oracle, resided. She sat on a tripod clutching the ribbons of the monolithic 'omphalos' of the world and, after inhaling sulphurous fumes, would utter meaningless jargon, which was interpreted equivocally by the attendant priests for those who came to consult her. Formerly the purpose of these lymph nodes was uncertain, and they were therefore called 'Delphic'.

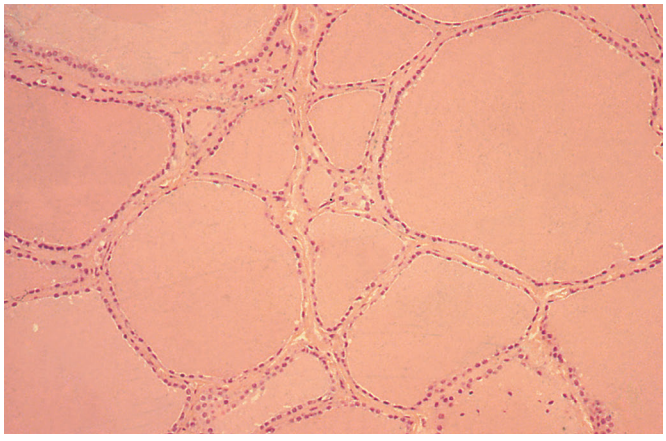

Figure 55.2 Histology of the normal thyroid.

operating surgeon. A branch of the vagus, the nerve recurs round the arch of the aorta on the left and the subclavian artery on the right. The clinical significance of this is that on the left the nerve has more distance in which to reach the tracheo-oesophageal groove and therefore runs in a medial plane. On the right, there is less distance and the nerve runs more obliquely to reach the tracheo-oesophageal groove. Approximately 2% of nerves on the right are non-recurrent and will enter the larynx from above.

The nerve runs posterior to the thyroid and enters the larynx at the cricothyroid joint. This entry point is at the level

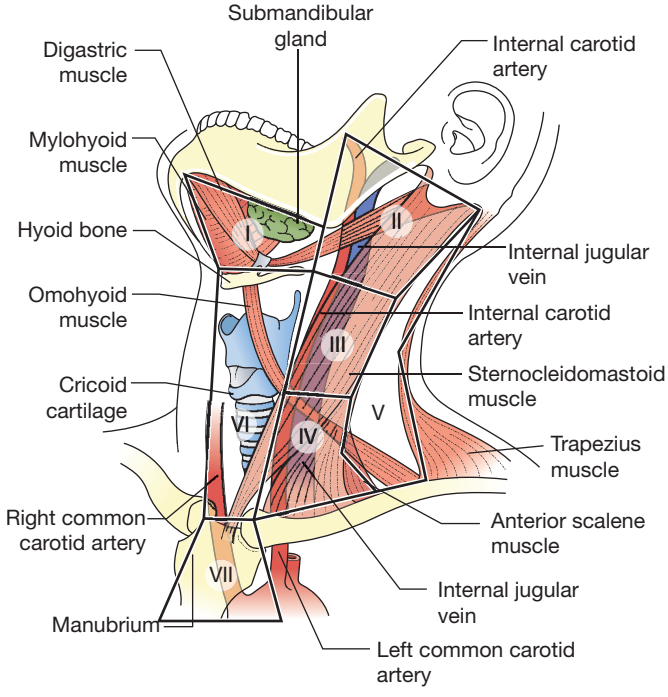

Figure 55.4 Cervical lymph node levels.

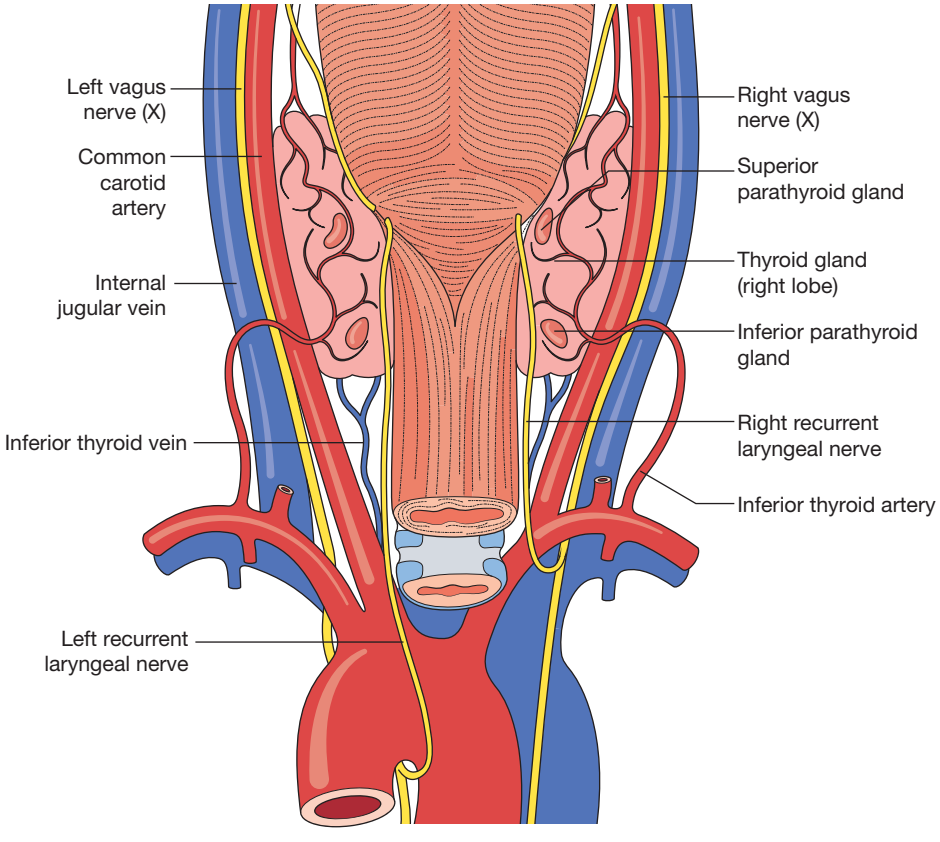

Figure 55.3 The thyroid gland from behind.

of Berry's ligament, a condensation of pretracheal fascia that binds the thyroid to the trachea. This is the point at which the nerve is at most risk of injury during surgery. In terms of surgical anatomy, the nerve can be located in the tracheo-oesophageal groove, where it forms one side of Beahrs' triangle (the other two sides are the carotid artery and the inferior thyroid artery) or at the cricothyroid joint. The nerve will normally be found as the thyroid lobe is mobilised laterally, lying under the most posterolateral portion of the gland called the tubercle of Zuckerkandl.

PHYSIOLOGY

Thyroxine

The hormones tri-iodothyronine (T_3) and L-thyroxine (T_4) are bound to thyroglobulin within the colloid. Synthesis within the thyroglobulin complex is controlled by several enzymes, in distinct steps:

- trapping of inorganic iodide from the blood;
- oxidation of iodide to iodine;
- binding of iodine with tyrosine to form iodotyrosine;
- coupling of monoiodotyrosines and di-iodotyrosines to form T_3 and T_4.

When hormones are required, the complex is resorbed into the cell and thyroglobulin is broken down. T_3 and T_4 are liberated and enter the blood, where they are bound to serum proteins: albumin, thyroxine-binding globulin (TBG) and thyroxine-binding prealbumin (TBPA). The small amount of hormone that remains free in the serum is biologically active.

The metabolic effects of the thyroid hormones are due to unbound free T_3 and T_4 (0.3% and 0.03% of the total circulating hormones, respectively). T_3 is the more important physiological hormone and is also produced in the periphery by conversion from T_4. T_3 is quick acting (within a few hours), whereas T_4 acts more slowly (4–14 days).

Calcitonin

The parafollicular C cells of the thyroid are of neuroendocrine origin and arrive in the thyroid via the ultimobranchial body (***Figure 55.1***). They produce calcitonin.

The pituitary–thyroid axis

Synthesis and release of thyroid hormones from the thyroid is controlled by thyroid-stimulating hormone (TSH) from the anterior pituitary. Secretion of TSH depends upon the level of circulating thyroid hormones and is modified in a negative feedback manner. In hyperthyroidism TSH production is suppressed, whereas in hypothyroidism it is stimulated. Regulation of TSH secretion also results from the action of thyrotrophin-releasing hormone (TRH) produced in the hypothalamus.

Thyroid-stimulating antibodies

A family of IgG immunoglobulins bind with TSH receptor sites (TRAbs) and activate TSH receptors on the follicular cell membrane. They have a more protracted action than TSH (16–24 versus 1.5–3 hours) and are responsible for virtually all cases of thyrotoxicosis not due to autonomous toxic nodules. Serum concentrations are very low but their measurement is not essential to make the diagnosis.

Serum thyroid hormones

Serum thyroid-stimulating hormone

TSH levels can be measured accurately down to very low serum concentrations with an immunochemiluminometric assay. Interpretation of deranged TSH levels depends on knowledge of the T_3 and T_4 values. In the euthyroid state, T_3, T_4 and TSH levels will all be within the normal range. Florid thyroid failure results in depressed T_3 and T_4 levels, with gross elevation of TSH. Incipient or developing thyroid failure is characterised by low normal values of T_3 and T_4 and elevation of TSH. In toxic states, the TSH level is suppressed (***Table 55.1***).

Thyroid autoantibodies

Serum levels of antibodies against thyroid peroxidase (TPO) and thyroglobulin are useful in determining the cause of thyroid dysfunction and swellings. Autoimmune thyroiditis may be associated with thyroid toxicity, failure or euthyroid goitre. Levels above 25 units/mL for TPO antibody and titres of greater than 1:100 for antithyroglobulin are considered significant,

TABLE 55.1 Results of thyroid function tests in normal and pathological states.

Thyroid functional state	TSH (0.3–3.3 mU/L)	Free T_4 (10–30 nmol/L)	Free T_3 (3.5–7.5 µmol/L)
Euthyroid	Normal	Normal	Normal
Thyrotoxic	Undetectable	High	High
Myxoedema	High	Low	Low
Suppressive T_4 therapy	Undetectable	High	High (often normal)
T_3 toxicity	Low/undetectable	Normal	High

T_3, tri-iodothyronine; T_4, L-thyroxine; TSH, thyroid-stimulating hormone.

Sir James Berry, 1860–1946, surgeon, Royal Free Hospital, London, UK.
Oliver H Beahrs, 1914–2006, surgeon, Mayo Clinic, Rochester, MN, USA.
Emil Zuckerkandl, 1849–1901, Austro-Hungarian anatomist, brother of urologist Otto Zuckerkandl.
Myxoedema was first described in 1873 by Sir William Withey Gull, 1816–1890, physician, Guy's Hospital, London, UK.

although a proportion of patients with histological evidence of lymphocytic (autoimmune) thyroiditis are seronegative. The presence of antithyroglobulin antibody interferes with assays of serum thyroglobulin, with implications for follow-up of thyroid cancers. TSH receptor antibodies (TSH-RAb or TRAB) are often present in Graves' disease. They are largely produced within the thyroid itself.

Summary box 55.1

Thyroid investigations

Essential

- Serum: TSH (T_3 and T_4 if abnormal); thyroid autoantibodies
- Fine-needle aspiration cytology (FNAC) of palpable discrete swellings

Optional

- Corrected serum calcium
- Serum calcitonin (carcinoembryonic antigen may be used as an alternative screening test for medullary cancer)
- Imaging: chest radiograph and thoracic inlet if tracheal deviation/retrosternal goitre; ultrasonography, computed tomography (CT) and magnetic resonance imaging (MRI) scan for known cancer, some reoperations and some retrosternal goitres; isotope scan if discrete swelling and toxicity coexist

Thyroid imaging

The workhorse investigation in thyroid disease for the surgeon is ultrasonography. This modality allows assessment of the gland and the regional lymphatics. Not only can the characteristics of the gland substance be quantified, but critically the presence and features of thyroid nodules can be described. Number, size, shape, margins, vascularity and specific features such as the presence of microcalcifications can be used to predict the risk of malignancy within a specific nodule. Regional lymphatics, particularly in the lateral neck, can be assessed accurately for the presence of metastatic deposits. During ultrasonography, fine-needle aspiration (FNA) can be performed more accurately than free-hand techniques allow.

Ultrasonography has the advantages that it is not associated with ionising radiation and is non-invasive and cheap (***Figure 55.5***). Visualisation of the central neck nodes, in particular those behind the sternum, is however limited. For this reason, when metastatic disease is detected cross-sectional imaging is required to fully stage the disease. Retrosternal extension, which can often be predicted on a plain chest radiograph (***Figure 55.6***), also requires more advanced techniques to determine the extent adequately prior to considering management. For most of these indications, the imaging modality of choice is CT. Rapid acquisition times minimise artefacts secondary to breathing and the lung fields can be accurately assessed simultaneously.

In the setting of an invasive primary thyroid cancer, both CT and MRI may have a role. Contrast-enhanced CT is useful

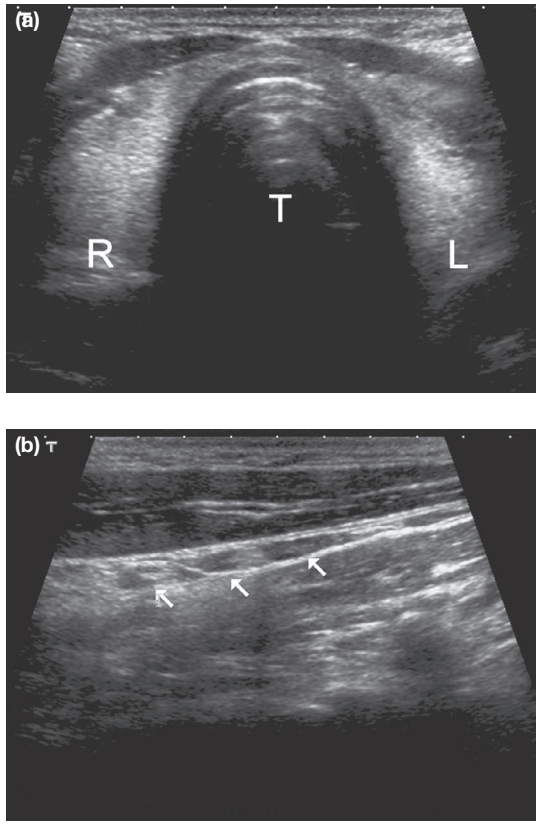

Figure 55.5 Ultrasonography. **(a)** Transverse scan of a normal thyroid. R, right lobe; L, left lobe; T, trachea. **(b)** Longitudinal scan of normal jugular lymph nodes (white arrows).

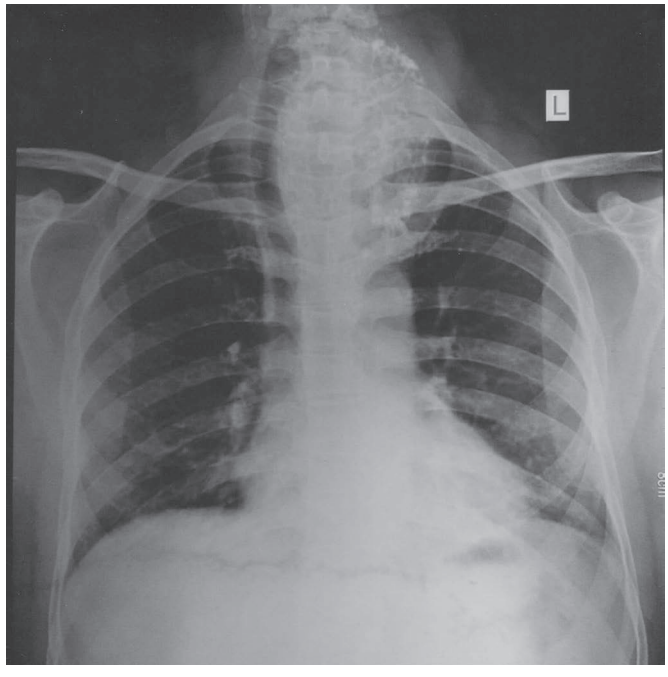

Figure 55.6 Chest radiograph showing a retrosternal goitre with calcification and tracheal displacement (courtesy of Dr Achleshwar Dayal, Hoshangabad, MP, India).

Robert James Graves, 1796–1853, physician, Meath Hospital, Dublin, Ireland, published an account of exophthalmic goitre in 1835. He was President of the Royal College of Physicians of Ireland and elected Fellow of the Royal Society (London, UK) in 1849.

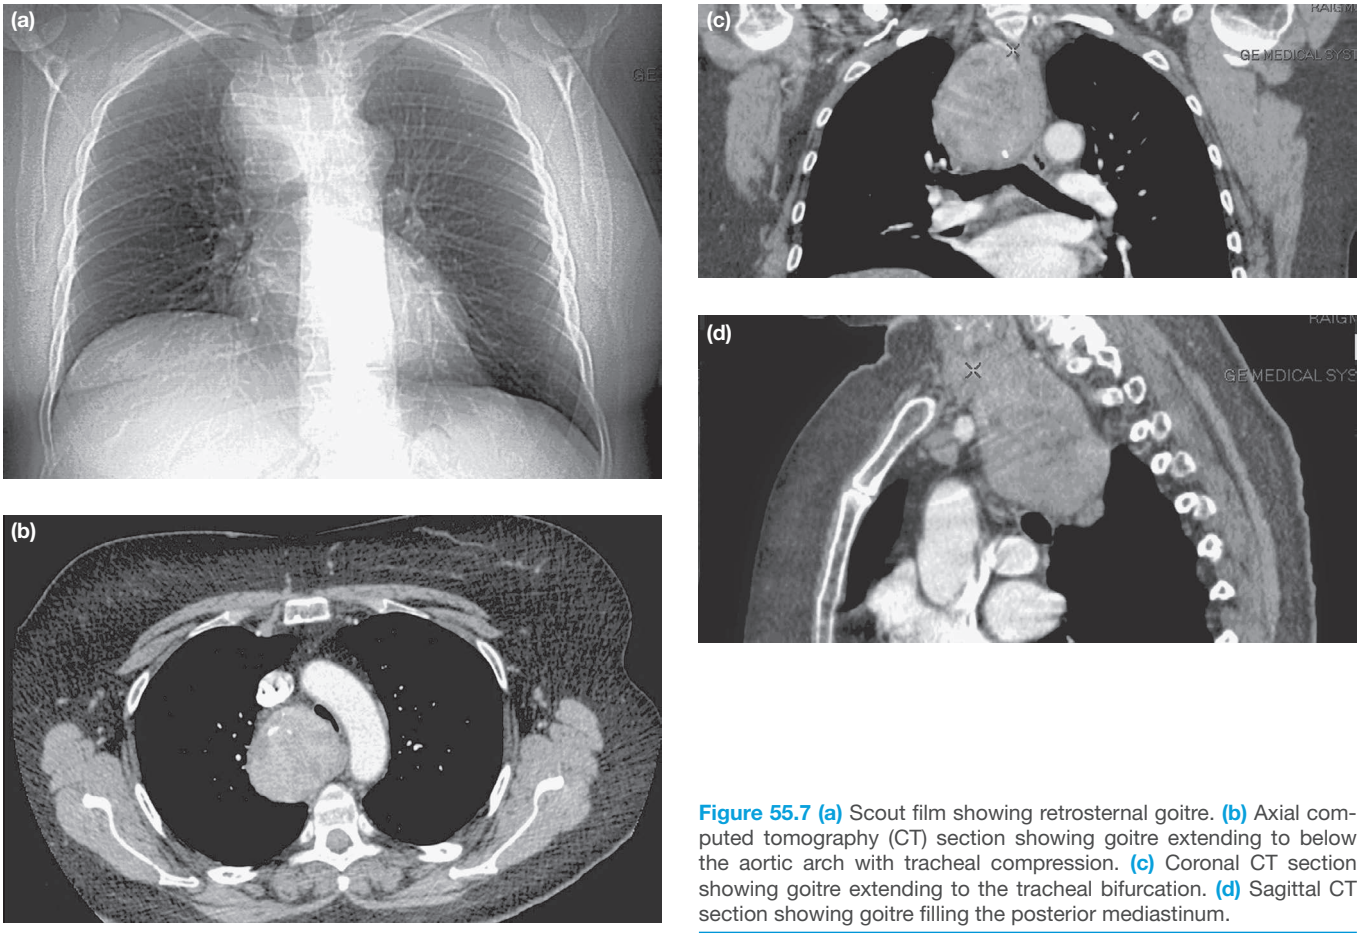

Figure 55.7 (a) Scout film showing retrosternal goitre. **(b)** Axial computed tomography (CT) section showing goitre extending to below the aortic arch with tracheal compression. **(c)** Coronal CT section showing goitre extending to the tracheal bifurcation. **(d)** Sagittal CT section showing goitre filling the posterior mediastinum.

for determining the extent of airway invasion (***Figure 55.7***) and MRI is superior at determining the presence of prevertebral fascia invasion.

Positron emission tomography (PET) scans have limited application in thyroid disease. They may be considered in the setting of recurrent thyroid cancer. This is particularly useful when the disease does not concentrate iodine, at which point fluorodeoxyglucose (FDG) uptake increases and lesions become positive on PET scans.

Isotope scanning

The uptake by the thyroid of a low dose of either radiolabelled iodine (^{123}I) or the cheaper technetium (^{99m}Tc) will demonstrate the distribution of activity in the whole gland. Routine isotope scanning is unnecessary and inappropriate for distinguishing benign from malignant lesions because the majority (80%) of 'cold' swellings are benign and some (5%) functioning or 'warm' swellings will be malignant. Its principal value is in the toxic patient with a nodule or nodularity of the thyroid. Localisation of overactivity in the gland will differentiate between a toxic nodule with suppression of the remainder of the gland and toxic multinodular goitre with several areas of increased uptake with important implications for therapy (***Figure 55.8***).

Whole-body scanning is used to demonstrate metastases. However, the patient must have all normally functioning thyroid tissue ablated by either surgery or radioiodine before the scan is performed because metastatic thyroid cancer tissue cannot compete with normal thyroid tissue in the uptake of iodine.

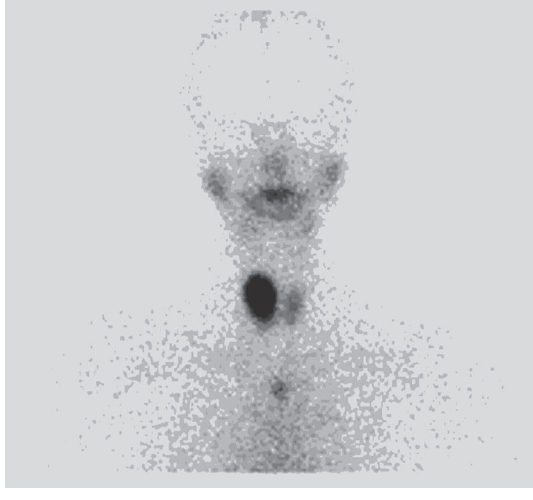

Figure 55.8 Technetium thyroid scan showing the appearance of a 1-cm 'toxic' adenoma in the right thyroid lobe with suppression of uptake in the left lobe. The intense uptake gives a false impression of the size of the swelling.

Fine-needle aspiration cytology

FNAC is the investigation of choice in discrete thyroid swellings. FNAC has excellent patient compliance, is simple and quick to perform in the outpatient department and is readily repeated. This technique, developed in Scandinavia 40 years ago, is now routine throughout the world. FNAC results should be reported using standard terminology (*Table 55.2*). Ultrasound guidance allows more accurate sampling and reduces the rate of unsatisfactory aspirates.

TABLE 55.2 Classification of fine-needle aspiration cytology reports.

Thy1	Non-diagnostic
Thy1c	Non-diagnostic cystic

Thy5	Malignant

THYROID ENLARGEMENT

The normal thyroid gland is impalpable. The term goitre (from the Latin guttur = the throat) is used to describe generalised enlargement of the thyroid gland. A discrete swelling (nodule) in one lobe with no palpable abnormality elsewhere is termed an isolated (or solitary) swelling. Discrete swellings with evidence of abnormality elsewhere in the gland are termed dominant.

A scheme for classifying thyroid enlargement is given in *Table 55.3*.

TABLE 55.3 Classification of thyroid swellings.

Simple goitre (euthyroid)	Diffuse hyperplastic	• Physiological • Pubertal • Pregnancy
	Multinodular goitre	
Toxic	Diffuse (Graves' disease)	
	Multinodular	
	Toxic adenoma	
Neoplastic	Benign	
	Malignant	
Inflammatory	Autoimmune	Chronic lymphocytic thyroiditis
		Hashimoto's disease
	Granulomatous	de Quervain's thyroiditis
	Fibrosing	Riedel's thyroiditis
	Infective	Acute (bacterial thyroiditis, viral thyroiditis, 'subacute thyroiditis')
		Chronic (tuberculous, syphilitic)
	Other	Amyloid

Simple goitre

Aetiology

Simple goitre may develop as a result of stimulation of the thyroid gland by TSH, either as a result of inappropriate secretion from a microadenoma in the anterior pituitary (which is rare) or in response to a chronically low level of circulating thyroid hormones. The most important factor in endemic goitre is dietary deficiency of iodine (see ***Iodine deficiency***), but defective hormone synthesis probably accounts for many sporadic goitres (see ***Dyshormonogenesis***).

TSH is not the only stimulus to thyroid follicular cell proliferation as other growth factors, including immunoglobulins, exert an influence. The heterogeneous structural and functional response in the thyroid resulting in characteristic nodularity may be due to the presence of clones of cells particularly sensitive to growth stimulation.

Iodine deficiency

The daily requirement of iodine is about 0.1–0.15 mg. In nearly all districts where simple goitre is endemic, there is a very low iodide content in the water and food. Endemic areas are in the mountainous ranges, such as the Rocky Mountains, the Alps, the Andes and the Himalayas, and in the UK areas of Derbyshire and Yorkshire. Endemic goitre is also found in lowland areas where the soil lacks iodide or the water supply comes from far away mountain ranges, e.g. the Great Lakes of North America, the plains of Lombardy, the Struma Valley, the Nile Valley and the Congo. Calcium is also goitrogenic and goitre is common in low-iodine areas on chalk or limestone, for example Derbyshire and southern Ireland. Although iodides in food and water may be adequate, failure of intestinal absorption may produce iodine deficiency.

Dyshormonogenesis

Enzyme deficiencies of varying severity may be responsible for many sporadic goitres, i.e. in non-endemic areas (***Figure 55.9***). There is often a family history, suggesting a genetic defect. Environmental factors may compensate in areas of high iodine intake; for example, goitre is almost unknown in Iceland where the fish diet is rich in iodine. Similarly, a low intake of iodine encourages goitre formation in those with a metabolic predisposition.

Hakaru Hashimoto, 1881–1934, Director, The Hashimoto Hospital, Mie, Japan, described chronic lymphocytic thyroiditis in 1912.
Friedrich Joseph de Quervain, 1868–1940, Professor of Surgery, Berne, Switzerland, described this form of thyroiditis in 1902.
Bernhard Riedel, 1846–1916, Surgeon, University of Jena, Thuringia, Germany
Struma. The River Struma arises in the mountains of Bulgaria and flows into the Aegean Sea. Along its banks and those of its tributaries dwell peoples of several nationalities, among whom endemic goitre has long been prevalent. Struma is a European continental term for goitre.

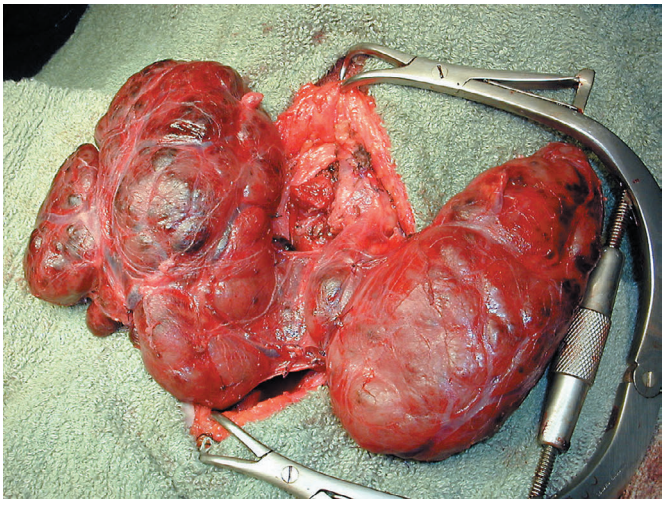

Figure 55.9 Total thyroidectomy for dyshormonogenetic goitre in a 14-year-old girl.

Goitrogens

Well-known goitrogens are the vegetables of the brassica family (cabbage, kale and rape), which contain thiocyanate, drugs such as para-aminosalicylic acid (PAS) and the antithyroid drugs. Thiocyanates and perchlorates interfere with iodide trapping; carbimazole and thiouracil compounds interfere with the oxidation of iodide and the binding of iodine to tyrosine.

Surprisingly, iodides in large quantities are goitrogenic because they inhibit the organic binding of iodine and produce an iodide goitre. Excessive iodine intake may be associated with an increased incidence of autoimmune thyroid disease.

The natural history of simple goitre

Stages in goitre formation are:

- Persistent growth stimulation causes diffuse hyperplasia; all lobules are composed of active follicles and iodine uptake is uniform. This is a diffuse hyperplastic goitre, which may persist but is reversible if stimulation ceases.
- Later, as a result of fluctuating stimulation, a mixed pattern develops with areas of active lobules and areas of inactive lobules.
- Active lobules become more vascular and hyperplastic until haemorrhage occurs, causing central necrosis and leaving only a surrounding rind of active follicles.
- Necrotic lobules coalesce to form nodules filled either with iodine-free colloid or a mass of new but inactive follicles.
- Continual repetition of this process results in a nodular goitre. Most nodules are inactive, and active follicles are present only in the internodular tissue.

Diffuse hyperplastic goitre

Diffuse hyperplasia corresponds to the first stages of the natural history. The goitre appears in childhood in endemic areas; in sporadic cases, it usually occurs at puberty, when metabolic demands are high. If TSH stimulation ceases the goitre may regress, but tends to recur later at times of stress such as pregnancy. The goitre is soft, diffuse and may become large enough to cause discomfort. A colloid goitre is a late stage of diffuse hyperplasia, when TSH stimulation has fallen off and when many follicles are inactive and full of colloid (***Figure 55.10***).

Nodular goitre

Nodules are usually multiple, forming a multinodular goitre (***Figure 55.11***). Occasionally, only one macroscopic nodule is found, but microscopic changes will be present throughout the gland; this is one form of a clinically solitary nodule. Nodules may be colloid or cellular, and cystic degeneration and haemorrhage are common, as is subsequent calcification. Nodules appear early in endemic goitre and later (between 20 and 30 years) in sporadic goitre, although the patient may be unaware of the goitre until his or her late forties or fifties. All types of simple goitre are more common in the female than in the male owing to the presence of oestrogen receptors in thyroid tissue.

Diagnosis

Diagnosis is usually straightforward. The patient is euthyroid and the nodules are palpable and often visible; they are smooth, usually firm and not hard and the goitre is painless and moves

Figure 55.10 Colloid goitre.

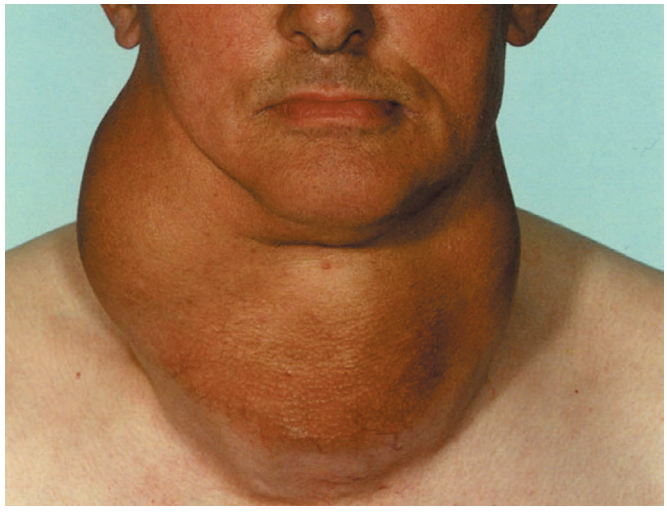

Figure 55.11 Large multinodular goitre.

freely on swallowing. Hardness and irregularity, due to calcification, may simulate carcinoma. A painful nodule, sudden appearance or rapid enlargement of a nodule raises suspicion of carcinoma but is usually due to haemorrhage into a simple nodule. Differential diagnosis from autoimmune thyroiditis may be difficult and the two conditions frequently coexist.

Investigations

Thyroid function should be assessed to exclude hyperthyroidism, and the presence of circulating thyroid antibodies tested to differentiate from autoimmune thyroiditis. Ultrasonography is the gold standard assessment when undertaken by a suitably trained and experienced operator. FNAC is only required for a nodule within the goitre that demonstrates ultrasonographic features of concern. This may or may not be the largest 'dominant' nodule. The biopsy should be performed under ultrasound guidance to ensure that the correct nodule is sampled. If there are swallowing or breathing symptoms then a CT scan of the chest and neck is the best modality to assess tracheal or oesophageal deviation or compression.

Complications

Tracheal obstruction may be due to gross lateral displacement or compression in a lateral or anteroposterior plane by retrosternal extension of the goitre (***Figure 55.7***). Acute respiratory obstruction may follow haemorrhage into a nodule impacted in the thoracic inlet.

Secondary thyrotoxicosis

Transient episodes of mild hyperthyroidism are common, occurring in up to 30% of patients.

Carcinoma

An increased incidence of cancer (usually follicular) has been reported from endemic areas. Dominant or rapidly growing nodules in longstanding goitres should always be subjected to aspiration cytology.

Prevention and treatment of simple goitre

In endemic areas the incidence of goitre has been strikingly reduced by the introduction of iodised salt. In the early stages, a hyperplastic goitre may regress if thyroxine is given in a dose of 0.15–0.2 mg daily for a few months.

Although the nodular stage of simple goitre is irreversible, more than half of benign nodules will regress in size over 10 years. Most patients with multinodular goitre are asymptomatic and do not require operation. Surgery is indicated for nodular goitres with features of underlying malignancy, for pressure symptoms if other causes have been excluded or for cosmetic reasons if the patient finds the goitre unsightly. If the goitre is causing tracheal compression then surgery should be considered. Many such patients are found incidentally and are asymptomatic and often very elderly. As these goitres often grow very slowly the risks and benefits of surgery should be considered carefully, particularly if a sternal split may be required for access.

There is a choice of surgical treatment in multinodular goitre: total thyroidectomy with immediate and lifelong replacement of thyroxine or some form of partial resection to conserve sufficient functioning thyroid tissue to subserve normal function while reducing the risk of hypoparathyroidism that accompanies total thyroidectomy. Historically subtotal thyroidectomy involves partial resection of each lobe, removing the bulk of the gland and leaving up to 8 g of relatively normal tissue in each remnant. The technique is essentially the same as described for toxic goitre, as are the postoperative complications. A significant problem with this approach is the propensity for regrowth. Therefore, unless there is a local shortage of thyroxine, most surgeons now favour total thyroidectomy in the setting of bilateral disease. More often, however, the multinodular change is asymmetrical, with one lobe more significantly involved than the other. In these circumstances, particularly in older patients, total lobectomy on the more affected side is the appropriate management. Although this can be used in combination with subtotal resection of the contralateral lobe (Dunhill procedure), most surgeons now prefer no intervention on the less affected side because of the potential for regrowth and the increased rate of complications associated with reoperation. In many cases, the causative factors persist and recurrence is likely.

Reoperation for recurrent nodular goitre is more difficult and hazardous and, for this reason, an increasing number of thyroid surgeons favour total thyroidectomy in younger patients. However, when the first operation comprised unilateral lobectomy alone for asymmetric goitre, reoperation and completion total thyroidectomy is straightforward if required for progression of nodularity in the remaining lobe. Total lobectomy and total thyroidectomy have the additional advantage of being therapeutic for incidental carcinomas.

Clinically discrete swellings

Discrete thyroid swellings (thyroid nodules) are common and are palpable in 3–4% of the adult population in the UK and USA. They are three to four times more frequent in women than in men.

Diagnosis

A discrete swelling in an otherwise impalpable gland is termed isolated or solitary, whereas the preferred term is dominant for a similar swelling in a gland with clinical evidence of generalised abnormality in the form of a palpable contralateral lobe or generalised mild nodularity. About 70% of discrete thyroid swellings are clinically isolated and about 30% are dominant. The true incidence of isolated swellings is somewhat less than the clinical estimate. Clinical classification is inevitably subjective and overestimates the frequency of truly isolated swellings. When such a gland is exposed at operation or examined by ultrasonography, CT or MRI, clinically impalpable nodules are often detected. The true frequency of thyroid nodularity compared with the clinical detection rate by palpation is shown in ***Figure 55.12***.

Sir Thomas Peel Dunhill, 1876–1957, surgeon, St Bartholomew's Hospital, London, UK.

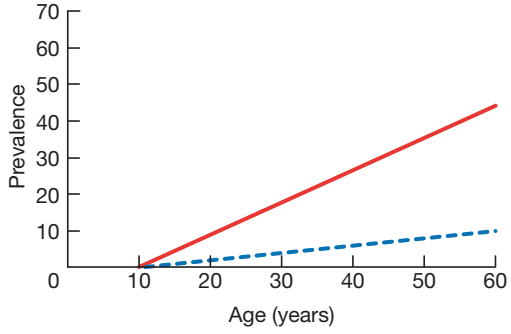

Figure 55.12 The prevalence of thyroid nodules detected on palpation (dashed line) or by ultrasonography or postmortem examination (solid line) (after Mazzaferri).

Demonstrating the presence of impalpable nodules does not change the management of palpable discrete swellings and begs the question of the necessity of investigating incidentally found nodules. The importance of discrete swellings lies in the risk of neoplasia compared with other thyroid swellings. Some 15% of isolated swellings prove to be malignant and an additional 30–40% are follicular adenomas. The remainder are non-neoplastic, largely consisting of areas of colloid degeneration, thyroiditis or cysts. Although the incidence of malignancy or follicular adenoma in clinically dominant swellings is approximately half of that of truly isolated swellings, it is substantial and cannot be ignored (***Figure 55.13***).

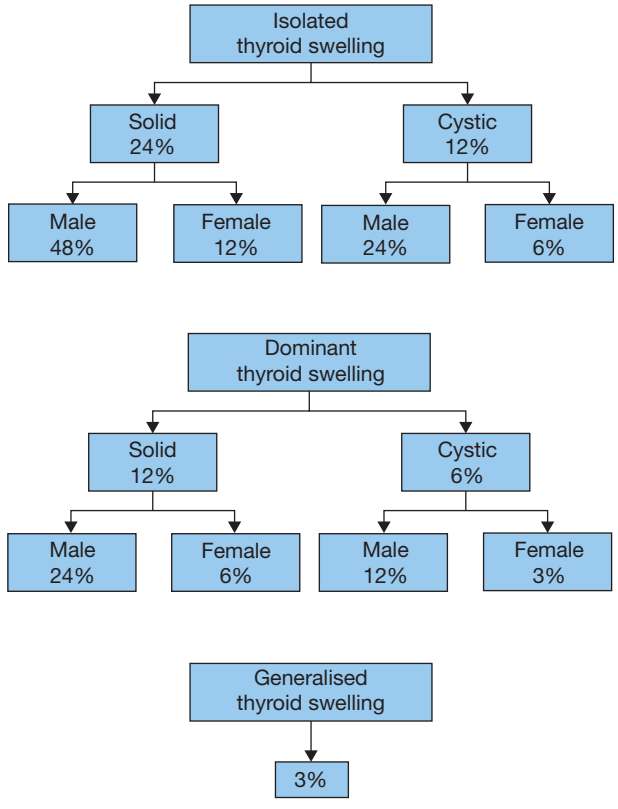

Figure 55.13 The risk of malignancy in thyroid swellings ('rule of 12'). The risk of cancer in a thyroid swelling can be expressed as a factor of 12. The risk is greater in isolated versus dominant swellings, solid versus cystic swellings and in men versus women.

Investigation

Thyroid function

Serum TSH and thyroid hormone levels should be measured. If hyperthyroidism associated with a discrete swelling is confirmed biochemically, it indicates either a 'toxic adenoma' or a manifestation of toxic multinodular goitre. The combination of toxicity and nodularity is important and is an indication for isotope scanning to localise the area(s) of hyperfunction.

Autoantibody titres

The autoantibody status may determine whether a swelling is a manifestation of chronic lymphocytic thyroiditis. The presence of circulating antibodies increases the risk of thyroid failure after lobectomy.

Isotope scan

Isotope scanning used to be the mainstay of investigation of discrete thyroid swellings but has been abandoned except when toxicity is associated with nodularity.

Ultrasonography

This is used to determine the physical characteristics of thyroid swellings. There are a number of ultrasonographic features in a thyroid swelling associated with thyroid neoplasia, including microcalcification and increased vascularity, but only macroscopic capsular breach and nodal involvement are diagnostic of malignancy. Ultrasonography should be used as the primary investigation of any thyroid nodule as a reassuring appearance mitigates the need for FNAC (see ***Fine-needle aspiration cytology***).

Fine-needle aspiration cytology

FNAC should be used, ideally under ultrasound guidance, on all nodules that do not fulfil a fully benign (U2) classification on ultrasonography. FNAC is reliable in identifying papillary thyroid carcinoma (PTC) but cannot distinguish between a benign follicular adenoma (***Figure 55.14***) and follicular carcinoma, as this distinction is dependent not on cytology but on histological criteria, which include capsular and vascular invasion.

FNAC is both highly specific and sensitive. Using ultrasonography improves this further, particularly in part cystic, part solid nodules in which ultrasonography allows targeting of the solid element for biopsy.

Radiology

Plain films have previously been used to assess tracheal compression and deviation, but the modality of choice now is CT scanning. CT scanning is also useful if ultrasonography has identified metastatic disease in the neck as it can assist surgical planning and also assess the superior mediastinum and lungs.

Ernest L Mazzaferri, 1936–2013, endocrinologist, Ohio State University School of Medicine, Columbus, OH, USA.

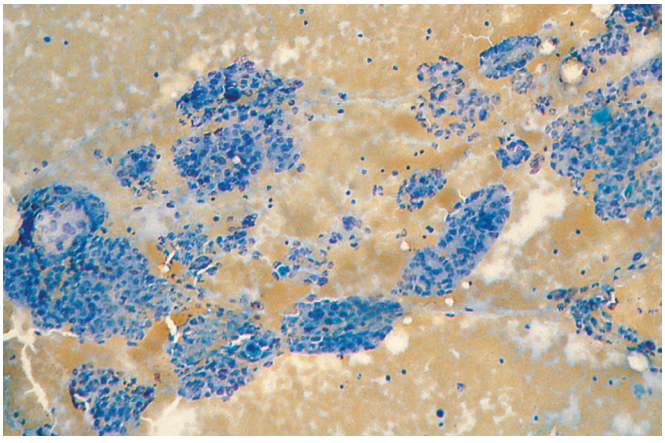

Figure 55.14 Thy3 aspiration cytology (***Table 55.2***). Follicular neoplasm showing increased cellularity with a follicular pattern.

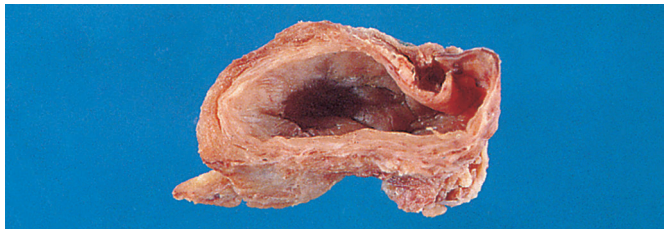

Figure 55.15 Apparently simple cystic thyroid swelling, the wall of which comprised follicular neoplastic tissue.

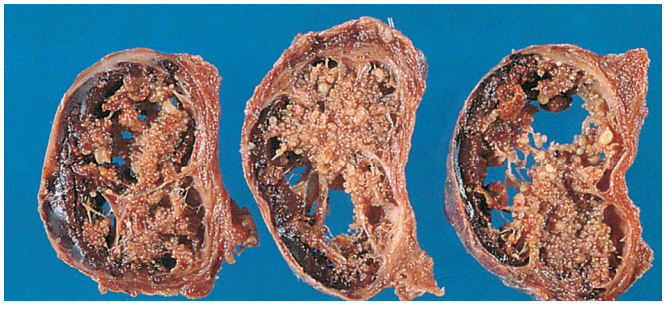

Figure 55.16 Cyst formation in a papillary carcinoma.

Laryngoscopy

Flexible laryngoscopy has rendered indirect laryngoscopy obsolete and is widely used preoperatively to determine the mobility of the vocal cords. The presence of a unilateral cord palsy coexisting with an ipsilateral thyroid nodule of concern is usually diagnostic of malignant disease.

Core biopsy

Core biopsy is rarely indicated in thyroid masses owing to the vascularity of the thyroid gland and the risk of postprocedure haemorrhage. It can be useful in the rapid diagnosis of widely invasive malignant disease, for example anaplastic carcinoma, or in the diagnosis of lymphadenopathy.

Indication for surgery

The main indication for operation is the risk of neoplasia, which includes follicular adenoma as well as malignant swellings. The reason for advocating the removal of all follicular neoplasms is that it is seldom possible to distinguish between a follicular adenoma and carcinoma cytologically. Even when the cytology is negative, the age and sex of the patient and the size of the swelling may be relative indications for surgery, especially when a large swelling is responsible for symptoms.

There are useful clinical criteria to assist in selection for operation according to the risk of neoplasia and malignancy. Hard texture alone is not reliable as tense cystic swellings may be suspiciously hard but a hard, irregular swelling with any apparent fixity, which is unusual, is highly suspicious. Evidence of RLN paralysis, suggested by hoarseness and a non-occlusive cough and confirmed by laryngoscopy, is almost pathognomonic. Cervical lymphadenopathy along the internal jugular vein in association with a clinically suspicious swelling is almost diagnostic of PTC. In most patients, however, such features are absent. The incidence of thyroid carcinoma in women is about three times that in men, but a discrete swelling in a male is much more likely to be malignant than in a female. The risk of carcinoma is increased at either end of the age range and a discrete swelling in a teenager of either sex must be provisionally diagnosed as carcinoma.

Thyroid cysts

Routine FNAC (or ultrasonography) shows that over 30% of clinically isolated swellings contain fluid and are cystic or partly cystic. Tense cysts may be hard and mimic carcinoma. Bleeding into a cyst often presents with a history of sudden painful swelling, which resolves to a variable extent over a period of weeks if untreated. Aspiration yields altered blood but reaccumulation is frequent. About 55% of cystic swellings are the result of colloid degeneration or are of uncertain aetiology because of an absence of epithelial cells in the lining. Although most of the remainder are the result of involution in follicular adenomas (***Figure 55.15***), some 10–15% of cystic follicular swellings are histologically malignant (30% in men and 10% in women). PTC is often associated with cyst formation (***Figure 55.16***).

Most patients with discrete swellings, however, are women, aged 20–40 years, in whom the risk of malignancy, although significant, is low and the indications for operation are not clear-cut.

Ultrasonography is the most useful tool for assessing cysts. If there is no discernible solid element, the cyst is almost certainly benign and does not need to be further investigated. As stated above, simple aspiration is associated with high rates of reaccumulation. However, ablation using either ethanol or thermal probes (radiofrequency, microwave, laser or high-frequency ultrasound) achieves cyst resolution in up to 90% of cases and should be considered for recurrent, symptomatic cysts. If there is an associated solid element, then consideration should be given to targeting that area with ultrasound-guided FNAC.

The indications for operation in isolated or dominant thyroid swellings are listed in ***Table 55.4***.

TABLE 55.4 Indications for operation in thyroid swellings.

Neoplasia	FNAC positive Thy3–5	
	Clinical suspicion	• Age • Male sex • Hard texture • Fixity • Recurrent laryngeal nerve palsy • Lymphadenopathy • Recurrent cyst
Toxic adenoma		
Pressure symptoms		
Cosmesis		
Patient's wishes		

FNAC, fine-needle aspiration cytology; Thy3–5, see ***Table 55.2***.

Selection of thyroid procedure

The choice of thyroid operation depends on:

- diagnosis (if known preoperatively);
- risk of thyroid failure;
- risk of RLN injury;
- risk of recurrence;
- Graves' disease;
- multinodular goitre;
- differentiated thyroid cancer;
- risk of hypoparathyroidism.

Total and near-total thyroidectomy do not conserve sufficient thyroid tissue for normal thyroid function and thyroid replacement therapy is necessary. In two-thirds of patients with negative antithyroid antibodies, one thyroid lobe will maintain normal function.

Subtotal resections for colloid goitre or Graves' disease run the risk of later growth of the remnant and, if a second operation is required years later, this greatly increases the risk to the RLN and parathyroid glands. In young patients, total thyroidectomy should be considered. It may be preferable to leave the least affected lobe untouched to permit a straightforward lobectomy in the future if required, rather than carry out subtotal resections.

In Graves' disease, preserving large remnants increases the risk of recurrence of the toxicity and, in these cases, it is better to err on the side of removing too much thyroid tissue rather than too little (***Table 55.5***). Thyroid failure should not be regarded as a failure of treatment, but recurrent toxicity is.

The relative merits of routine total versus selective total thyroidectomy in differentiated thyroid cancer are discussed below.

Summary box 55.2

Thyroid operations

All thyroid operations can be assembled from three basic elements:

1. Total lobectomy
2. Isthmusectomy
3. Subtotal lobectomy

Total thyroidectomy = 2 × total lobectomy + isthmusectomy

Subtotal thyroidectomy = 2 × subtotal lobectomy + isthmusectomy

Near-total thyroidectomy = total lobectomy + isthmusectomy + subtotal lobectomy (Dunhill procedure)

Lobectomy = total lobectomy + isthmusectomy

Retrosternal goitre

Retrosternal goitre tends to arise from the slow growth of a multinodular gland down into the mediastinum. As the gland enlarges within the thoracic inlet, pressure may lead to dysphagia, tracheal compression and eventually airway symptoms. The vast majority of patients have minimal symptoms. Patients should be considered for surgery if there is significant airway compression, if symptoms are present or in young patients in whom symptoms are likely to develop. In elderly patients with incidentally discovered retrosternal goitres, most surgeons would observe rather than treat prophylactically. Clearly a balance between risk and benefit must be made.

If a decision is made to proceed to surgery, assessment of the extent of disease is critical. The vast majority (>95%) of retrosternal goitres can be removed transcervically. Patients most at risk of requiring conversion to an open sternotomy approach include those with malignant disease or who are undergoing revision, those whose goitres that extend into the posterior mediastinum and those in whom the diameter of the goitre exceeds that of the thoracic inlet. In such cases a joint case with thoracic surgery should be planned.

All patients should have cross-sectional imaging. Ideally this is performed in the surgical position and, when interpreting CT chest scans, the surgeon should pay attention to the arm position. If the arms are up (as for standard CT chest)

TABLE 55.5 Comparison of surgical options for Graves' disease.

	Total thyroidectomy	Subtotal thyroidectomy
Control of toxicity	Immediate	Immediate
Return to euthyroid state	Immediate	Variable – up to 12 months
Risk of recurrence	None	Lifelong – up to 5%[a]
Risk of thyroid failure	100%	Lifelong – up to 100% at 30 years[a]
Risk of permanent hypoparathyroidism	5%	1%
Need for follow-up	Minimal	Lifelong

[a]The risks of recurrence and late failure are a function of the size of the remnant as a proportion of the total gland weight. Large remnants in small glands have a higher risk of recurrence and a low risk of failure, and small remnants in large glands have a higher risk of thyroid failure but a low risk of recurrence.

there will be a great deal of difference in thyroid position compared with when the arms are down and the neck extended.

The approach to surgery is as described in ***Surgical technique of thyroidectomy***. A longer incision is required. The surgeon may mobilise the sternomastoid muscle from the strap muscles to improve access. The ligamentous tissue between the sternal heads of the clavicles may be gently divided to increase the opening for gland delivery. Blunt dissection on the capsule of the gland allows mobilisation. Gentle traction is applied to deliver the gland into the neck. If the goitre has developed from a posteriorly positioned nodule there is a risk that the RLN may be displaced anteriorly, so great care must be taken in dividing apparent fascial bands that overlie the gland. The blood supply is from the neck, reducing the risk of catastrophic bleeding from the great vessels. Nonetheless, care should be taken in the region of the major blood vessels in the neck and chest.

If the gland is fixed and immobile or too large to deliver through a cervical approach, a midline sternotomy is performed and the gland can be dissected from below to achieve a safe total thyroidectomy.

HYPERTHYROIDISM

Thyrotoxicosis

The term thyrotoxicosis is retained because hyperthyroidism, i.e. symptoms due to a raised level of circulating thyroid hormones, is not responsible for all manifestations of the disease. Clinical types are:

- diffuse toxic goitre (Graves' disease);
- toxic nodular goitre;
- toxic nodule;
- hyperthyroidism due to rarer causes.

Diffuse toxic goitre

Graves' disease, a diffuse vascular goitre appearing at the same time as hyperthyroidism, usually occurs in younger women and is frequently associated with eye signs (***Figure 55.17***). The syndrome is that of primary thyrotoxicosis; 55% of patients have a family history of autoimmune endocrine diseases. The whole of the functioning thyroid tissue is involved, and the hypertrophy and hyperplasia are due to abnormal TSH-RAb that bind to TSH receptor sites and produce a disproportionate and prolonged effect.

Toxic nodular goitre

A simple nodular goitre is present for a long time before the hyperthyroidism, usually in the middle-aged or elderly, and very infrequently is associated with eye signs. The syndrome is that of secondary thyrotoxicosis.

In many cases of toxic nodular goitre, the nodules are inactive, and it is the internodular thyroid tissue that is overactive. However, in some toxic nodular goitres, one or more nodules are overactive and here the hyperthyroidism is due to autonomous thyroid tissue as in a toxic adenoma.

Toxic nodule

A toxic nodule is a solitary overactive nodule, which may be part of a generalised nodularity or a true toxic adenoma. It is autonomous and its hypertrophy and hyperplasia are not due to TSH-RAb. TSH secretion is suppressed by the high level of circulating thyroid hormones and the normal thyroid tissue surrounding the nodule is itself suppressed and inactive.

Figure 55.17 Graves' disease.

Histology

The normal thyroid gland consists of acini lined with flattened cuboidal epithelium and filled with homogeneous colloid (***Figure 55.2***). In hyperthyroidism (***Figure 55.18***), there is hyperplasia of acini, which are lined by high columnar epithelium. Many of them are empty, and others contain vacuolated colloid with a characteristic 'scalloped' pattern adjacent to the thyrocytes.

Principles of treatment of thyrotoxicosis

Non-specific measures are rest and sedation and in established thyrotoxicosis should be used only in conjunction with specific measures, i.e. the use of antithyroid drugs, surgery and radioiodine.

Antithyroid drugs

Those in common use are carbimazole and propylthiouracil. Antithyroid drugs are used to restore the patient to a euthyroid

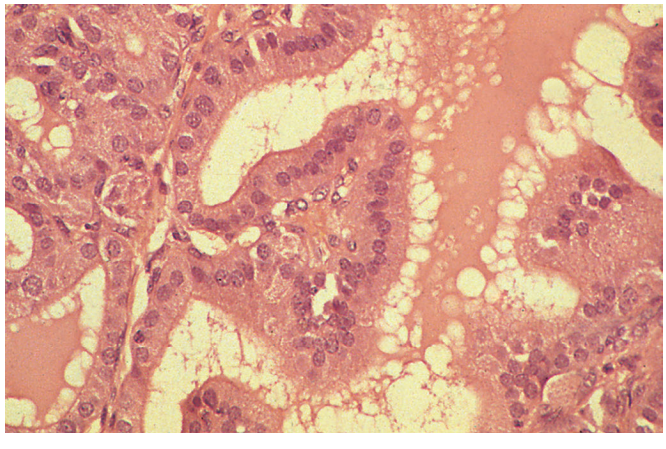

Figure 55.18 Histology of thyrotoxicosis.

state and to maintain this for a prolonged period in the hope that a permanent remission will occur, i.e. that production of TSH-RAb will diminish or cease. Antithyroid drugs cannot cure a toxic nodule. The overactive thyroid tissue is autonomous and recurrence of the hyperthyroidism is certain when the drug is discontinued.

- **Advantages**. No surgery and no use of radioactive materials.
- **Disadvantages**. Treatment is prolonged and the failure rate is at least 55%. The duration of treatment may be tailored to the severity of the toxicity, with milder cases being treated for only 6 months and severe cases for 2 years before stopping therapy.

Surgery

In diffuse toxic goitre and toxic nodular goitre with overactive internodular tissue, surgery cures by reducing the mass of overactive tissue by reducing the thyroid below a critical mass. After subtotal thyroidectomy the patient should return to a euthyroid state, albeit after a variable period of hypothyroidism. There are, however, long-term risks of recurrence and eventual thyroid failure. In contrast total/near-total thyroidectomy accepts immediate thyroid failure and lifelong thyroxine replacement to eliminate the risk of recurrence and simplify follow-up. Operation may result in a reduction in TSH-RAb. In the autonomous toxic nodule, and in toxic nodular goitre with overactive autonomous toxic nodules, surgery cures by removing all the overactive thyroid tissue; this allows the suppressed normal tissue to function again.

- **Advantages**. The goitre is removed, the cure is rapid and the cure rate is high if surgery has been adequate.
- **Disadvantages**. Recurrence of thyrotoxicosis occurs in at least 5% of cases when subtotal thyroidectomy is carried out. There is a risk of permanent hypoparathyroidism and nerve injury. Young women tend to have a poorer cosmetic result from the scar.

Every operation carries a risk, but with suitable preparation and an experienced surgeon the mortality is negligible and the morbidity low.

Radioiodine

Radioiodine destroys thyroid cells and, as in thyroidectomy, reduces the mass of functioning thyroid tissue to below a critical level.

- **Advantages**. No surgery and no prolonged drug therapy.
- **Disadvantages**. Isotope facilities must be available. The patient must be quarantined while radiation levels are high and avoid pregnancy and close physical contact, particularly with children. Eye signs may be aggravated.

Choice of therapy

Each case must be considered individually. Below are listed guiding principles on the most satisfactory treatment for a particular toxic goitre at a particular age; these must, however, be modified according to the facilities available and the personality and wishes of the individual patient and any other coexistent medical or surgical condition. Access to post-treatment care and availability of replacement thyroxine can be important considerations in some areas.

Diffuse toxic goitre

Most patients have an initial course of antithyroid drugs with radioiodine for relapse. Exceptions are those who refuse radiation, those who have large goitres or progressive eye signs and those who are pregnant.

Toxic nodular goitre

Toxic nodular goitre is often large and uncomfortable and enlarges still further with antithyroid drugs. Large goitres should be treated surgically because they do not respond as well or as rapidly to radioiodine or antithyroid drugs as does a diffuse toxic goitre.

Toxic nodule

Surgery or radioiodine treatment is appropriate. Resection is easy, certain and has limited morbidity. Radioiodine is a good alternative for patients over the age of 45 years because the suppressed thyroid tissue does not take up iodine and thus there is minimal risk of delayed thyroid insufficiency.

Failure of previous treatment with antithyroid drugs or radioiodine

In this case, surgery or thyroid ablation with ^{123}I is appropriate.

Surgery for thyrotoxicosis

Preoperative preparation

Traditional preparation aims to make the patient biochemically euthyroid at operation. Preparation is as an outpatient and only rarely is admission to hospital necessary on account of severe symptoms at presentation, failure to control the hyperthyroidism or non-compliance with medication. Care should be coordinated with endocrinology input.

Carbimazole 30–40 mg/day is the drug of choice for preparation. When euthyroid (after 8–12 weeks), the dose may be reduced to 5 mg 8-hourly or a 'block and replace' regime used. In this case, the high dose of carbimazole is continued to inhibit T_3 and T_4 production and a maintenance dose of 0.1–0.15 mg thyroxine is given daily. The last dose of carbimazole may be given on the evening before surgery. Iodides are not used alone because, if the patient needs preoperative treatment, a more effective drug should be given.

An alternative method of preparation is to abolish the clinical manifestations of the toxic state, using β-adrenergic blocking drugs. These act on the target organs and not on the gland itself. Propranolol also inhibits the peripheral conversion of T_4 to T_3. The appropriate dosages are propranolol 40 mg three times daily. Clinical response to β-blockade is rapid and the patient may be rendered clinically euthyroid and operation arranged in a few days rather than weeks. The dose of β-adrenergic blocking drug is increased to achieve the required clinical response and quite often larger doses (propranolol 80 mg three times daily or nadolol 320 mg once daily) are necessary.

β-Adrenergic blocking drugs do not interfere with synthesis of thyroid hormones, and hormone levels remain high during treatment and for some days after thyroidectomy. It is, therefore, important to continue treatment for 7 days postoperatively.

Iodine may be given with carbimazole or a β-adrenergic blocking drug for 10 days before operation. Iodide alone produces a transient remission and may reduce vascularity, thereby marginally improving safety. The use of iodine preparations is not universal because of more effective alternatives. Iodine gives an additional measure of safety in case the early morning dose of β-adrenergic blocking drug is mistakenly omitted on the day of operation.

The extent of the resection depends on the size of the gland, the age of the patient, the experience of the surgeon, the need to minimise the risk of recurrent toxicity and the wish to avoid postoperative thyroid replacement (***Table 55.5***).

Surgical technique of thyroidectomy

The aim of thyroidectomy is to remove the entire thyroid lobe (bilaterally if total thyroidectomy), encompassing all disease and preserving the cervical strap muscles, external branches of the superior laryngeal nerve, the RLN, parathyroid glands and their blood supply in each case while minimising cosmetic impact.

Set-up. With the patient under general anaesthesia, supine, arms at their side, with their head on a ring and neck extended with a shoulder roll or the head of the table extended with the head of the bed raised (reverse Trendelenburg), the operative field is prepared from lower lip to upper chest.

A nerve monitor endotracheal tube or electrode wrap can be used (see ***New technology in thyroidectomy***). The position of the tube should be checked after positioning the patient as extending the neck can withdraw the tube and compromise the contact of the electrodes in the larynx.

Either use a head drape or square off the surgical site. If head draping, include the nerve monitor leads in the head drape. Alternatively, squaring off the surgical site can give easier access to the endotracheal tube if required.

Exposure. The skin incision is placed in a skin crease as close as possible to the cricoid at the superior edge of the thyroid isthmus, which is usually palpable. The length of the incision is determined by the size of the thyroid; however, there is little benefit in extending the incision much beyond the medial edge of the sternocleidomastoid muscle. Mark the incision before prepping and infiltrate with local anaesthetic and adrenaline (epinephrine).

A scalpel is used for the skin incision. Incise through the dermis, making sure to use the full extent of the incision.

Monopolar diathermy can be used to expose and divide the platysma. This plane is then used to raise a subplatysmal flap to the thyroid notch of the thyroid cartilage superiorly and to the suprasternal notch inferiorly.

The midline is identified between the strap muscles superiorly as, often, the sternohyoid muscles separate around the thyroid eminence. The sternohyoid muscles are raised with toothed forceps and monopolar diathermy is used to divide the fascia, avoiding injury to the anterior jugular veins. A Langenbeck retractor helps dissect superior and inferior limits.

The plane is developed to dissect between the muscle layers, elevating sternohyoid laterally until the ansa cervicalis is visualised. The sternothyroid muscle is then mobilised from the gland, taking great care with the delicate vasculature. If required, the strap muscles may be divided superiorly to afford greater exposure. There is usually an artery and a vein travelling between the two strap muscles superiolaterally; these can be injured if overly enthusiastic blunt dissection is used. Once the internal jugular vein is identified dissection medial and deep to this will allow identification of the common carotid artery, and between the vessels the vagus nerve. This should be stimulated to prove that the nerve monitor is functioning properly. If the latency reading on the nerve monitor is unexpectedly short on the right side then consider a non-recurrent right laryngeal nerve.

At this point the gland is exposed and ready for dissection. Minimal blood loss should have been encountered.

Upper pole. The assistant now places Langenbeck retractors under sternohyoid, one lateral to the upper pole and one medial. This displays the superior thyroid vascular pedicle, which is controlled with ties or a bipolar energy device. This not only mobilises the superior pole but also preserves the blood supply to the superior parathyroid gland. In addition, it minimises risk to the superior laryngeal nerve, which can often be seen passing medially towards the cricothyroid muscle. Gradually the superior pole is mobilised, taking care not to dissect below the cricoid cartilage, at which point the RLN is at risk (***Figure 55.19***).

Mobilising the rest of the gland. Gentle traction on the fascia over the gland, immediately next to the superior plane, will show a plane to follow over the main thyroid. This is followed inferiorly, avoiding excessive lateral dissection to prevent inadvertent damage to the RLN. Blunt dissection will allow much of this fascia to be mobilised. Occasional vessels require bipolar cautery.

Next, the trachea is identified in the midline below the isthmus, staying on the cartilage and close to the gland in order to prevent damage to vessels that may contribute to arcades supplying the inferior parathyroid gland.

At this point, the RLN is superior and lateral to the trachea and inferior to the plane developed superiorly. Depending on just how compliant the fascia is and how large the lobe is, much of the dissection may now be complete. A pledget may be used to brush fascia laterally.

Identification of the recurrent laryngeal nerve. It is not uncommon that the RLN can be seen at this point. Assuming

Friedrich Trendelenburg, 1844–1924, successively Professor of Surgery at Rostock (1875–1882), Bonn (1822–1895) and Leipzig (1895–1911), Germany. The Trendelenburg position was first described in 1885.
Bernhard Rudolf Konrad von Langenbeck, 1810–1887, Professor of Surgery, successively at Kiel and Berlin, Germany.

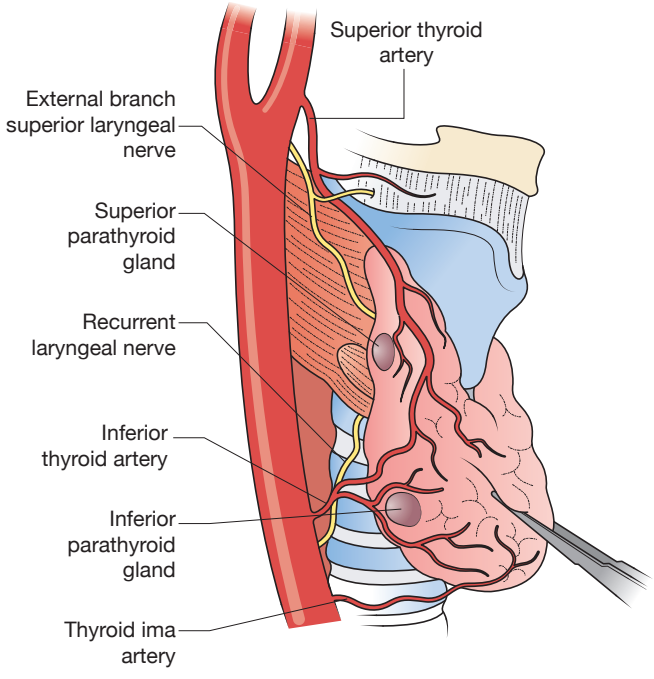

Figure 55.19 General anatomy of a thyroidectomy.

it is not, dissection proceeds by gently mobilising the fascia around the gland, staying directly on the gland and not dividing anything that could be neural. The RLN will be close, often but not always behind the inferior thyroid artery (approximately 70%). By remaining vigilant, never dividing any structure that could remotely be neural and slowly dissecting fascia, the lobe can be delivered from above and below, mobilising in the direction of Berry's ligament. Using this approach, the RLN will be identified and can be confirmed with the nerve stimulator.

Once the nerve has been identified a number of approaches are possible. Ideally the nerve is largely lateral to the gland. This allows dissection to progress until only Berry's ligament remains. However, if the nerve lies medially, it may actually lie on the thyroid and require gentle dissection to free it from the thyroid surface. If this is the case, stay directly on the nerve and slowly dissect the nerve free of the surrounding tissue, endeavouring not to injure the nerve by direct pressure.

The nerve should be traced towards the cricothyroid joint as it enters the larynx. The pretracheal fascia condenses into Berry's ligament at this point. Small vessels within the ligament retract if not controlled with bipolar cautery or ties, and the resulting bleeding can disorientate the surgeon, placing the nerve at risk. In order to avoid this, pre-emptive diathermy to the ligament and careful layer-by-layer dissection allows final mobilisation of the thyroid lobe. Some surgeons prefer to isolate the ligament and apply a careful tie to achieve haemostasis. Whichever method is preferred, great care must be taken at this point.

Management of Berry's ligament. The exact anatomy here will depend on how extensive the condensation of fascia (Berry's ligament) is and how it relates to the RLN. This is variable and this relationship dictates how easy the next steps are. In some the ligament is distant from the nerve. In others the nerve runs up to and even through the ligament. Keeping the nerve in direct vision, minimal division of the ligament allows the RLN to move back and expose more of the ligament, allowing the process to continue, layer by layer, until the nerve is well lateral and the ligament has been divided.

If, during this process, bleeding is encountered the use of targeted pressure and occasionally fine-tip suction to identify the specific bleeding point and careful use of bipolar cautery will achieve haemostasis. This must be meticulous as re-exploration of this area for bleeding puts the RLN at significant risk.

Delivery of the gland. Loose pretrachea fascia can now be opened with monopolar diathermy over the trachea to the midline and beyond to remove the isthmus, which is divided, encompassing any pyramidal lobe tissue. The residual isthmus is either oversewn or sealed with bipolar cautery. If a total thyroidectomy is required, the procedure is repeated on the other side.

Closure. The operative field should be inspected. Irrigation with saline helps identification of small bleeding points. The anatomy should be confirmed, ideally with confirmation of neural integrity by stimulating the vagus (if previously located). Bipolar cautery is used carefully to avoid nerve or parathyroid injury.

Most surgeons do not place a drain. Interrupted sutures are placed through the sternohyoid muscle to prevent adhesion between the trachea and skin. The aim is not to perform a watertight closure of the muscle in case this promotes pressure in the event of a haematoma.

The platysma closure is followed by subcuticular skin closure with an absorbable suture.

New technology in thyroidectomy

The major immediate risk following thyroidectomy is haemorrhage; conventionally, artery forceps, ligatures and sutures have been used to secure the meticulous haemostasis necessary to minimise the risk of this potentially life-threatening complication. Ultrasonic shears, enhanced bipolar diathermy and harmonic vessel sealing devices are increasingly used in thyroid surgery and may be advantageous in complex procedures.

Monitoring of the RLN and vagus nerve has become available over the last few years. By placing electrodes on the endotracheal tube between the vocal cords, movements can be detected when the nerve is stimulated. Such intermittent nerve monitoring is gaining in popularity. Advocates consider the monitor particularly useful in recurrent operations where scar tissue makes the nerve difficult to identify. In addition, some find that operative time is reduced and that this is a valuable tool for training. There is also some support for the use of nerve monitoring during bilateral thyroid surgery, as the information provided can aid in the identification of a unilateral palsy to prevent bilateral palsy that can require tracheostomy. Those who do not support the use of the nerve monitor highlight the lack of evidence that there is any real difference in outcome associated with this practice. In addition, there is the expense of the base machine and the electrodes.

In contrast to intermittent nerve monitoring that allows identification of a damaged nerve, continuous nerve monitoring has now been developed. In theory, this provides the opportunity to identify a nerve when function is threatened (by excessive traction, for example). This technique, although theoretically advantageous, requires an electrode to be placed on the vagus nerve and has not gained widespread acceptance (***Figure 55.20***).

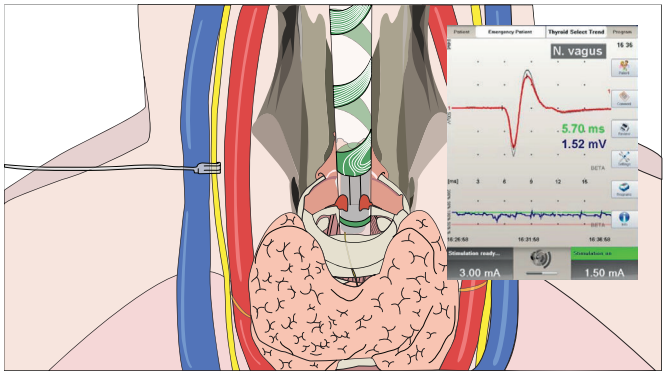

Figure 55.20 Continuous monitoring of the vagus nerve (adapted from an image provided by Inomed UK Ltd).

Alternative surgical techniques

Over the past two decades, increasing experience has been gained in alternative approaches to thyroid surgery. Minimally invasive video-assisted techniques have been developed that allow surgeons to operate through an incision <2 cm in length. With appropriately modified dissectors, experienced operators and advanced haemostatic electrosurgical devices, such procedures offer reduced scar length. However, they are only appropriate for small-volume disease and as such are not suitable for many thyroid cases.

Remote access thyroid surgery is of increasing interest. A number of approaches have been developed via axillary or breast incisions and also through the oral cavity. These approaches can be used with laparoscopic or robotic techniques to allow a magnified view of the operative site. Such 'maximally invasive' techniques require extended dissection over the chest wall or neck and again are most suitable for small-volume disease. Experienced centres continue to expand the indications for these techniques. However, they are associated with increased and significant time, which currently limits their application to most thyroid surgical practice.

Postoperative complications

Haemorrhage is the most frequent life-threatening complication of thyroidectomy. Around 1 in 50 patients will develop a haematoma, and in almost all cases this will develop in the first 24 hours. If an arterial bleed occurs, the tension in the central compartment pressure can rise until it exceeds venous pressure. Venous oedema of the larynx can then develop and cause airway obstruction, leading to death. Although improvements in understanding of the blood supply to the larynx and technical developments in terms of haemostatic technologies have been made, this complication has not been eliminated. Although many surgeons worldwide practise day case thyroidectomy, bleeding is the reason that, in the UK, thyroidectomy remains an inpatient procedure.

Intraoperative attention to detail in terms of haemostasis is critical. When closing the wound, avoiding a watertight closure of the strap muscles may allow a haematoma to escape into the subcutaneous tissues. Wound drains have not been shown to have a protective effect. Close monitoring of the wound is advised postoperatively. If a haematoma develops, clinical staff should know to remove skin sutures in order to release some pressure and seek senior advice immediately. Endotracheal intubation should be used to secure the airway while the haematoma is evacuated and the bleeding point controlled.

RLN paralysis and voice change RLN injury may be unilateral or bilateral, transient or permanent. Early routine postoperative laryngoscopy reveals a much higher incidence of transient cord paralysis than is detectable by simple assessment of the integrity of the voice and cough. Such temporary dysfunction is not clinically important, however, but voice and cord function should be assessed at first follow-up 4 weeks postoperatively. A British Association of Endocrine and Thyroid Surgeons audit revealed an RLN palsy rate of 1.8% at 1 month, declining to 0.5% at 3 months for first-time operations. Permanent paralysis is rare if the nerve has been identified at operation.

If an RLN is injured during surgery and the transected ends are identified, they should be reanastomosed. In the event that a length of nerve is excised (owing to invasion by malignancy, for example), anastomosis of the ansa cervicalis may be considered. This does not return mobility of the vocal cord but maintains neurological input to the muscles of the larynx. By avoiding denervation and related muscle atrophy, the vocal quality is improved. Permanent vocal cord paralysis should be treated conservatively with speech therapy. If voice quality is unacceptable, medialisation procedures can be performed. Nerve grafting has shown promise but experience is limited.

Injury to the external branch of the superior laryngeal nerve is more common because of its proximity to the superior thyroid artery. This leads to loss of tension in the vocal cord with diminished power and range in the voice. Patients, particularly those who use their voice professionally, must be advised that any thyroid operation will result in change to the voice even in the absence of nerve trauma. Fortunately, for most patients the changes are subtle and only demonstrable on formal voice assessment.

Thyroid insufficiency. Thyroxine replacement will be required following total thyroidectomy. Around one in three patients who has a lobectomy will require supplementation; rates are higher in those with thyroid autoantibodies. Subtotal thyroidectomy was at one time performed with the aim of leaving sufficient tissue to maintain thyroid function. However, this is difficult to judge and, over the years, the benign process that necessitated primary surgery may recur, requiring difficult revision procedures. For this reason, the practice of subtotal thyroidectomy has been more or less abandoned outside environments where exogenous thyroxine is not available.

Parathyroid insufficiency. This is due to removal of the parathyroid glands or infarction through damage to the parathyroid end arteries; often both factors occur together. Vascular injury is probably far more important than inadvertent removal. The incidence of permanent hypoparathyroidism should be less than 1% and most cases present dramatically 2–5 days after operation; very rarely, the onset is delayed for 2–3 weeks or a patient with marked hypocalcaemia may be asymptomatic. The complication is limited to total thyroidectomy, as when lobectomy is performed the contralateral parathyroid glands are sufficient to maintain calcium levels. In particular, total thyroidectomy with central neck dissection places the parathyroid glands and their vascular supply at great risk and should only be performed when there is evidence of metastatic disease or high risk of occult disease in the regional lymph nodes.

Thyrotoxic crisis (storm). This is an acute exacerbation of hyperthyroidism. It occurs if a thyrotoxic patient has been inadequately prepared for thyroidectomy and is now extremely rare. Very rarely, a thyrotoxic patient presents in a crisis and this may follow an unrelated operation. Symptomatic and supportive treatment is for dehydration, hyperpyrexia and restlessness. This requires the administration of intravenous fluids, cooling the patient with ice packs, administration of oxygen, diuretics for cardiac failure, digoxin for uncontrolled atrial fibrillation, sedation and intravenous hydrocortisone. Specific treatment is by carbimazole 10–20 mg 6-hourly, Lugol's iodine 10 drops 8-hourly by mouth or sodium iodide 1 g intravenously. Propranolol intravenously (1–2 mg) or orally (40 g 6-hourly) will block β-adrenergic effects.

Wound infection. Cellulitis requiring prescription of antibiotics, often by the general practitioner, is more common than most surgeons appreciate. A significant subcutaneous or deep cervical abscess is exceptionally rare and should be drained.

Hypertrophic or keloid scar. This is more likely to form if the incision overlies the sternum and in dark-skinned individuals. Intradermal injections of corticosteroid should be given at once and repeated monthly if necessary. Scar revision rarely results in significant long-term improvement.

Stitch granuloma. This may occur with or without sinus formation and is seen after the use of non-absorbable, particularly silk, suture material. Absorbable ligatures and sutures should be used throughout thyroid surgery.

Postoperative care

Following surgery, the patient should be returned to the recovery room and nursed overnight on the ward. Wound care should include vigilance for signs of a haematoma. Following total thyroidectomy, calcium levels should be checked postoperatively. Not all patients develop immediate hypocalcaemia and they should be educated about the signs (paraesthesia of the fingers and toes or around the mouth). Serial calcium monitoring should be recommended for those at highest risk. Those patients who had a total thyroidectomy require thyroxine replacement, which should start on day 1 postoperatively. On clinic review, in addition to checking the histology report, the wound should be inspected and the larynx examined for vocal cord function. Biochemical assessment of thyroid function and calcium, if required, should be arranged.

NEOPLASMS OF THE THYROID

Classification of thyroid neoplasms is presented in ***Table 55.6*** and the relative incidence of malignancies in ***Table 55.7***.

TABLE 55.6 Classification of thyroid neoplasms.

Benign	Follicular adenoma		
Malignant	Primary	Follicular epithelium – differentiated	Follicular Papillary
		Follicular epithelium – poorly differentiated	Anaplastic
		Parafollicular cells	Medullar
		Lymphoid cells	
	Secondary	Metastatic	
		Local infiltration	

TABLE 55.7 Relative incidence of primary malignant tumours of the thyroid gland.

Malignancy	Relative incidence (%)
Papillary carcinoma	80
Follicular carcinoma	10
Poorly differentiated/anaplastic carcinoma	5
Medullary carcinoma	2.5
Lymphoma	2.5

Benign tumours

Follicular adenomas present as clinically solitary nodules (***Figure 55.21***) and the distinction between a follicular carcinoma and an adenoma can only be made by histological examination; in the adenoma there is no invasion of the capsule or of pericapsular blood vessels. For this reason, FNA, which provides cytological detail but not tissue architecture, cannot differentiate between benign and malignant follicular lesions. Diagnosis and treatment is, therefore, by wide excision, i.e. total lobectomy. The remaining thyroid tissue is normal so that prolonged follow-up is unnecessary.

Malignant tumours

The vast majority of primary malignancies are carcinomas derived from the follicular cells (***Table 55.6***). Such tumours

Jean Guillaume Auguste Lugol, 1786–1851, Physician, Hôpital Saint-Louis, Paris, France.

Figure 55.21 Isolated swelling in the upper pole of the right thyroid lobe.

Figure 55.22 Metastasis in the humerus from thyroid carcinoma (courtesy of DS Devadatta, Vellore, India).

were thought of as differentiated (papillary, follicular and Hürthle cell) and undifferentiated (anaplastic). However, now an intermediate class of 'poorly differentiated carcinoma' is recognised, which is likely to represent a state of dedifferentiated – between classic differentiated and undifferentiated diseases. The parafollicular C cells can undergo malignant transformation into medullary carcinoma, and thyroid lymphoma is another primary thyroid malignancy. In addition, the thyroid can be involved by direct spread from surrounding structures (larynx and oesophagus) or metastases (most commonly from renal cell carcinoma). Lymph node and blood-borne metastases of thyroid cancer occur primarily to bone and lung and may be the mode of presentation (***Figure 55.22***).

Aetiology of malignant thyroid tumours

The great majority of thyroid cancers have no known aetiological factor. The most important identifiable aetiological factor in differentiated thyroid carcinoma (particularly papillary) is irradiation of the thyroid under 5 years of age. In the town of Gomel, Ukraine, the incidence of childhood thyroid cancer rose from <1 per million to 96 per million following the Chernobyl nuclear disaster.

Short latency aggressive PTC is associated with the *ret/PTC3* oncogene and later developing, possibly less aggressive, cancers with *ret/PTC1*. The incidence of follicular carcinoma is high in endemic goitrous areas, possibly because of TSH stimulation. Malignant lymphomas sometimes develop in autoimmune thyroiditis, and the lymphocytic infiltration in the autoimmune process may be an aetiological factor.

Clinical features of thyroid cancers

The annual incidence is about 0.8 per million of the population and the sex ratio is three females to one male. However, the incidence of PTC is increasing rapidly across the world. This is mostly due to increased rates of imaging detecting previously occult disease. For that reason, although the incidence is increasing, the mortality rates remain static at over 80% 5-year survival for all groups. In particular, anaplastic carcinoma predicts poor outcome with differentiated carcinomas generally having excellent outcomes. The most common presenting symptom is a thyroid swelling (***Figures 55.21 and 55.23***). Enlarged cervical lymph nodes may be the presentation of PTC. RLN paralysis is very suggestive of locally advanced disease.

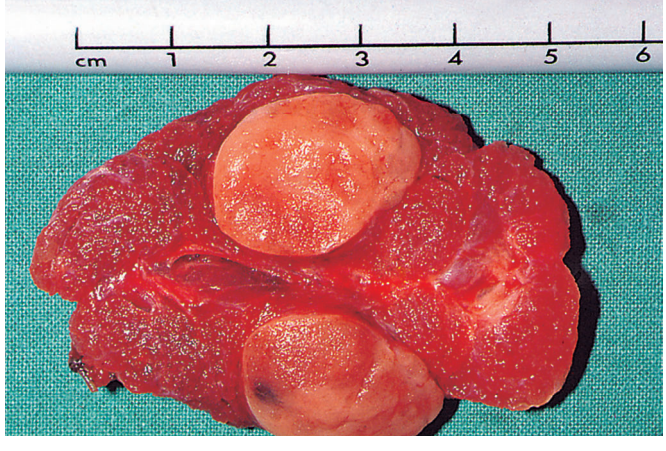

Figure 55.23 Follicular neoplasm of the thyroid presenting as an isolated swelling.

Karl Hürthle, 1866–1945, histopathologist, Breslau, Germany (now Wrocław, Poland).

Anaplastic cancers are usually hard, irregular and infiltrating. A differentiated carcinoma may be suspiciously firm and irregular, but is often indistinguishable from a benign swelling. Small papillary tumours may be impalpable, even when lymphatic metastases are present. Pain, often referred to the ear, is suggestive of nerve involvement from infiltrating tumours.

Diagnosis of thyroid neoplasms

Clinical history and examination continue to be the cornerstone of diagnosis of thyroid neoplasms. As previously mentioned, radiation exposure and family history should be discussed. Examination of the central neck and regional lymphatics should be combined with assessment of vocal cord function. Biochemical assessment of thyroid function should also be considered in this first encounter, if not already performed.

Following initial assessment, the next step is ultrasonography. This non-invasive investigation is most accurate at assessing thyroid swellings. Not only can a judgement be made on the presence, size and number of thyroid nodules present, but an estimate of risk of malignancy can be made depending on these findings.

Following ultrasonography, lesions can be categorised as benign, indeterminate or malignant. Benign lesions require no further assessment unless surgery is considered for compressive symptoms. Indeterminate or malignant lesions should be investigated with FNAC.

Occasionally, the surgeon will encounter a thyrotoxic patient. Such cases are one of the few indications for a radioiodine uptake scan. This allows assessment of the function of a nodule. Hot nodules are very rarely malignant. Cold nodules will require assessment as for all other thyroid neoplasms.

Following clinical, ultrasonographic and cytological assessment, the vast majority of lesions will be characterised as benign, malignant or indeterminate. Further treatment will be planned accordingly.

Certain situations require specific consideration. For patients with widespread nodal disease or suspicion of locally invasive disease affecting the airway, contrast-enhanced imaging should be considered. This should cover the neck and chest. This not only allows accurate assessment of any visceral invasion, but is superior to ultrasonography at defining disease in the mediastinum and thorax. Concerns over the impact of iodine-containing contrast on delays to radioactive iodine therapy have been overplayed, and it is more critical that the surgeon has an accurate assessment of disease extent prior to surgery.

Patients with a rapidly growing thyroid mass, particularly if solid and fixed, should be considered at risk of anaplastic carcinoma. However, this diagnosis can be difficult to differentiate from thyroid lymphoma or occasionally thyroiditis. Despite the difficulty, an accurate diagnosis is critical as anaplastic carcinoma is rapidly fatal and palliative measures are generally recommended, whereas confounding disease processes may respond to therapy. In this setting, core or even open biopsy may be required to make a confident diagnosis.

Papillary thyroid carcinoma

PTC is the most common thyroid malignancy. Interestingly, up to 30% of patients who die of non-thyroid disease have deposits of PTC in autopsy studies, suggesting that many patients live with this disease undetected. Nonetheless, when PTC is diagnosed most patients will be offered treatment. The disease is known for its propensity for lymph node metastases. These are more common in younger patients, in whom they do not affect the otherwise excellent survival. This finding is in contrast to most malignancies, where the finding of metastatic disease confers a poor outcome. One contentious finding in patients with PTC is a high rate of occult micrometastases (as high as 40% of N0 patients in the central neck). Despite the presence of metastases, few patients progress to have clinically meaningful disease and the role of elective nodal surgery is in question. Distant metastases are uncommon in PTC.

Recently, increasing interest has focused on 'papillary microcarcinoma'. This term is used to describe PTC that is <10 mm in size. These lesions are common (detected in about 10% of benign thyroid resections) and not associated with adverse outcomes, including recurrence or non-survival. As such, management and follow-up of patients with these lesions of doubtful clinical significance is controversial. In Korea, for example, national screening has led to a significant increase in these cases. In Japan groups are opting for an observational approach without surgery. These studies have shown that at least two-thirds never progress. In the USA some groups are attempting non-surgical management with ablation techniques using ethanol or radiofrequency. In most of the world, however, groups try to avoid diagnosing these small, insignificant lesions by limiting biopsies to >10 mm lesions and being conservative in the management of lesions following their diagnosis.

Follicular carcinoma

Follicular carcinoma can normally only be differentiated from follicular adenoma by the architecture on histology. For this reason, follicular lesions on FNA are unable to be diagnosed as malignant in the absence of clinical features such as metastases (***Figure 55.24***). Multiple foci of follicular carcinoma are seldom seen and lymph node involvement is much less common than in PTC. Blood-borne metastases are more common and the eventual mortality rate, although still low, is twice that of PTC (***Figure 55.25***).

Hürthle cell tumours are a rare variant of follicular neoplasm in which oxyphil (Hürthle, Askanazy) cells predominate histologically. Hürthle cell cancers are associated with a poor prognosis.

Prognosis in differentiated thyroid carcinoma

The prognosis in differentiated thyroid cancers is generally excellent. In terms of survival, older patients, those with large tumours or those with extrathyroid extension or distant metastases have worse outcomes. A system of risk stratification can

be used to predict the risk on an individual basis. In a young patient with a low-risk tumour, the risk of death following appropriate treatment is almost zero. In an older patient with a high-risk tumour (extrathyroid extension or distant metastases), the risk is as high as 55% at 5 years. Older patients with low-risk tumours and younger patients with high-risk tumours are an intermediate-risk group. Nodal metastases deserve special mention. In younger patients they predict for recurrence but not for death. This is because recurrent neck disease in young patients can almost always be successfully salvaged. In contrast, for older patients neck metastases (particularly in the lateral neck) are a marker of distant metastases in some, and therefore carry a negative prognostic implication for both recurrence and death.

The American Joint Committee on Cancer system stages all patients <55 years as stage I unless they have distant metastases, when they are stage II. Older T1N0M0 patients are stage I and T2N0M0 patients are stage II. The presence of nodal disease upstages older patients to stage II, as does T3 disease. All older patients with locally invasive primary disease (T4) or distant metastases are stage IV.

Surgical treatment for differentiated thyroid cancer

This subject has many contentious aspects. For the vast majority of patients, outcome is excellent irrespective of the extent of surgery. The low number of recurrences and deaths has made prospective trials difficult; as such, very few exist.

The aim of surgery is to rid the patient of macroscopic disease, reduce the chance of recurrence and minimise surgical morbidity. Achieving a balance between these aims is critical. In addition, the surgeon must consider whether radioactive iodine is to be recommended. In low-risk cases this is rarely indicated, whereas in high-risk patients it is used almost universally. Risk stratification is therefore critical.

In high-risk patients with nodal or distant metastases, total thyroidectomy will be performed to eradicate disease in the thyroid and prepare the patient for radioactive iodine. For low-risk patients with a single focus of disease limited to the thyroid, a thyroid lobectomy can be offered. This has the significant advantage of protecting the contralateral RLN and parathyroid glands. This approach is now considered appropriate unless there are high-risk features of disease.

In terms of the neck, when metastatic disease is present, a therapeutic compartment-orientated neck dissection should be performed to remove disease from the central or lateral neck, depending on the site of involvement.

The role of elective neck surgery when no disease in the nodes is detected preoperatively is far more controversial. Lateral neck dissection carries significant morbidity and, despite high rates of occult metastases in PTC, has been abandoned. The reason for this is that, even in patients who are thought to have occult metastases, very few progress to clinically meaningful disease. In contrast, the morbidity of central neck dissection is lower, and the compartment has to be opened during a thyroidectomy. In addition, salvage surgery in the central neck carries a high risk to the RLN and parathyroid glands. For these reasons elective central neck dissection has been popular in the last few decades. However, increased recognition that performing such surgery in all patients with PTC leads to high rates of morbidity and the lack of evidence that outcomes improve as a result of more aggressive surgery have led to a move away from this practice. At this point, patients who are considered at highest risk of having occult metastases in the central neck (those with extrathyroid extension, for example) are considered most likely to benefit from elective surgery. It is not recommended routinely in low-risk patients.

Many patients will only be diagnosed with their thyroid cancer following a diagnostic lobectomy. In this setting, risk

assessment is again critical. If the patient is considered low risk, further surgery is unlikely to be beneficial and active surveillance should be considered. This approach, pioneered in Japan, has been adopted in a number of centres for PTCs <1 cm as only 30% of patients develop tumour growth that requires intervention. Larger tumours and younger patients are at higher risk and radioactive iodine may be recommended, in which case completion thyroidectomy may be required.

Given the complexity of decision making in thyroid cancer and the different groups involved (surgeons, endocrinologists, radiologists, cytologists, pathologists and nuclear medicine physicians), all cases should be discussed in a multidisciplinary setting.

Thyroxine

Following surgery, thyroid cells (both normal and malignant) can be suppressed using high doses of thyroxine. This was once considered routine for all differentiated thyroid cancers during follow-up. Again, risk stratification has modified the approach to these patients. Following surgery, patients can be considered high or low risk. For those patients at high risk from disease, thyroxine will be prescribed at levels that suppress TSH without making the patient biochemically hyperthyroid. In contrast, low-risk patients may be considered for thyroxine replacement at physiological levels. In this patient group, a balance of benefit (remember these patients have extremely low rates of recurrence or death) versus risk must be made. In particular, long-term TSH suppression can result in cardiac arrhythmia and osteoporosis. As such the multidisciplinary team should consider all risks during follow-up to strike this balance.

Radioiodine

^{131}I can be given to deliver tumoricidal doses of radioactivity directly to thyroid tissue, both benign and malignant. In the setting of thyroid cancer, all normal tissue should be removed (total thyroidectomy) along with any gross neck disease (neck dissection) in order for any residual microscopic disease or distant metastases to receive an optimal dose. Radioiodine treatment is not an alternative to surgical resection for resectable disease.

In order to effectively drive the radioiodine into cells, high levels of TSH are required. This can be achieved by rendering the patient hypothyroid (off thyroxine) or by using recombinant TSH, which is injected prior to radioiodine administration.

Following radioiodine administration, an uptake scan is performed. This demonstrates areas of iodine uptake in the whole body and can be used to identify any metastatic disease not recognised on initial imaging. This information is useful for risk stratification following initial therapy.

Outside the setting of primary treatment, radioiodine treatment may be considered in cases of recurrence. Multiple doses can be used to treat unresectable disease or distant metastases.

Most differentiated thyroid cancers will concentrate iodine. However, with advancing patient age and particularly if disease is multiply recurrent the tumour will lose iodine avidity. This is called radioiodine refractory disease. Such cases may be considered for external beam radiotherapy, although this is uncommon.

Thyroglobulin

Thyroglobulin is a tumour marker produced by normal thyroid cells and most differentiated thyroid cancers and offers an extremely accurate method of following patients postoperatively. If a lobectomy has been performed the level will not be undetectable, but trends can be used to monitor for recurrence. Following total thyroidectomy, the aim is to have an undetectable thyroglobulin. Patients who achieve this point are at extremely low risk of recurrence. Serial thyroglobulin measurement (6- to 12-monthly) combined with ultrasonographic assessment of the neck can then be used to monitor patients during follow-up.

If an undetectable level is not achieved, the thyroglobulin can be followed. If it increases, imaging should be performed to look for gross recurrent disease. Resectable disease should be addressed surgically, and normally further radioactive iodine would be indicated. The role of radioactive iodine in a rising thyroglobulin without structural disease is controversial.

Undifferentiated (anaplastic) carcinoma

This is one of the most aggressive malignancies in humans. Thankfully it is rare. It may develop *de novo* or present as dedifferentiation of a papillary or poorly differentiated carcinoma. The disease is characterised by rapid growth, visceral invasion and distant metastases. The surgeon's role in this disease is crucial. Thyroid lymphoma can be incorrectly diagnosed as anaplastic cancer and so biopsy is critical. This can be done using a core or open technique.

Management is controversial because of the extremely poor prognosis. Occasional patients may present with disease limited to the neck, which appears resectable on imaging. Such patients seem to have a slightly better outcome if treated with aggressive surgery and postoperative adjuvant therapy (radiotherapy with/without chemotherapy). However, in the majority, treatment is palliative. Those who develop airway symptoms are generally better managed without tracheostomy, despite the potentially distressing mode of death.

Medullary carcinoma

These are tumours of the parafollicular (C cells) derived from the neural crest that are not unlike those of a carcinoid tumour (***Figure 55.26***). High levels of serum calcitonin and carcinoembryonic antigen are produced. Calcitonin levels fall after resection and rise again with recurrence, making it a valuable tumour marker in the follow-up of patients with this disease. Diarrhoea is a feature in 30% of cases and this may be due to 5-hydroxytryptamine or prostaglandins produced by the tumour cells.

Medullary carcinoma may occur in combination with adrenal phaeochromocytoma and hyperparathyroidism (usually due to hyperplasia) in the syndrome known as multiple endocrine neoplasia type 2A (MEN-2A). The familial form of the disease frequently affects children and young adults, whereas the sporadic cases occur at any age with no sex predominance. When the familial form is associated with prominent mucosal

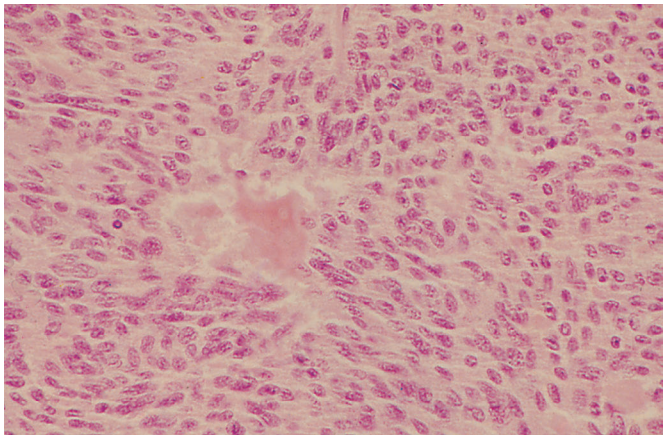

Figure 55.26 Histology of medullary carcinoma showing characteristic 'cell balls' and amyloid (courtesy of Dr SWB Ewen, Aberdeen, UK).

neuromas involving the lips, tongue and inner aspect of the eyelids, with a Marfanoid habitus, the syndrome is referred to as MEN type 2B (see ***Chapter 57***).

Involvement of lymph nodes occurs in 55–60% of cases and blood-borne metastases are common. Tumours are not TSH dependent and do not take up radioactive iodine. The prognosis is variable and depends on the stage at diagnosis. Any nodal involvement virtually eliminates the prospect of cure and, unfortunately, even small tumours confined to the thyroid gland may have spread by the time of diagnosis, particularly in familial cancers. In common with many endocrine tumours the progression of disease may be very slow, with a characteristically indolent course and long survival, even in the absence of cure.

In familial cases of medullary thyroid cancer, genetic screening of relatives should be recommended and the information used to make recommendations concerning prophylactic thyroidectomy. Some relatives may be monitored into adulthood with serial calcitonin monitoring. In contrast, the highest risk mutations are associated with early-onset disease and total thyroidectomy is recommended during infancy.

Treatment

When medullary carcinoma is diagnosed, staging of the neck and chest should be performed. For patients with disease confined to the thyroid, total thyroidectomy is recommended to remove all C cells with elective dissection of the central neck nodes. If there is evidence of nodal metastases, gross disease should be excised but the surgeon should be mindful of morbidity. Such patients are highly likely to develop recurrent disease, hence a pragmatic approach should be adopted (see ***Chapter 56***).

Malignant lymphoma

In the past, many malignant lymphomas were diagnosed as small round-cell anaplastic carcinomas. Response to irradiation is dramatic (***Figure 55.27***) and radical surgery is unnecessary

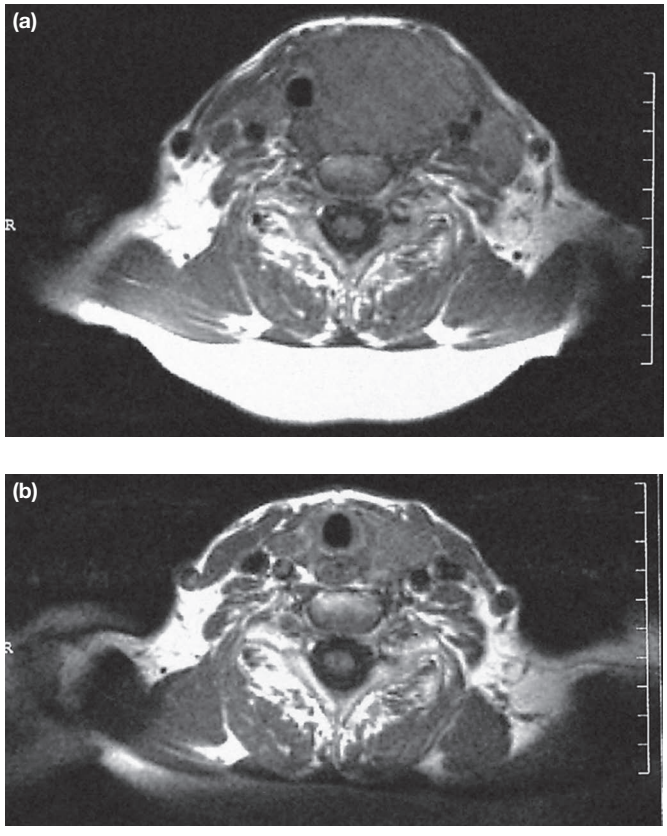

Figure 55.27 Magnetic resonance imaging scans of extensive malignant lymphoma **(a)** before and **(b)** after 7 days of external beam radiotherapy (courtesy of Dr FW Smith, Aberdeen, UK).

once the diagnosis is established by biopsy. In patients with tracheal compression, isthmusectomy is the most appropriate form of biopsy, although the response to therapy is so rapid that this should rarely be necessary unless there has been difficulty in making a histological diagnosis. The prognosis is good, particularly if there is no involvement of cervical lymph nodes. Rarely, the tumour is part of widespread malignant lymphoma disease and the prognosis in these cases is worse. Most lymphomas occur against a background of lymphocytic thyroiditis.

THYROIDITIS

Chronic lymphocytic (autoimmune) thyroiditis (Hashimoto's disease)

This common condition is usually associated with raised titres of thyroid antibodies. It commonly presents as a goitre, which may be diffuse or nodular with a characteristic 'bosselated' feel or with established or subclinical thyroid failure. The diagnosis often follows investigation of a discrete swelling. Features of chronic lymphocytic (focal) thyroiditis are commonly present on histological examination in association with other thyroid disease, notably toxic goitre (***Figure 55.28***). Primary

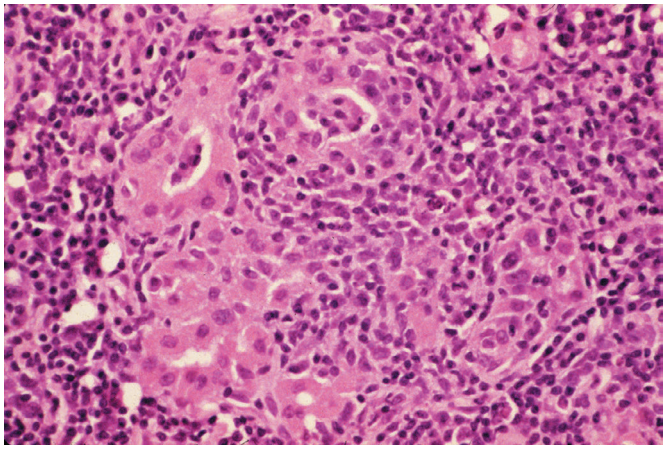

Figure 55.28 Autoimmune thyroiditis (Hashimoto's disease; struma lymphomatosa). Intense lymphocytic–plasma cell infiltration, acinar destruction and fibrosis.

myxoedema without detectable thyroid enlargement represents the end stage of the pathological process.

Granulomatous thyroiditis (subacute thyroiditis, de Quervain's thyroiditis)

This may follow a viral infection. In a typical subacute presentation, there is pain in the neck, fever, malaise and a firm, irregular enlargement of one or both thyroid lobes. There are raised inflammatory markers, absent thyroid antibodies, the serum T_4 is high normal or slightly raised and the ^{123}I uptake of the gland is low. The condition is self-limiting and, in a few months, the goitre subsides and there may be a period of months of hypothyroidism before eventual recovery.

In 10% of cases the onset is acute, the goitre is very painful and tender and there may be symptoms of hyperthyroidism. One-third of cases are asymptomatic but for the presence of the goitre. If diagnosis is in doubt, it may be confirmed by FNAC, radioactive iodine uptake and a rapid symptomatic response to prednisone. The specific treatment for the acute patient with severe pain is to give prednisone l0–20 mg daily for 7 days and the dose is then gradually reduced over the next month. If thyroid failure is prominent, treatment with thyroxine may be required until function recovers.

Riedel's thyroiditis

This is very rare, accounting for 0.5% of goitres. Thyroid tissue is replaced by cellular fibrous tissue, which infiltrates through the capsule into muscles and adjacent structures, including parathyroids, recurrent nerves and the carotid sheath. It may occur in association with retroperitoneal and mediastinal fibrosis and is most probably a collagen disease. The goitre may be unilateral or bilateral and is very hard and fixed. The differential diagnosis from anaplastic carcinoma can be made with certainty only by biopsy, when a wedge of the isthmus should also be removed to free the trachea. If unilateral, the other lobe is usually involved later and subsequent hypothyroidism is common. Treatment is with high-dose steroids, tamoxifen and thyroxine replacement. Reduction in the size of the goitre and long-term improvement in symptoms are to be expected if treatment is commenced early.

PART 8 | Endocrine and breast

CHAPTER

56 The parathyroid glands

Learning objectives

To understand:

- The anatomy of the parathyroid glands
- The physiology of calcium regulation
- The underlying causes of hypercalcaemia and appropriate emergency management
- The aetiology, presentation, investigation and management of primary hyperparathyroidism and associated special cases
- The aetiology, presentation, investigation and management of secondary and tertiary hyperparathyroidism
- The aetiology and management of parathyroid carcinoma

INTRODUCTION

The parathyroid glands were first described by Sir Richard Owen in a neck dissection of an Indian rhinoceros at the London Zoological Gardens in 1850. Credit for recognition of the 'glandulae parathyreoidae' goes, however, to Sandström, who published a monograph in 1887 on dissection of the parathyroid glands and their blood supply in animals and human cadavers. Unfortunately, Sandström committed suicide at the age of 37 and it was not until the 1890s that his work was rediscovered by Gley, who associated tetany following thyroid surgery with removal of the parathyroid glands. In 1905, MacCallum found that he could relieve postoperative tetany by the injection of parathyroid extract. While the association between parathyroid enlargement and bone disease was reported in 1907, it was not until 1925 that the first parathyroidectomy was performed by Mandl in Vienna on Albert Gahne, a tram conductor with severe primary hyperparathyroidism (PHPT) and osteitis fibrosa cystica.

ANATOMY OF THE PARATHYROID GLANDS

The developmental embryology and surgical anatomy of the parathyroid glands are intimately linked, and knowledge of both is essential for successful surgical treatment of parathyroid disease.

The parathyroid glands, of which there are four, develop from the third and fourth pharyngeal pouches between the fifth and 12th weeks of gestation. They are typically described as 'Portland brick' (yellow/brown) in colour and weigh approximately 30 mg. Approximately 13% of the population have abnormal parathyroid tissue, with 5% having a true supernumerary gland. The blood supply of both the superior and inferior parathyroid glands arises from the inferior thyroidal artery. While the location of the individual glands may vary significantly, there appears to be a degree of symmetry between opposite sides that can be helpful during surgical dissection.

The inferior parathyroid gland and the thymus arise from the third pharyngeal pouch. As a result of the longer normal embryological descent, there is correspondingly more variation in their anatomical position. However, in more than 50% of cases they are located at the inferior pole of the thyroid gland, on the anterior, lateral or posterior surface. The gland itself is freely mobile within a globule of fat adjacent to the lower pole (***Figure 56.1a***).

The superior parathyroid glands arise from the dorsal portion of the fourth pharyngeal pouch. As a result of their more limited embryological descent they are more constant in position. In more than 80% of patients, the superior parathyroid glands are located at the posterior aspect of the thyroid lobe in an area 2 cm in diameter, centred 1 cm around the junction of the inferior thyroid artery and the recurrent laryngeal nerve in strict proximity to the cricothyroid junction (***Figure 56.1b***). The parathyroid glands are closely associated with, but contained within, a halo of fat that is freely mobile over the thyroid capsule.

CALCIUM AND PARATHYROID HORMONE REGULATION

The parathyroid glands play a central role in the regulation of serum calcium levels through the production of the active 84-amino-acid peptide, parathyroid hormone (PTH). PTH is secreted in response to low serum calcium or high serum magnesium levels. It is initially cleaved in the liver, yielding an inactive C-terminal that is cleared by the kidneys. The N-terminal fragment is responsible for the biological activity of PTH on peripheral tissues. The active circulating molecule has a half-life of approximately 3–5 minutes in patients with normal renal function.

PTH acts directly on the kidneys, bone and the gastrointestinal tract to activate intracellular second messengers, including cyclic AMP and calcium. In the kidneys, PTH increases serum calcium levels by increasing resorption of calcium from the renal tubules and increasing the hydroxylation of 25-hydroxyvitamin D to the biologically active 1,25-dihydroxyvitamin D. Active vitamin D increases both the resorption of phosphorus in the kidneys and the absorption of calcium from the gastrointestinal tract. In bone, PTH acts on

osteoblasts and osteoclasts to increase bone turnover, thereby increasing the amount of calcium in the extracellular space (***Figure 56.2***).

Calcitonin, which is synthesised by the parafollicular C cells of the thyroid gland, acts as the physiological antagonist to PTH. Calcitonin decreases serum calcium by decreasing bone turnover.

PRIMARY HYPERPARATHYROIDISM

The early descriptions of patients with PHPT were dominated by those with osteitis fibrosa cystica. Brown tumours of the long bones and associated subperiosteal bone reabsorption, distal tapering of the clavicles and the classical 'salt and pepper' erosions of the skull were typical findings. Over 80% of patients had associated renal stones, significant neuromuscular dysfunction and muscle weakness. This led to the traditional mnemonic that patients with PHPT presented with 'bones, stones, abdominal groans and psychiatric overtones'. The introduction of the automated serum chemical autoanalyser in the 1970s as well as the radioimmune assay to accurately measure circulating PTH levels radically improved early diagnosis of PHPT, such that the majority of patients are now identified incidentally on routine biochemical investigations and are asymptomatic. The current controversies, therefore, centre on the indications for intervention, either surgically or medically.

Presentation

PHPT is defined as hypercalcaemia in the presence of an unsuppressed and therefore relatively, or absolutely, elevated PTH level. Prevalence of the disease is reported to be 0.2–0.5%, with approximately 100 000 new cases per year in the USA. The majority of PHPT is sporadic in nature. Familial disease can occur in multiple endocrine neoplasia (MEN) type 1 or type 2A or as a familial cluster. Patients usually present in the fifth or sixth decades and there is a female predominance with a ratio of 3:1.

Patients are typically identified incidentally with an elevated total calcium or following routine assessment of bone densitometry (DEXA scan). Most patients will, however, have some vague constitutional symptoms, such as fatigue, muscle weakness, depression or some mild memory impairment on questioning. The presence of kidney stones remains the most common clinical manifestation of symptomatic PHPT. Between 15% and 20% of patients will have nephrolithiasis and over 40% of patients will have hypercalciuria. Increasingly, postmenopausal women present with significant osteopenia or osteoporosis in the distal one-third of the radius with a minimal reduction in the lumbar spine, which prompts further investigation. This distribution arises as PTH appears to be catabolic at cortical sites (distal one-third of the radius) and anabolic at cancellous sites (lumbar spine).

PHPT may present with pancreatitis, although it is rarely seen in patients with milder forms of the disease. Common epidemiologically linked disorders, such as hypertension and peptic ulcer disease, are often encountered. Clinical examination is usually normal. Band keratopathy, pathognomonic of the disease and due to deposition of calcium phosphate crystals in the cornea, is now rarely identified.

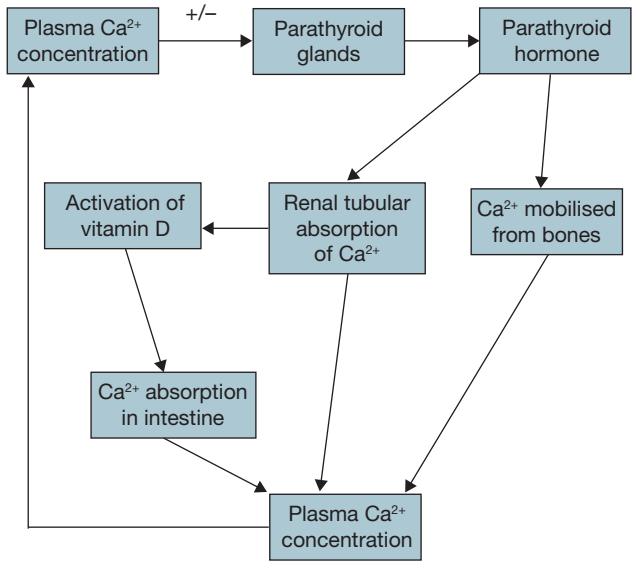

Figure 56.2 The actions of parathyroid hormone.

The differential diagnosis of PHPT includes other causes of hypercalcaemia, which are usually readily distinguishable (***Table 56.1***). It is important to exclude the presence of a widespread malignancy, in which patients will typically have other symptoms. The exception to this rule is multiple myeloma, in which hypercalcaemia can be the presenting

complaint. Improvements in the immunoradiometric and immunochemiluminometric assays for PTH can help to distinguish these conditions, as in malignancy PTH levels are typically suppressed.

Hypercalcaemic crisis: presentation and management

Hypercalcaemia is documented in 0.5% of the general population and in up to 5% of hospitalised patients. The vast majority are asymptomatic with a mild to moderate elevation of serum calcium (<3 mmol/L and 3–3.5 mmol/L, respectively) and respond to treatment of the underlying aetiology with associated dietary modification. A small proportion of patients will present symptomatically with a total calcium of >3.5 mmol/L. This is referred to as a hypercalcaemic crisis and requires aggressive medical management.

Although symptoms can be varied, the typical presentation is of acute confusion, abdominal pain, vomiting, dehydration and anuria. Prolongation of the PR interval with a shortened QT interval can be identified on an electrocardiogram (ECG) prior to potentially lethal cardiac arrhythmias. Where the calcium is >4.5 mmol/L, coma and cardiac arrest can occur.

Treatment revolves around increasing renal excretion of calcium, reducing skeletal release of calcium and treatment of the underlying cause. Aggressive rehydration plays a pivotal role. Typically, 200–500 mL/h of normal saline is given to maintain a urine output >100 mL/h, with the caveat that this may be modified to account for associated patient comorbidities. Once intravascular volume has been adequately restored, loop diuretics, such as furosemide, can be used to enhance the renal excretion of calcium. The majority of patients will have normalisation of their calcium with these simple measures.

In patients with advanced malignancy and a serum calcium level >3 mmol/L, agents that blunt the release of calcium from skeletal stores may be required. First-line treatment includes administration of bisphosphonates. These are pyrophosphate analogues that inhibit osteoclast activity in areas of high bone turnover. In the acute setting, these are given intravenously owing to poor absorption in the gastrointestinal tract. Calcitonin can be used to both decrease osteoclastic activity and increase renal excretion of calcium. It has a short duration of action and is usually used as a bridge to reduce calcium until the sustained action of the bisphosphonates is seen. Finally, glucocorticoids (prednisolone) can be used to enhance the action of calcitonin. They increase calciuresis and decrease intestinal absorption of calcium. As a result, they may also play a role in diseases associated with vitamin D excess.

Pathology

The underlying aetiology of PHPT is usually a solitary parathyroid adenoma; however, in a small number of patients (2–4%) there are double adenomas. It may occur in a sporadic fashion or it can be familial (approximately 10%) (MEN type 1, type 4, type 2A or hyperparathyroidism–jaw tumour syndrome [HPT-JT]) in nature.

The only known risk factor for the development of PHPT is a history of prior neck irradiation. The underlying genetic pathogenesis of PHPT remains unclear. However, genes regulating the cell cycle, such as *MEN1* and *CCND1*, have been recognised as playing an important role owing to the clonal nature of adenomas. Somatic mutations in *MEN1*, which encodes menin, occur in 12–35% of sporadic cases and rearrangements or overexpression of *CCND1*, which encodes cyclin D1, have been demonstrated in 20–40% of patients. Upregulation of cyclin D may lead to a clonal proliferation within the parathyroid glands. This does not alter the set point of calcium but the hyperplasic nature of the parathyroid cells themselves causes excessive secretion of PTH.

Multigland disease is less common, occurring in approximately 15% of patients. No clinical features differentiate single from multigland disease, although multigland disease is more commonly associated with familial syndromes such as MEN types 1 and 2A, as well as the chronic ingestion of lithium.

Diagnosis

PHPT is a biochemical diagnosis. Only when the disease has been confirmed biochemically should localisation studies be undertaken. Positive imaging does not confirm the diagnosis and negative findings cannot rule it out.

PHPT is defined as an elevated total, or more specifically ionised, calcium in the presence of an inappropriately elevated or unsuppressed PTH. It is associated with a low serum phosphate in the setting of normal creatinine and vitamin D levels; 24-hour urinary excretion of calcium may be normal or elevated. It is important to perform a 24-hour urinary collection to rule out the presence of the rare familial hypocalciuric hypercalcaemia (FHH). Alkaline phosphatase may be elevated in patients in whom there is concomitant bone disease. This is important to recognise preoperatively as the surgeon should anticipate significant postoperative hypocalcaemia due to the development of hungry bone syndrome.

Localisation studies

> In my opinion, the only localising study required in a patient with untreated primary hyperparathyroidism is to localise an experienced parathyroid surgeon.
>
> John Doppman, 1986

Historically, preoperative localisation studies for PHPT were considered less important than identifying an experienced surgeon. However, with a shift away from the traditional four-gland (cervical neck) exploration to more minimally invasive procedures, accurate preoperative identification is critically important to guide surgical strategy.

There are a variety of both non-invasive and invasive studies commonly in use. Non-invasive radiology includes nuclear medicine-based studies, ultrasonography and four-dimensional (4D) computed tomography (CT) scanning. Invasive imaging is largely reserved for reoperative surgery and includes ultrasound or CT-guided fine-needle aspiration with

John L Doppman, 1928–2000, radiologist, National Institutes of Health, USA, developed the technique of selective venous sampling for parathyroid localisation.

concomitant PTH assays, parathyroid angiography or selective venous sampling for the PTH gradient.

Nuclear medicine-based studies (sestamibi scanning)

The use of sestamibi (2-methoxy-2-methylpropylisonitrile [MIBI]) for parathyroid localisation was first described in 1989 and is now regarded as the most accurate and reliable method for imaging the parathyroid glands. It is safe and reproducible and, while it has a sensitivity and specificity similar to ultrasonography, it may image glands in ectopic positions better (***Figure 56.3a***).

Sestamibi accumulates in mitochondria and therefore washes out at differential rates depending on the number of mitochondria within individual tissues. Parathyroid adenomas often have a high concentration of oxyphilic cells with high mitochondrial content. These retain tracer, and adenomas are therefore associated with a slow washout when compared with the thyroid gland. There are three different protocols for sestamibi scanning: single-isotope dual-phase scan, dual-isotope subtraction imaging and single-photon emission computed tomography (SPECT). The sensitivity and specificity of sestamibi, regardless of the protocol used, are 79% and 90%, respectively. False positives are rare but may arise from some solid thyroid nodules, such as Hürthle cell nodules, that are associated with high oxyphilic content. These can be reduced by the addition of a thyroid-specific radioactive tracer, such as ^{99}Tc-pertechnetate and subsequent subtraction images.

Ultrasonography

Ultrasonography is a non-invasive, inexpensive method of imaging the parathyroid glands (***Figure 56.3b***). Parathyroid adenomas are typically oval or elongated, bi- or multilobed hypoechoic structures. Rarely, adenomas may be cystic or heterogeneous in nature. Giant adenomas are described as those over 3 cm in size. Ultrasonography is not associated with any radiation exposure and has the advantage of being able to identify and facilitate biopsy of any concomitant thyroid pathology. However, ultrasonography is operator, lesion size and location dependent. Critically, ultrasonography may

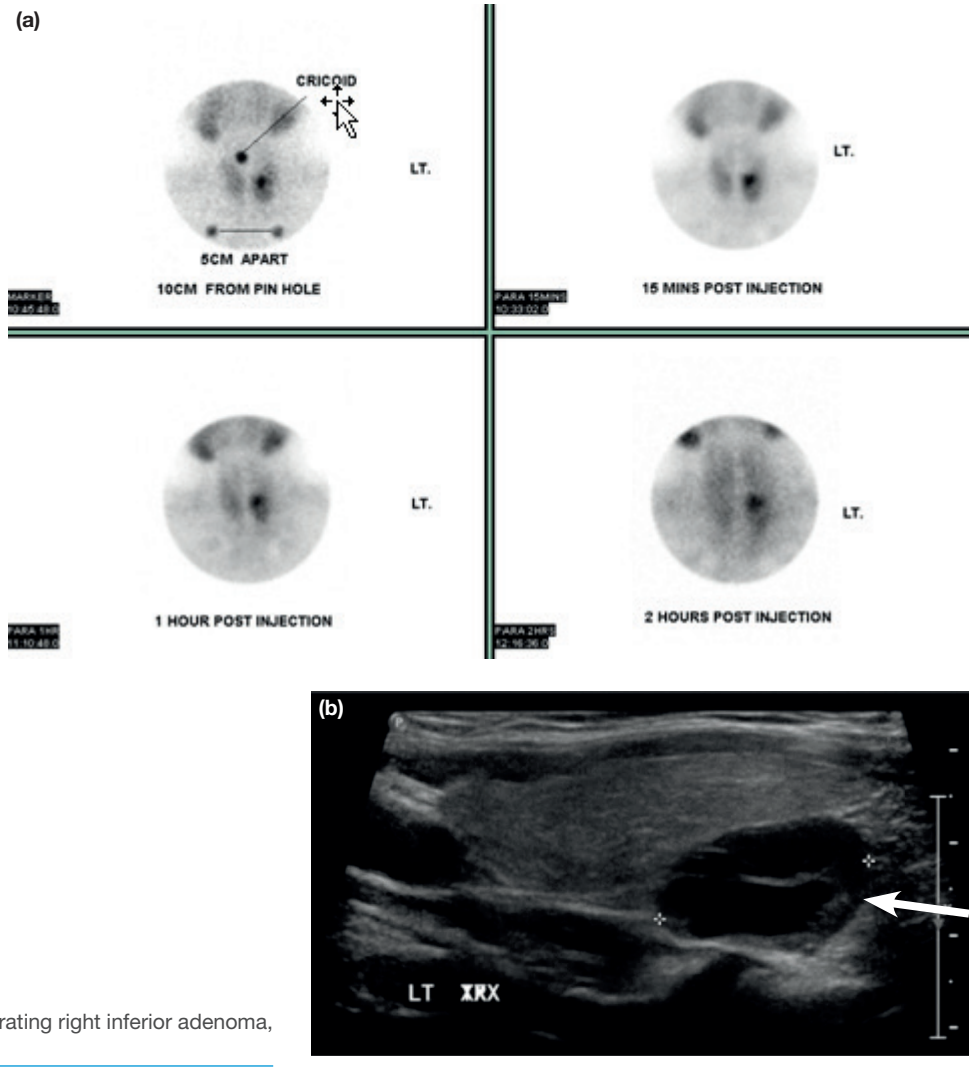

Figure 56.3 Sestamibi scan **(a)** demonstrating right inferior adenoma, with concordant ultrasonography **(b)**.

Karl Hürthle, 1866–1945, histopathologist, Breslau, Germany (now Wrocław, Poland).

miss adenomas located in retro-oesophageal, retrosternal or retrotracheal areas. It can also be difficult to differentiate between a small parathyroid gland and a normal-appearing lymph node. A meta-analysis of preoperative localisation techniques in PHPT demonstrated that ultrasonography and sestamibi-SPECT have comparable accuracy, with pooled sensitivities of 76.1% and 78.9%, respectively, and positive predictive values (PPVs) of 93.2% and 90.7%, respectively (Krakauer *et al.*, 2016).

Four-dimensional computed tomography scanning/positron emission tomography–computed tomography

Multiphase CT imaging (4D-CT) has become widely utilised to localise disease (***Figure 56.4***). It gives both anatomical and functional information about the parathyroid glands. Using precontrast, postcontrast and delayed images, it demonstrates not only detailed anatomical localisation but, combined with rapid uptake and washout, allows hyperfunctioning glands to be differentiated from lymph nodes that demonstrate a progressive enhancement pattern. The potential disadvantage of 4D-CT scanning is the higher radiation dose when compared with traditional imaging modalities. Modification of the protocol now allows fewer phases to be obtained without compromising outcomes. The initial study in 2006 reported a sensitivity of 88% for lateralisation and 70% for localisation of parathyroid adenomas (Rodgers *et al.*, 2006). A more recent meta-analysis, although limited by the small number of studies, demonstrated a sensitivity and PPV of 89.4% and 93.5%, respectively, when 4D-CT was used as the primary imaging modality. This was reduced to 71.8% and 74.9%, respectively, in cases of negative or inconclusive prior imaging (Cheung *et al.*, 2012).

Positron emission tomography (PET) scanning remains expensive and is not widely available. However, recent data suggest that there may be an incremental value to ^{18}F-fluoro-choline PET with the addition of CT scanning for localisation of ectopic adenomas.

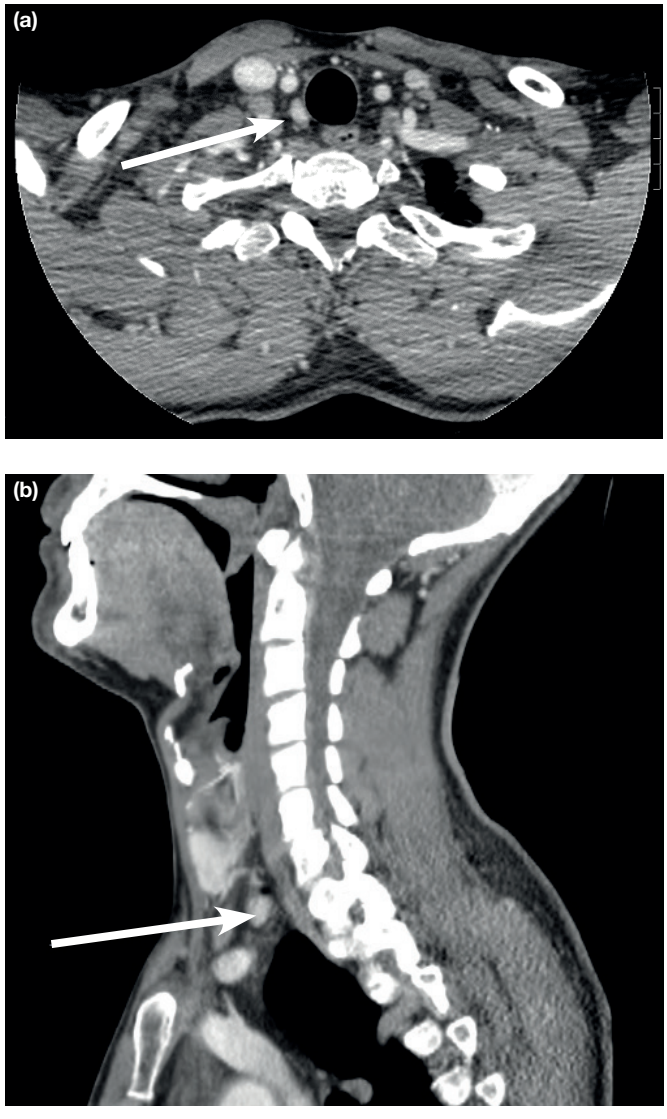

Figure 56.4 (a, b) Four-dimensional computed tomography scanning demonstrating a right inferior parathyroid adenoma (arrows).

Magnetic resonance imaging

Magnetic resonance imaging (MRI) is not commonly used to image the parathyroid glands. However, on T2-weighted images, enlarged parathyroid glands demonstrate significantly increased intensity. In reoperative cases or where the adenoma is located in the mediastinum, MRI may be beneficial, with higher reported sensitivities (50–88%). While the sensitivity of MRI is slightly better than that for CT (64–88%) in primary disease, it has significant limitations. It is expensive, patients can be poorly compliant owing to claustrophobia and the resolution for normal glands or adenomas <5 mm is poor. Similarly, it can be difficult to localise superior glands because of their posterior location, which allows them to be obscured by the thyroid gland.

Parathyroid angiography and venous sampling for parathyroid hormone

Parathyroid angiography is reserved for reoperative cases and is now rarely required owing to improvements in non-invasive imaging modalities. It involves examination of both thyrocervical trunks, both internal mammary arteries and both carotids, with occasional selective superior thyroid artery catheterisation. Vascular parathyroid adenomas appear as a persistent oval or round 'stain' on angiography. Serious complications such as contrast-induced renal failure, embolisation and neurological damage have limited its utility.

Selective venous sampling for PTH can allow accurate localisation of adenomas but an experienced interventional radiologist is vital for success. The venous drainage of the lesion is established when there is a twofold drop in the PTH between the sampled blood and the serum PTH. The sensitivity is reported to be 80% and is equally effective in localising cervical and mediastinal adenomas. However, the false-positive rate of between 6% and 18% limits its utility to reoperative cases.

Management strategies

Surgical management

The mainstay of treatment for PHPT is surgery, addressing the underlying aetiology and allowing not only resolution of biochemical abnormalities but also sustained improvements in end-organ damage. Traditionally a bilateral cervical exploration was performed with reported cure rates of 95–98%. With improvements in preoperative radiological localisation, a more minimally invasive approach has been developed and widely adopted (***Figure 56.5***).

All symptomatic patients should be offered surgery. An expert panel published recommendations on which asymptomatic patients should be considered for surgical intervention (***Table 56.2***). Guidelines from the American Association of Endocrine Surgeons have more liberal indications for surgery. These included patients with cognitive or psychiatric symptoms attributable to PHPT, cardiovascular disease (excluding hypertension) and more non-specific symptoms, such as muscle weakness, impaired functional capacity and abnormal sleep patterns. When criteria have been met and where a single adenoma has been confidently identified by radiological means, a minimally invasive parathyroidectomy may be offered. Conversely, where there is discordant imaging or where imaging fails to identify any parathyroid abnormalities, then a bilateral neck exploration and a three-and-a-half-gland parathyroidectomy or a four-gland parathyroidectomy and autotransplantation should be performed.

Consent for a parathyroidectomy must include the possibility of recurrent laryngeal nerve damage (risk <1%), permanent hypoparathyroidism (requiring lifelong calcium and vitamin D supplementation; risk 0.5%) and persistent (5%) or recurrent hyperparathyroidism. Persistent disease is defined as an elevated serum calcium within 6 weeks of surgical intervention and recurrent disease is defined as an increase in calcium levels after 6 months but with an intervening period of normocalcaemia.

TABLE 56.2 Consensus guidelines for surgical intervention in asymptomatic primary hyperparathyroidism.

Measurement of serum calcium	0.25 mmol/L (1.0 mg/dL) above the upper limit of normal
Skeletal	• BMD by DEXA; T score –2.5 at lumbar spine, total hip, femoral neck or distal one-third of radius • Vertebral fracture
Renal	• Creatinine clearance <60 mL/min • 24-hour urinary calcium >10 mmol/dL (>400 mL/day) or increased risk of stone formation by risk analysis
Age	<50 years

BMD, bone mineral density; DEXA, bone densitometry.

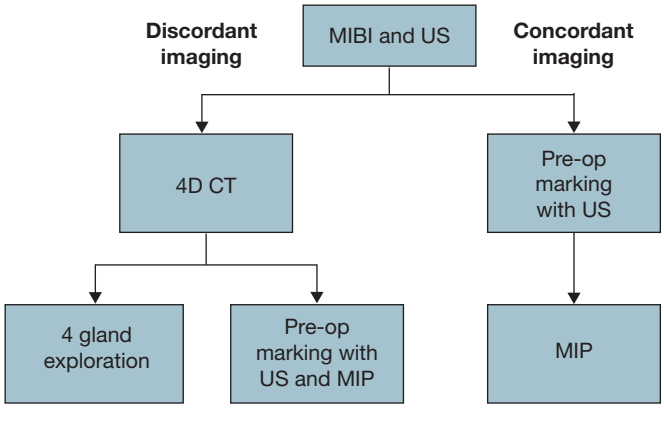

Figure 56.5 Localisation paradigm and management strategies. 4D CT, four-dimensional computed tomography; MIBI, 2-methoxy-2-methylpropylisonitrile; MIP, minimally invasive parathyroidectomy; US, ultrasonography.

Minimally invasive (focused) parathyroidectomy

Minimally invasive approaches are based on the principle that over 80% of individuals with PHPT have a single adenoma. Although there is no strict definition of the procedure, it commonly refers to the removal of a localised abnormal parathyroid gland through an incision less than 3 cm in length (***Figure 56.6***). The term encompasses open approaches (central and lateral incisions) and video-assisted and radio-guided parathyroidectomies. A number of randomised studies have shown that the focused approach has similar cure rates to

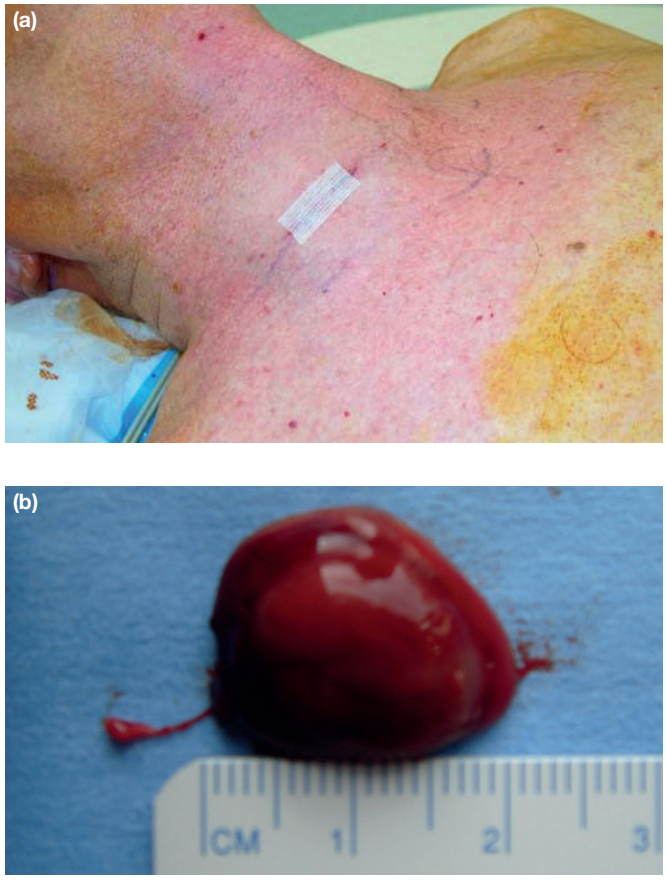

Figure 56.6 (a) Minimally invasive parathyroidectomy through a lateral approach; **(b)** the excised parathyroid adenoma.

a cervical exploration but with reduced rates of postoperative hypocalcaemia, shorter operating times, potentially less pain and better cosmesis.

The need to convert from a focused to a cervical exploration may be guided by the use of intraoperative PTH measurements. Routine use is, however, controversial owing to high false-positive and false-negative rates. The basic concept is that the half-life of circulating PTH is 3–5 minutes and there should therefore be a significant drop detected in the plasma PTH following resection of a single adenoma. If no such drop is detected, then multigland disease may be suspected and conversion to a bilateral neck exploration should be considered. The Miami criteria were developed to determine the extent of resection. A drop in the PTH into the normal range and to less than half the maximum preoperative PTH at 10 minutes appears to accurately predict single-gland disease (***Figure 56.7***).

Bilateral neck exploration

A traditional cervical neck exploration is required where imaging is negative or discordant, in MEN (type 1 or type 2A) or in lithium-induced PHPT. A transverse collar (Kocher's) incision is made and the subplatysmal plane developed. The deep cervical fascia is divided between the strap muscles and these are retracted. The thyroid lobes are mobilised and the middle thyroid vein may be divided when present.

Identification of the recurrent laryngeal nerve and the middle thyroid artery allows a starting point for a systematic exploration (see ***Chapter 55***). All four glands are identified. Three and a half glands are resected, with half of a vascularised parathyroid left *in situ*. The other half of the gland should be sent for frozen section to confirm the presence of parathyroid tissue (***Figure 56.8***). Ideally the most normal-appearing parathyroid is left *in situ*. With this caveat in mind, where possible an inferior gland should be left. It is marked with a non-absorbable suture to aid identification in the presence of recurrent disease, where resection can be achieved without increasing the risk of damage to the recurrent laryngeal nerve. Alternatively, all four glands can be resected and a forearm autotransplant created. Small pieces of parathyroid are sutured into pockets created in the brachioradialis muscle. Cure rates and rates of persistent and recurrent disease appear to be similar, regardless of the type of procedure used. However, in recurrent disease it can be difficult to identify the location of the recurrent tissue when an autotransplant is performed.

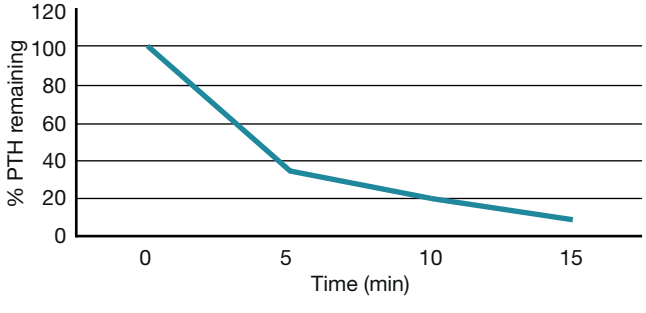

Figure 56.7 Miami criteria for intraoperative parathyroid hormone (PTH) measurement. Drop of PTH into the normal range and less than half the maximum value at 10 minutes postresection.

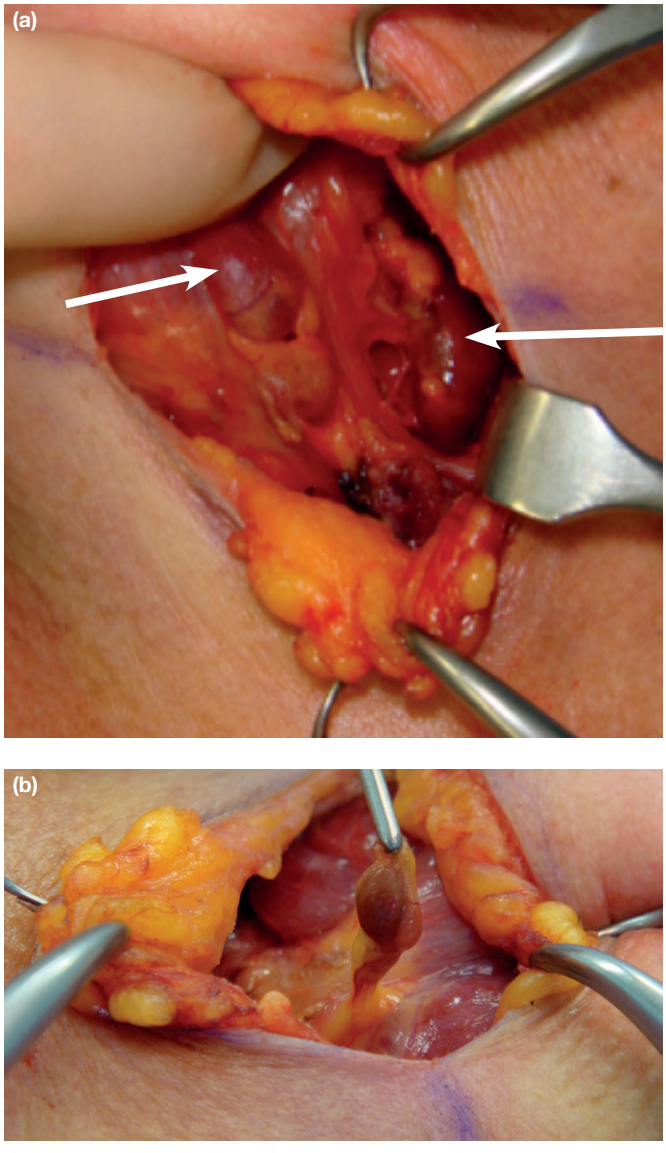

Figure 56.8 Parathyroidectomy with exposure of the left superior and inferior parathyroid glands (white arrows) *in situ* **(a)** and left superior gland mobilised on its vascular pedicle **(b)**.

Thymectomy and resection of mediastinal adenomas

The incidence of clinically significant supernumerary glands is increased in patients with multigland disease or those with hereditary syndromes. A thymectomy should be routinely undertaken for patients with *MEN1*-associated PHPT or in secondary hyperparathyroidism. A cervical thymectomy is performed by dissecting close to the thymic capsule, exploring the cervical part of the gland. The mediastinal part of the gland can be removed by gentle upwards traction, with ligation of the veins draining into the innominate vein. The end of the

Emil Theodor Kocher, 1841–1917, surgeon, Berne, Switzerland, awarded the Nobel Prize in Physiology or Medicine in 1909 for his research on the thyroid.

gland is tapered and rarely requires formal ligation. A median sternotomy is not required where a prophylactic thymectomy is being performed.

Mediastinal adenomas are rare, accounting for less than 1% of all parathyroid adenomas. They will be typically identified on preoperative imaging. Resection can be achieved either by an open sternotomy or increasingly by a thoracoscopic approach. A minimally invasive approach can be particularly effective where the abnormal gland lies immediately deep to the mediastinal pleura. It can confer significant advantages in length of hospital stay and complication rates.

Permanent hypoparathyroidism

Permanent hypoparathyroidism is defined as the continuing need for calcium and/or vitamin D replacement at 1 year postoperatively. It is a rare complication when surgery is undertaken for PHPT (0.5%), but in secondary hyperparathyroidism it can range from 4% to 12%. Symptoms and signs relate to serum calcium levels. Symptoms include mild circumoral or digital numbness and paraesthesia, carpopedal or laryngeal spasms and cardiac arrhythmias. Chvostek's and Trousseau's signs may be elicited. Chvostek's sign refers to contraction of the ipsilateral facial muscles on percussion of the facial nerve below the zygoma. Trousseau's sign refers to the development of carpopedal spasm secondary to occlusion of the arm (usually with a blood pressure cuff).

Biochemical investigations include total and ionised calcium levels as well as serum magnesium levels. An ECG may demonstrate a prolonged QT interval or QRS complex changes. Mild hypocalcaemia can be treated with oral calcium and vitamin D supplementation. Acute symptomatic hypocalcaemia is an emergency and should be corrected with intravenous as well as oral calcium and vitamin D replacement. Traditionally, 10 mL of 10% calcium gluconate is administered slowly intravenously. Supplemental magnesium may also be required, owing to the synergistic action of transporters for calcium and magnesium.

Medical management

Medical management is warranted in patients who are deemed unfit or who have contraindications to surgical intervention, in patients with failed surgical intervention or in the long-term management of parathyroid carcinoma. The aims are to prevent skeletal complications (improve bone mineral density and reduce fracture risk) and to stabilise biochemical parameters. There are only limited data on the long-term efficacy of such an approach as surgery is known to provide durable responses.

Bisphosphonates/denosumab

Bisphosphonates are pyrophosphate analogues that are concentrated in areas of high bone turnover. They inhibit osteoclast activity and apoptosis, thereby increasing bone mineralisation and reducing bone turnover. Studies looking at the management of PHTP utilising bisphosphonates are limited by small numbers and short follow-up. However, use does appear to stabilise bone mineral density without markedly altering the underlying serum biochemistry. Denosumab is a monoclonal antibody that works as a receptor activator of nuclear factor- κB (RANK) ligand inhibitor. Data from the DENOCINA trial suggest that it may be a valid treatment option for patients in whom surgery is undesirable.

Hormone replacement therapy and selective oestrogen receptor antagonists

Hormone replacement therapy (HRT) has been shown to improve bone mineral density and reduce the associated fracture risk in postmenopausal women by reducing bone turnover. Two non-randomised controlled trials have shown a durable and similar response to surgery for PHTP at 4 years, with improvements in bone mineral density but without any improvement in the underlying serum biochemistry. The rationale for the use of selective oestrogen receptor antagonists (SERMs) is that they should confer the benefits of HRT but without the potential adverse vascular and breast effects. The effect on the bone mineral, however, appears to be less significant than that of HRT.

Calcimimetics

The extracellular calcium-sensing receptor on the parathyroid cell surface negatively regulates secretion of PTH. Activation of the receptor decreases secretion of PTH, thereby decreasing bone turnover. Calcimimetics, such as cinacalcet, amplify the sensitivity of the calcium-sensing receptor to extracellular calcium, altering the set point and thereby decreasing PTH production. Cinacalcet was approved for use in PHPT by the European Medicines Agency in 2008 and subsequently by the US Food and Drug Administration in 2011 for the treatment of severe hypercalcaemia in patients with PHPT who were unfit for parathyroidectomy. Normalisation of serum calcium levels can be achieved with a similar reduction in the level of PTH, although not to within the normal range. Despite this, neither the urinary calcium nor the bone mineral density appear to change even after 3 years of treatment. Drug tolerance, especially gastrointestinal side effects, can be problematic and may limit the duration of usage.

SPECIAL CASES

Lithium-induced hyperparathyroidism

Lithium-induced hyperparathyroidism occurs in 10–15% of patients treated with long-term lithium. It is generally associated with a mild elevation in calcium with failure to suppress PTH. The underlying aetiology can be either gland hyperplasia, with lithium originally thought to stimulate all parathyroid tissue, or a single adenoma, which has been shown to occur in 33–49% of cases. It has recently been suggested that the hyperparathyroidism may be caused by interference with the parathyroid kinase C signal transduction system and the Wnt pathway. Biochemical abnormalities may resolve with discontinuation

Frantisek Chvostek, 1835–1884, physician, The Jasefsacademie, Vienna, Austria.
Armand Trousseau, 1801–1867, physician, Hôtel Dieu, Paris, France.

of lithium. Surgery is indicated where ongoing treatment with lithium is required or where abnormalities persist following withdrawal of lithium. Minimally invasive surgery is relatively contraindicated in these patients because of the high incidence of multigland disease. Excision, however, should be limited to those glands that are obviously enlarged at exploration rather than a formal three-and-a-half-gland excision.

Familial syndromes

Familial hyperparathyroidism can be part of a well-recognised endocrine disorder, but it may also occur in isolation in a non-syndromic form. PHPT occurs as a central facet in multiple MEN type 1, type 4, type 2A, HPT-JT, autosomal dominant mild hyperparathyroidism and FHH.

Familial isolated hyperparathyroidism

Familial isolated hyperparathyroidism occurs when patients have PHPT without any other associated endocrinopathies. The underlying genetic abnormality has yet to be fully elucidated, but the syndrome has been linked to known mutations in the *MEN1* gene, the *HRPT2* gene as well as the calcium-sensing receptor gene. A significant proportion of patients will belong to the MEN 1 family, with documented recognised mutations but without expression of other endocrinopathies. Hyperparathyroidism should be treated with a formal bilateral neck exploration and management as per patients with MEN.

MEN type 1-associated hyperparathyroidism

MEN type 1 is a rare autosomal dominant syndrome consisting of tumours of the parathyroids, endocrine pancreas–duodenum and the pituitary (the three Ps). It occurs in approximately 1 per 30 000 individuals. It can also be associated with adrenal adenomas or carcinoma, foregut carcinoids and lipomas. Mutations, of which there are over 1000 identified in different families, occur in the *MEN1* gene, which encodes the protein menin. Menin acts as a tumour suppressor. Patients typically present with young onset (20–30 years of age) of symptomatic hyperparathyroidism and over 95% of patients will have PHPT before the age of 40 years.

Surgical intervention in MEN type 1 aims to obtain and maintain normocalcaemia for the longest time possible. In general, it is associated with the presence of multigland parathyroid disease and as such has mandated a bilateral cervical exploration with at least a subtotal parathyroidectomy and cervical thymectomy. A subtotal parathyroidectomy removes three and a half glands with half of the most normal-appearing parathyroid left *in situ* with a marking stitch to facilitate reoperative intervention. A total parathyroidectomy and forearm autotransplantation is an acceptable alternative. Detailed intraoperative notes, including diagrams, should be kept. Despite meticulous and extensive surgery, the rates of both persistent and recurrent disease remain high in this group of patients (up to 62%) regardless of the type of surgery performed. Unfortunately, the rates of postoperative permanent hypocalcaemia are also high, with published rates up to 47%.

MEN type 4-associated hyperparathyroidism

MEN type 4 is an autosomal dominant syndrome that comprises the same combination of tumours as MEN type 1 but is a rarer cause of hereditary PHPT. It arises as a result of an inactivating pathogenic variant in the cyclin-dependent kinase inhibitor *CDKN1B* gene. It should be managed in the same fashion as MEN type 1.

MEN type 2A-associated hyperparathyroidism

MEN type 2A consists of medullary thyroid carcinoma (MTC), unilateral or bilateral phaeochromocytomas and PHPT. PHPT occurs in approximately 20% of patients and is associated with mutations in codon 634 in the RET proto-oncogene. The majority of patients will be asymptomatic, with a mild elevation in calcium and asymmetrically enlarged parathyroid glands. It is extremely important that the presence of a phaeochromocytoma is excluded prior to surgical intervention. Surgery is usually performed for MTC, with the parathyroid enlargement often being a coincidental intraoperative finding (see ***Chapter 55***). In this setting, with extensive surgery for MTC, the primary aim of treatment is to avoid hypoparathyroidism. A conservative stance is adopted with resection of grossly enlarged glands, but with preservation of parathyroid tissue where possible and identification with a marking stitch in the neck.

Hyperparathyroidism–jaw tumour syndrome

HPT-JT is a rare cause of PHPT. It arises as a result of inactivating mutations in the *HRPT2/CDC73* gene on chromosome 1q21–q31, encoding parafibromin. It classically presents with early-onset PHPT (mean age of 32 years), the aetiology of which can be either single- or multigland disease but is predominantly cystic in nature. It presents with severe hypercalcaemia and is associated with an increased risk of an underlying parathyroid carcinoma. Approximately 40% of patients will have the pathognomonic ossifying jaw fibromas of the maxilla or mandible. Other associated abnormalities include renal pathology (hamartomas, polycystic kidney disease and adult Wilms' tumours) and female patients may have uterine malignancies. Surgical intervention involves removal of all enlarged parathyroid glands.

Where there is concern for a parathyroid carcinoma, great care must be taken to avoid tumour spillage. Whether or not an en bloc resection of the enlarged suspicious parathyroid and the adjacent thyroid lobectomy is required remains controversial.

Autosomal dominant mild hyperparathyroidism

This is a rare autosomal dominant syndrome presenting with hypercalcaemia and hypercalciuria. It is associated with a mutation in the calcium-sensing receptor gene. It typically presents in patients who are over 40 years of age and all patients have PHPT. Surgical intervention requires a bilateral neck exploration as it is associated with multigland disease.

Max Wilms, 1867–1918, Professor of Surgery, University of Heidelberg, Germany.

Familial hypocalciuric hypercalcaemia

FHH is not a surgical disease and therefore preoperative diagnosis is imperative for the surgeon. FHH arises as a result of heterozygous mutations in the calcium-sensing receptor gene on chromosome 3. Benign FHH typically presents with mild hypercalcaemia in young (<10 years of age) asymptomatic patients. Patients with FHH have a normal or slightly elevated PTH level, increased serum magnesium levels and hypocalciuria. A low urinary calcium–creatinine clearance ratio is used to discriminate between FHH and mild PHPT. Patients rarely require intervention and surgical intervention is not indicated.

Criteria for genetic testing

In clinical practice, specific criteria can be employed to determine which patients are at the highest risk of hereditary PHPT. The current NHS England National Genomic Test Directory testing criteria from March 2019 for familial hyperparathyroidism state that testing should be considered for patients with PHPT and a creatinine clearance ratio >0.02 who meet **one** of the following criteria:

1. presenting before the age of 35 years **or**
2. presenting before the age of 45 years with **one** of:
   - **a** proven multigland involvement **or**
   - **b** hyperplasia on histology **or**
   - **c** ossifying fibroma(s) of the maxilla or mandible **or**
   - **d** at least one first-degree relative with unexplained hyperparathyroidism.

The testing criterion for FHH is a creatinine clearance ratio <0.02.

Summary box 56.1

Primary hyperparathyroidism

- Presentation is now typically asymptomatic rather than the classical 'bones, stones, abdominal groans and psychiatric overtones'
- The diagnosis of PHPT is a biochemical one
- Presence of an elevated ionised calcium with an inappropriately elevated/not suppressed PTH level confirms the diagnosis
- Sestamibi and focused neck ultrasonography are the first-line radiological investigations
- 85% of cases are due to a single adenoma
- Minimally invasive parathyroidectomy is a safe and acceptable alternative to a four-gland exploration in the presence of localised disease
- Familial syndromes and disease that is not localised require a formal four-gland exploration and three-and-a-half-gland parathyroidectomy

SECONDARY HYPERPARATHYROIDISM

Secondary hyperparathyroidism is defined as a derangement in calcium homeostasis, which leads to a compensatory increase in PTH secretion. It occurs primarily as a result of chronic kidney disease and is therefore sometimes referred to as renal hyperparathyroidism. Other underlying causes include gastrointestinal malabsorption, vitamin D deficiency, liver disease or chronic lithium usage.

The pathogenesis of secondary hyperparathyroidism is related to renal dysfunction. Abnormalities in the renal tubular absorption of phosphate lead to hyperphosphataemia. This acts directly on the parathyroid cells and stimulates PTH secretion. More recent translational research has identified a novel phosphaturia hormone, fibroblast growth factor 23 (FGF23). This is progressively secreted from osteocytes to compensate for chronic phosphate retention that in turn leads to a reduction in 1,25-dihydroxyvitamin D, which by reducing the intestinal absorption of calcium also acts to increase secretion of PTH. Previous studies in patients with chronic renal disease have shown that there is a reduction in the expression of the vitamin D receptor and the calcium-sensing receptor, with associated skeletal resistance to PTH. These factors interact to form the complex pattern leading to progressive secondary hyperparathyroidism in the setting of chronic renal disease.

The pathological characteristics associated with secondary hyperparathyroidism include hyperplasia, asymmetrical glandular enlargement or nodularity. This differentiation is important as, when the parathyroid gland becomes nodular, it loses expression of the vitamin D receptor and the calcium-sensing receptor gene. It has been proposed that nodular parathyroid glands may be resistant to calcimimetics and therefore refractory to medical management.

Diagnosis

The classical symptoms associated with secondary hyperparathyroidism are seen less commonly now, with greater awareness of the disease and the resultant earlier medical intervention. However, progressive bone disease, especially bone pain, can occur with associated soft-tissue calcium deposits (***Figure 56.9***).

The diagnosis of secondary hyperparathyroidism is characterised by hypocalcaemia or normocalcaemia with an elevated PTH. Patients have a high serum phosphate and a low vitamin D. Traditional plain radiographs now rarely demonstrate the pathognomonic osteitis fibrosa cystica. However, bone densitometry (DEXA scan) typically demonstrates osteopenia or osteoporosis.

The diagnosis of secondary hyperparathyroidism is a biochemical one. In general, localisation studies are not undertaken as minimally invasive surgery is not indicated. However, neck ultrasonography can be performed to identify patients with nodular hyperplasia who may be refractory to medical management. Localisation studies are helpful in patients with recurrent disease in order to identify ectopic parathyroid tissue, especially in the mediastinum. In cases of recurrent disease, when there is no evidence of active disease in the neck and a previous allograft has been used to the forearm, selective venous sampling for PTH in the neck and the brachial vein on the side of the graft can be useful. This is known as the Casanova test and to prove that the recurrent disease is located in the grafted arm (graft hyperplasia) the ratio must be greater than 20:1.

Daniel Casanova, contemporary, University of Cantabria, Santander, Spain.

Figure 56.9 Secondary hyperparathyroidism. Radiograph showing ectopic calcification.

Calciphylaxis

Calciphylaxis (calcific uraemic arteriolopathy) is a syndrome of disseminated calcification resulting in both vascular calcification and skin necrosis. It accounts for approximately 4% of patients undergoing surgical intervention for secondary hyperparathyroidism. It presents with expanding painful cutaneous purpuric lesions, predominantly on the extremities, although they can also be seen on the lower abdomen. The underlying tissue calcification within the arteriolar and small vascular walls leads to ischaemic necrosis and the development of gangrene, which in turn leads to overwhelming sepsis and death. The majority of these patients will have an elevated calcium × phosphate product but it is not usually associated with an extremely high PTH level. The underlying aetiology remains unclear but a number of potential factors have been postulated. A reduction in the serum levels of a calcification inhibitory protein, α_2-Heremans–Schmid glycoprotein, and abnormalities in smooth muscle cell biology in uraemic patients may play a role in the development of the syndrome. Prognosis for these patients is extremely poor, with a mortality of up to 87%. An urgent parathyroidectomy has been shown to decrease pain, improve wound healing and reduce the risk of amputation in these patients. It has also been associated with an increase in median survival.

Management

Renal transplantation remains the only definite treatment for secondary hyperparathyroidism. Other therapies are a bridge to this or aim to provide symptom relief. Standard management includes replacement of calcium and vitamin D and the reduction of phosphate levels by the use of phosphate binders. Treatment of this disease changed radically with the introduction of calcimimetic drugs, such as cinacalcet. Calcimimetics alter the set point of the calcium-sensing receptor, thereby reducing the constant stimulation of the parathyroid glands and lowering the PTH level. This obviously does not address the underlying renal disease. It remains controversial as to which patients may benefit from the use of calcimimetics and which patients may benefit from earlier surgical intervention. Indications for pursuing medical management include those patients who are deemed non-surgical candidates by reason of medical comorbidities. Similarly, where there is persistent or recurrent disease, the origin of which cannot be clearly elucidated, surgical management should be avoided. However, there are definite indications for surgical intervention in secondary hyperparathyroidism (***Table 56.3***), although these have been modified to reflect the current use, where available, of calcimimetics (***Table 56.4***).

There are a wide variety of operations that can be utilised for the management of secondary hyperparathyroidism, none of which appears significantly superior in terms of clinical outcomes (persistent or recurrent disease). These include a subtotal parathyroidectomy, a total parathyroidectomy with autograft or a total parathyroidectomy without autograft. Cryopreservation of resected tissue, where available, should be

TABLE 56.3 Indications for surgical intervention in secondary hyperparathyroidism.

Essential components
1. Persistently high serum level of intact PTH >500 pg/mL 2. Hyperphosphataemia (serum PO_4 >6 mg/dL) or hypercalcaemia (serum Ca >2.5 mmol/L or 10 mg/dL) which is refractory to medical management 3. Estimated volume of the largest gland >300–500 mm^3 or long axis >1 cm
Clinical findings
If patients have one of these symptoms, parathyroidectomy should be recommended: • Severe osteitis fibrosa with associated high bone turnover • Subjective symptoms (bone and joint pain, arthralgia, muscle weakness, irritability, pruritus, depression) • Progressive ectopic calcification • Calciphylaxis • Progressive reduction in bone mineral content • Anaemia resistant to ESA • Dilated cardiomyopathy/cardiac failure

ESA, erythropoietin-stimulating agent; PTH, parathyroid hormone.

J F Heremans, 1927–1975, Professor of Medicine, Catholic University of Louvain, Belgium.
Karl Schmid, 1920–2009, Biochemist, Boston Medical Center, Boston, MA, USA.

TABLE 56.4 Proposed indications for surgical management of secondary hyperparathyroidism (SHPT) in the era of calcimimetics.

- When SHPT is refractory to vitamin D replacement or vitamin D analogues and prolonged survival is anticipated
- Severely impaired quality of life owing to either SHPT or intolerance to calcimimetics
- When sufficient reduction in parathyroid hormone cannot be achieved with use of calcimimetics
- Thyroid surgery is also required (thyroid carcinoma)

performed in cases of significant postoperative hypocalcaemia. The first two procedures are most widely accepted and the type of operation performed depends upon the surgeon.

A subtotal parathyroidectomy is where three and a half parathyroid glands are excised, with the remnant being marked with a non-absorbable stitch to facilitate identification in the event of recurrent disease. A biopsy of the final gland that is to be left *in situ* is mandatory to confirm the presence of residual parathyroid tissue. Ideally an inferior gland is left *in situ* to facilitate reoperative surgery and minimise potential damage to the recurrent laryngeal nerve in that setting (***Figure 56.10***). A total parathyroidectomy with a forearm autograft involves removal of all parathyroid tissue in the neck, with reimplantation of a small amount of morcellated tissue within a pocket formed in the brachioradialis muscle. Overall, regardless of the operative approach utilised the cure rate ranges between 90% and 96%, with similar complication rates. A randomised study looking at 40 patients who underwent either a subtotal or total parathyroidectomy with autotransplant demonstrated no significant difference between the two operations in terms of efficacy and recurrence rate (Rothmund *et al.*, 1991).

The response to surgical intervention is often dramatic. The biochemical parameters may resolve almost immediately and appear to be sustained for up to 3 years postoperatively. Patients subjectively report improvements in the symptoms of secondary hyperparathyroidism, including bone pain, pruritus, fatigue and depression. Finally, bone metabolism is improved with an approximate 10% increase in trabecular bone, with almost immediate suppression of bone resorption and acceleration of new bone formation.

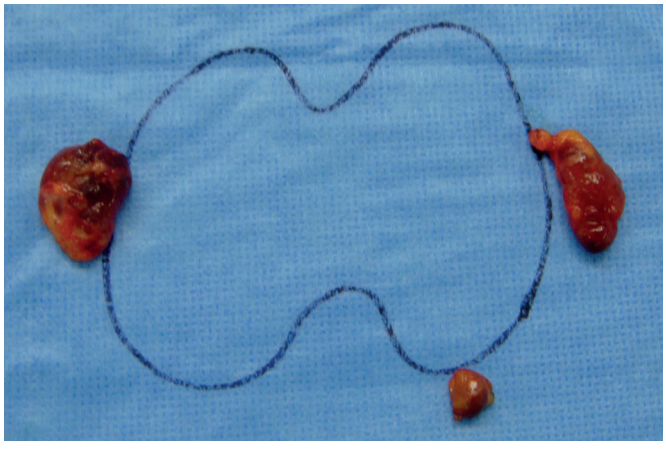

Figure 56.10 Subtotal parathyroidectomy for parathyroid hyperplasia. Right inferior gland biopsied and half left *in situ*.

Summary box 56.2

Secondary hyperparathyroidism

- Primarily due to underlying chronic kidney disease
- Associated with parathyroid hyperplasia
- Diagnosis is made biochemically with a low or normal calcium and an elevated PTH. High phosphate levels and low vitamin D levels are seen
- No localisation studies are required
- Mainstay of treatment is renal transplantation. Medical management with calcium and vitamin D replacements and phosphate binders is a bridge to transplantation
- Use of calcimimetics has reduced the requirement for surgical intervention
- Subtotal parathyroidectomy remains the surgical intervention of choice when indicated

TERTIARY HYPERPARATHYROIDISM

Tertiary hyperparathyroidism is a persistent autonomous hypercalcaemic hyperparathyroidism occurring after kidney transplantation. A number of proposed factors may prevent involution of the hyperplastic parathyroid glands following resolution of the underlying renal impairment. These include impaired graft function, non-suppressible PTH secretion, slow involution of enlarged glands or insufficient calcitriol conversion by the transplanted kidney.

The biochemical diagnosis is confirmed by an elevated total or ionised calcium, with an associated elevated or unsuppressed PTH and a reduced phosphate occurring at least 1 year post renal transplantation. Differentiation from PHPT can be difficult. Fewer than 1% of patients with tertiary hyperparathyroidism will require surgical intervention (***Table 56.5***). The only new evidence for intervention is the presence of nodular hyperplasia of the glands themselves. Traditionally, localisation studies or imaging of the neck was not indicated in tertiary hyperparathyroidism. However, increasing knowledge of the clonal nature of gland hyperplasia suggests that where there is a nodule within the parathyroid with a volume of tissue greater than 500 mm^3, then resolution of electrolyte abnormalities is unlikely.

TABLE 56.5 Indications for surgical intervention in tertiary hyperparathyroidism.

- Subacute severe hypercalcaemia (>3 mmol/L)
- Impaired graft function
- Nodular hyperplasia of the parathyroid gland(s)
- Progressive symptoms (>2 years following transplantation)
  - Worsening bone disease (pain, fracture, bone loss)
  - Renal stones/nephrocalcinosis
  - Soft-tissue or vascular calcifications

The use of calcimimetics in tertiary hyperparathyroidism remains controversial and has not been approved for this indication. However, isolated reports have documented control of hypercalcaemia with minimal side effects in individual patients. Surgical intervention remains the definitive management strategy. Subtotal parathyroidectomy or total

parathyroidectomy with autotransplantation are acceptable surgical options. The majority of endocrine surgeons will opt for a subtotal parathyroidectomy in this setting, leaving a gland approximately four times normal in volume to minimise postoperative complications. Total parathyroidectomy without an autograft is not a treatment option because of the postoperative and persistent difficulties in managing the associated hypocalcaemia.

Summary box 56.3

Tertiary hyperparathyroidism

- Persistent autonomous hypercalcaemic hyperparathyroidism occurring after kidney transplantation
- Diagnosis is made by demonstrating an elevated total or ionised calcium with an associated elevated or unsuppressed PTH and a reduced phosphate occurring at least 1 year post renal transplantation
- Localisation studies are not required but a focused neck ultrasonography may confirm the presence of nodular enlargement
- Surgical intervention remains the mainstay of treatment and involves a subtotal parathyroidectomy

PARATHYROID CARCINOMA

Parathyroid carcinoma is a rare malignancy occurring in approximately 1% of cases of PHPT, with an estimated prevalence of 0.005% of all cancers. While the aetiology remains unclear, recent advances in molecular biology suggest that there may be an underlying genetic basis. Currently, a history of previous neck irradiation remains the only known environmental risk factor. However, given that it can arise in patients with end-stage renal disease as well as in those with MEN type 1, malignant transformation in hyperplastic glands may also occur.

A significant proportion of patients (>10%) with a parathyroid carcinoma will have HPT-JT. The underlying mutation is in the *HRPT2/CDC73* gene at chromosome 1q21–q31, a tumour suppressor gene that encodes the protein parafibromin. Parafibromin is involved in the regulation of cellular transcription and histone modification. *HRPT2* mutations, leading to inactivation of parafibromin, are therefore an important contributor to the pathogenesis of parathyroid carcinoma. Similarly, up to 18% of patients with a parathyroid carcinoma will have an inactivating mutation of the *PRUNE2* gene, located on chromosome 9q21.2. This is a tumour suppressor gene that encodes the RAS homologue family member A, leading to suppression of oncogenic cellular transformation.

Parathyroid carcinoma remains difficult to diagnose preoperatively as it biochemically resembles PHPT. There are, however, a number of suggestive features. First, the diagnosis is typically made a decade earlier, with an equal gender preponderance when compared with PHPT. Second, a greater proportion of these patients will be symptomatic at presentation. A palpable neck mass is found in 36–52% of patients with parathyroid carcinomas but rarely (<5%) in cases of PHPT. Finally, the biochemical abnormalities tend to be exaggerated with an average total calcium of between 3.75 and 3.97 mmol/L and a PTH level 5–10 times the normal range.

The leading cause of morbidity and mortality from parathyroid carcinoma is hypercalcaemia due to inappropriate PTH secretion. Treatment is focused on controlling hypercalcaemia and removal of the carcinoma where possible. Surgery remains the mainstay of treatment for primary presentations and locally recurrent disease. Complete resection of the tumour, avoiding spillage, is vital in preventing seeding and thus recurrent disease. En bloc resection of the tumour, associated thyroid lobectomy and central neck dissection remain controversial.

Complete R0 resection was thought to provide the only means of a cure. However, a number of recent studies have failed to demonstrate an improvement in local recurrence rates with such comprehensive resection. Adjuvant chemotherapy has not been shown to confer a disease-free or overall survival benefit. Use of external beam radiotherapy should be considered on an individual basis. Traditionally, it has not been deemed effective, but more recent single-institution case series challenge this assumption. It may be considered where it is difficult to achieve a complete surgical resection or in patients with multifocal recurrent soft-tissue deposits.

Histological confirmation of a parathyroid carcinoma remains difficult. The World Health Organization criteria (2017) for the diagnosis of a parathyroid carcinoma emphasise the need for definite invasion of the surrounding soft tissue and/or metastatic disease. The classical description that included trabecular architecture, mitotic figures, thick fibrous bands and capsular and vascular invasion is largely non-specific. New molecular markers may aid the diagnosis and stratify patients for more intensive follow-up (***Figure 56.11***). Immunohistochemical evidence of downregulation of parafibromin has a sensitivity of 67% and a specificity of 100% for detecting parathyroid carcinoma and the protein gene product 9.5 (PGP 9.5). Parafibromin immunohistochemistry may be used with immunohistochemistry for PGP 9.5. This is a protein encoded by ubiquitin carboxyl-terminal esterase LI. It is upregulated in parathyroid carcinoma and has a sensitivity of 78% and a specificity of 100%. All parafibromin-negative and PGP 9.5-positive tumours should be considered for genetic screening.

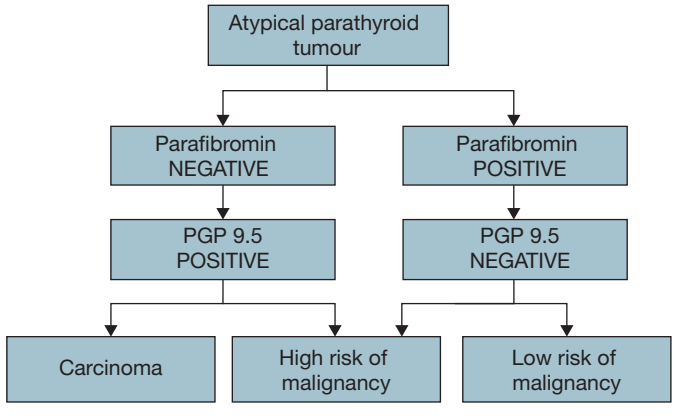

Figure 56.11 Proposed decision tree for atypical parathyroid tumours using parafibromin and PGP 9.5 immunohistochemistry.

Parathyroid carcinoma is an indolent but progressive disease. Metastatic spread can occur to the lungs, liver and bones. Recurrence rates range from 33% to 80% and it typically occurs in the first 3 years. Overall survival is reported to be 85–90% at 5 years and 49–77% at 10 years.

Summary box 56.4

Parathyroid carcinoma

- Accounts for approximately 1% of all cases of PHPT
- A history of previous neck irradiation remains the only known environmental risk factor
- The tumours remain difficult to diagnose preoperatively as they biochemically resemble PHPT
- Treatment is focused on controlling hypercalcaemia and removal of the carcinoma where possible
- Surgery remains the mainstay of treatment for primary presentations and locally recurrent disease. Complete resection of the tumour avoiding spillage is vital in preventing seeding and thus recurrent disease

PERSISTENT HYPERPARATHYROIDISM

Persistent hyperparathyroidism is defined as an elevated calcium within 6 weeks of surgical intervention. For all parathyroid operations (minimally invasive parathyroidectomy [MIP] and bilateral exploration) the rate of persistent hypercalcaemia is approximately 6% in sporadic disease and between 16% and 20% in hereditary disease. It usually arises as a result of a technical error during the first operation because of either a missed adenoma or asymmetrical disease. When this occurs all preoperative biochemistry, radiological imaging, intraoperative findings and pathology must be carefully reviewed. If reoperation is appropriate, repeat imaging of the neck and mediastinum is required (sestamibi, ultrasonography and 4D-CT scanning). Surgical intervention can be straightforward where there are intact tissue planes, such as following a minimally invasive parathyroidectomy. Complications, including recurrent laryngeal nerve damage and permanent hypocalcaemia, are increased when extensive previous dissection has occurred and the patient must be consented appropriately.

RECURRENT HYPERPARATHYROIDISM

Recurrent hyperparathyroidism is defined as hypercalcaemia occurring 6 months after surgery but with an intervening period of normocalcaemia. Common causes include missed pathology at the first operation; hyperplasia in remaining or autotransplanted tissue; parathyromatosis; or, very rarely, the development of a second parathyroid adenoma. Parathyromatosis refers to disseminated parathyroid tissue within the soft tissues of the neck and superior mediastinum owing to rupture of the parathyroid gland during the primary surgery. A definitive indication for surgical intervention must be present prior to embarking on localisation studies. Surgical intervention will be guided by the radiological imaging. Complication rates of recurrent laryngeal nerve damage and permanent hypocalcaemia are higher in reoperative surgery.

PART 8 | Endocrine and breast

CHAPTER 57

The adrenal glands and other abdominal endocrine disorders

Learning objectives

Adrenal gland
- To understand the investigation and diagnosis of disorders of the adrenal gland
- To know of the principles and postoperative management of adrenalectomy

Pancreatic endocrine disorders and gastrointestinal neuroendocrine tumours (GI-NETs)
- To understand the investigation and diagnosis of pancreatic endocrine tumours/GI-NETs
- To know the principles of management of pancreatic endocrine tumours/GI-NETs, including surgery
- To understand the immediate and long-term care after surgery

Multiple endocrine neoplasia (MEN syndromes)
- To understand the genetics and various presentations of patients with MEN
- To be able to manage patients with MEN disorders and familial medullary thyroid cancer
- To understand the principles of surgery and postoperative management of patients with MEN

INTRODUCTION

Two major systems are held responsible for the regulation of homeostasis of the human body: the endocrine and neuroendocrine systems. Both interact with their target organs or target tissues via secretion of ubiquitous messenger molecules, which can be peptides, amines or steroids.

The **endocrine system** consists of various specialist cells in a variety of richly vascularised ductless glands that synthesise and release hormones into the bloodstream.

The **neuroendocrine system** involves neuroendocrine cells that receive nerve impulses to release neurohormones into the bloodstream. Neuroendocrine glands are found in almost every organ of the body. They are mainly found scattered in the gastrointestinal tract, pancreas (islet cells) and thyroid (C cells). For this reason they are known as the diffuse neuroendocrine system. A shared characteristic in the adrenal medulla, gut and pancreatic endocrine tissues are the amine precursor uptake and decarboxylation (APUD) cells, now known as neuroendocrine cells. For many years they were believed to have a common embryological derivation in the neural crest, from which cells migrated to tissues throughout the body. It is now believed that, along with neurones, they share a common neuroendocrine programming influence during their differentiation (see ***Further reading***). Finally, somatostatin receptors (SSTRs) are present on the cell surface of neuroendocrine cells, providing a unique and specific molecular target for imaging and therapy. Nuclear imaging physicians and specialists in radiopharmaceutical therapy are important additional members of the endocrine surgery multidisciplinary team.

Throughout the chapter, the diagnosis and management of various conditions are considered. For each and every disease the principles of endocrine surgery are followed in a stepwise manner:

- confirm the diagnosis with biochemical tests;
- render the patient safe (e.g. treat hypertension, hypoglycaemia, hypokalaemia);
- consider whether localisation studies are necessary;
- decide if surgery is indicated;
- if so, what operative approach is best?

ANATOMY

Adrenal glands

The weight of a normal adrenal gland is approximately 4 g. The adrenal glands are paired and situated in the retroperitoneum, near the upper poles of the kidneys, within Gerota's capsule. They are not symmetrical. The right adrenal gland is located between the right liver lobe and the diaphragm, close to and partly behind the inferior vena cava (IVC). The left adrenal gland lies superior–medial to the upper pole of the left kidney and the renal pedicle. It is covered by the pancreatic tail and the spleen (***Figure 57.1***). Each adrenal gland is supplied by multiple small arterial branches from three main vessels: the aorta, the inferior phrenic artery and the renal artery. A usually single large adrenal vein drains into the IVC on the right side and into the renal vein on the left side.

Dumitru Gerota, 1867–1939, Professor of Surgery, Bucharest, Romania.

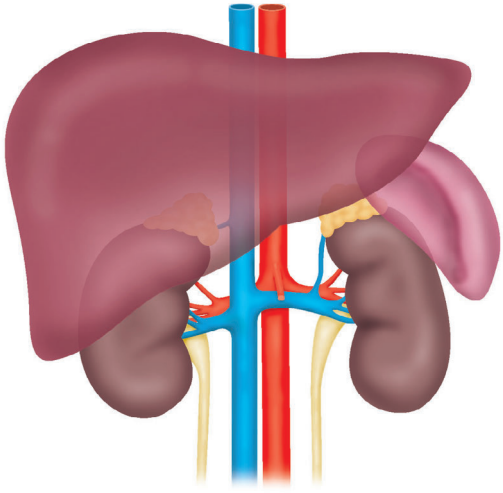

Figure 57.1 Anatomy of the adrenal glands.

Extra-adrenal paraganglia

Paraganglia are neuroendocrine cells associated with the autonomic nervous system. They can be adrenal (medulla) or extra-adrenal. Extra-adrenal paraganglia occur throughout the sympathetic nervous system and along some branches of the parasympathetic glossopharyngeal and vagus nerves. There are four subgroups:

1. **Sympathetic**: the largest cluster is the organ of Zuckerkandl, which is located at the aortic bifurcation or close to the origin of the inferior mesenteric artery.
2. **Chemoreceptor**: including aortic and carotid bodies that assist in the regulation of respiration.
3. **Visceral–autonomic**: in the urinary bladder and peripheral blood vessels.
4. **Intravagal**: situated within or adjacent to the vagal trunk.

Neoplasms of extra-adrenal paraganglia are called paragangliomas (PGLs). Tumours of chemoreceptors are usually referred to as chemodectomas (see *Chapter 52*) and those from parasympathetic ganglia are termed glomus tumours.

EMBRYOLOGY

There are two distinct functional units in the adrenal gland: cortex and medulla. The cortex is derived from the mesoderm. At about the fifth week of life the fetal cortex develops; this is subsequently surrounded by a second wave of mesothelial cells that will eventually form the definitive cortex. After birth the fetal cortex regresses except for its outermost layer, which differentiates into the reticular zone. The adrenal medulla is derived from ectodermal chromaffin cells that are believed to have migrated from the neural crest.

The adrenal cortex represents 90% of the gland and is arranged in a zonal configuration. The outer **zona glomerulosa** contains small, compact cells loosely arranged in cords. The central **zona fasciculata** can be identified by larger, lipoid-rich cells, which are arranged in radial columns. This is the largest layer (70%). Compact and pigmented cells characterise the inner **zona reticularis**.

The adrenal medulla is the inner core that consists of a thin layer of large chromaffin cells (stain yellow with chromium), which synthesise, store and secrete catecholamines.

PHYSIOLOGY

The outer **zona glomerulosa** secretes the C21 steroid aldosterone. The **zona fasciculata** secretes (C21 steroid) cortisol and the inner **zona reticularis** secretes (C19 steroid) androgens.

Aldosterone regulates sodium–potassium homeostasis; it promotes sodium retention and potassium excretion. The target organs of aldosterone are the kidneys, the sweat and salivary glands and the intestinal mucosa. The most important regulators of aldosterone secretion are the renin–angiotensin system and serum potassium concentration.

Renin, produced by the juxtaglomerular cells in the kidneys, acts on its substrate angiotensinogen to generate angiotensin I. Angiotensin I is converted by angiotensin-converting enzyme (ACE) to the octapeptide angiotensin II, which is modified to angiotensin III. Both stimulate secretion of aldosterone from the adrenal cortex. A decrease in renal blood flow (haemorrhage, dehydration, salt depletion, orthostasis, renal artery stenosis) or hyponatraemia increases renin secretion, resulting in sodium retention, potassium excretion and an increased plasma volume.

Cortisol secretion by the cells of the **zona fasciculata** is regulated by adrenocorticotropic hormone (ACTH), which is produced by the anterior pituitary gland. The hypothalamus controls ACTH secretion by secreting corticotropin-releasing hormone (CRH). The serum cortisol level inhibits the release of CRH and ACTH via a closed-loop system (negative feedback loop).

Cortisol has numerous metabolic and immunological effects. It increases gluconeogenesis and lipolysis, decreases peripheral glucose utilisation, inhibits immunological response and, in time, reduces muscular mass. It affects fat distribution, wound healing and bone mineralisation; it also alters mood (causing euphoria or, rarely, depression) and brain cortical activity and alertness. Cells in the zona reticularis synthesise adrenal androgen dehydroepiandrosterone (DHEA) and its sulphate, DHEAS. Adrenal androgen accounts for about 20% of total male activity and is under the control of ACTH.

Cells of the adrenal medulla synthesise mainly adrenaline (epinephrine; 80%) but also noradrenaline (norepinephrine; 20%) and dopamine. Unlike other adrenergic neurones, those of the medulla express phenylethanolamine-*N*-methyltransferase (PNMT), which catalyses the conversion of noradrenaline to adrenaline. These catecholamines act as hormones as they are secreted directly into the circulation. Their effects, which are mediated through α and β receptors on target organs, include the cardiovascular system, resulting in an increase in blood pressure, heart rate and cardiac contractility; vasoconstriction of vessels in the splanchnic system and vasodilatation of vessels

Emil Zuckerkandl, 1849–1910, Professor of Anatomy, Vienna, Austria

in the muscles; bronchodilatation; and increased glycogenolysis in liver and muscles, all of which are necessary for the flight/fight response.

INCIDENTALOMA

Definition

An asymptomatic adrenal mass detected on imaging not performed for suspected adrenal disease is termed an incidentaloma. The aetiology includes benign and malignant tumours of the cortex and medulla or of extra-adrenal origin. These tumours can be either non-functioning (silent) or functioning (secreting excess hormones).

Incidence

Autopsy studies suggest a prevalence of clinically inapparent adrenal masses of the order of 2%, which increases with age. Radiological incidentalomas are seen in about 3% of scans at the age of 50, rising to 10% in the elderly.

Investigation

Incidentaloma embraces all adrenal pathology and so the steps to management are described here and the detail for each pathology will follow in the individual sections of the chapter.

A clear evidence-based algorithm for assessing patients with adrenal incidentaloma has been derived (***Figure 57.2***). The following should be assessed in parallel:

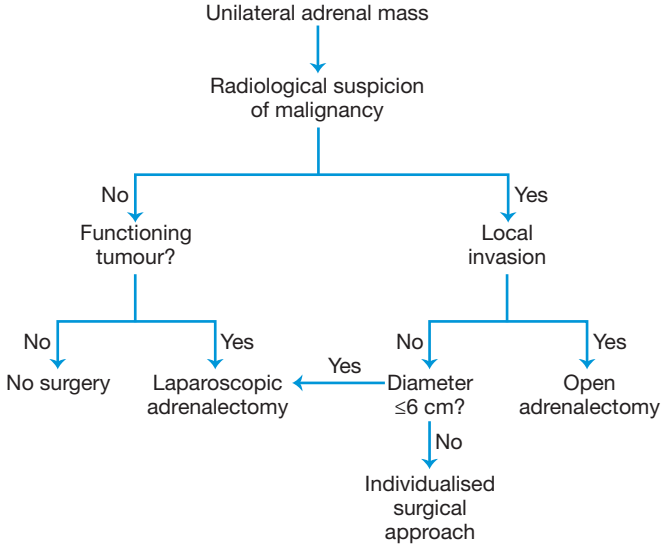

Figure 57.2 Algorithm for the investigation of adrenal incidentaloma. (After Fassnacht M, Arlt W, Bancos I *et al*. Management of adrenal incidentalomas: European Society of Endocrinology Clinical Practice Guideline in collaboration with the European Network for the Study of Adrenal Tumors. *Eur J Endocrinol* 2016; **175**(2): G1–G34.)

- **Is the tumour benign or malignant?** Clinically, Cushing's syndrome and virilising tumours are associated with higher rates of malignancy (50% and 30%, respectively). The optimal way to determine malignancy is by means of a non-contrast computed tomography (CT) scan and measurement of the density of the lesion by Hounsfield units (HU). Benign tumours are low density (≤10 HU). In cases of uncertainty, consideration is given to fluorodeoxyglucose (FDG)–positron emission tomography (PET) scanning, magnetic resonance imaging (MRI) with chemical shift or contrast CT and measurement of washout. Radiological findings suspicious of malignancy are shown in ***Summary box 57.1***.
- **Is the tumour functionally active?** This is determined by:
  - Clinical assessment
  - 1 mg overnight dexamethasone suppression test (DST)
  - Measurement of plasma or urinary metanephrines
  - Plasma aldosterone–renin ratio (ARR)
  - Sex hormones and steroid precursors

Summary box 57.1

Radiological features suspicious of adrenal malignancy

- Diameter >40 mm and >10 HU density
- Contrast-enhanced washout CT
  - Relative <40%
  - Absolute <60%
- MRI chemical shift: no change in signal intensity on out-of-phase imaging
- FDG-PET: positive uptake

Management

All patients should be discussed in a multidisciplinary setting. Small (<40 mm), benign non-functioning tumours do not require surgery, but patients should undergo a follow-up CT/MRI at 6 months. There is no consensus about follow-up beyond that period. However, there is evidence that a tumour >30 mm has an increased risk of developing hyperfunction over time.

Adrenalectomy is the standard of care for patients with unilateral tumours causing hormone excess. Adrenalectomy is recommended for all tumours >40 mm in diameter, tumours showing imaging characteristics of malignancy and tumours showing significant growth.

Laparoscopic adrenalectomy is recommended for unilateral adrenal masses with radiological findings suspicious of malignancy and a diameter <60 mm, but without evidence of local invasion. Open adrenalectomy is recommended for unilateral adrenal masses with radiological findings suspicious of malignancy. An individualised approach is required for patients whose tumours fall outside the above categories.

Harvey Williams Cushing, 1869–1939, Professor of Surgery, Harvard University Medical School, Boston, MA, USA.
Sir Godfrey Newbold Hounsfield, 1919–2004, British electrical engineer, won the 1979 Nobel Prize in Physiology or Medicine for helping to develop the diagnostic imaging technique known as X-ray computed tomography.

DISORDERS OF CORTEX

Conn's syndrome (primary hyperaldosteronism)

Definition

First described in 1957 in a patient with hypertension and low serum potassium, primary hyperaldosteronism (PA) now comprises a heterogeneous group of disorders characterised by hypertension and inappropriately raised plasma aldosterone concentrations. It is of importance not only because, if left untreated, it can lead to cardiovascular and renal complications, but also because a significant proportion of patients can be improved or cured with surgery.

Incidence

PA is the most common cause of endocrine hypertension and may be present in up to one-fifth of patients investigated for hypertension. It is twice as common in females as in males and its prevalence increases significantly in those with drug-resistant hypertension. About 30–40% of cases are due to an aldosterone-producing adenoma (APA) of the cortex and just over one-third of patients will have hypokalaemia at presentation.

Pathology

Although Conn originally described a patient with an APA, PA may also be due to bilateral adrenal hyperplasia, adrenocortical carcinoma (ACC), unilateral hyperplasia and familial hyperaldosteronism (FH). Determining the underlying cause is key because this will determine the most appropriate treatment modality (surgery versus medical therapy). In all its forms, PA is characterised by volume expansion secondary to sodium retention and the variable occurrence of hypokalaemia due to increased potassium excretion into the renal tubule. Resultant hypertension leads to an increased risk of cardiovascular morbidity (stroke, myocardial infarction and atrial fibrillation) and mortality compared with matched controls. Furthermore, glucose intolerance, type 2 diabetes and the metabolic syndrome are also more common in those with PA.

Aldosterone-producing adenoma

Arising in the zona glomerulosa, these tumours are typically between 10 and 20 mm in maximal diameter at presentation, well circumscribed and macroscopically golden yellow on slicing (the 'canary tumour'). Ninety per cent contain somatic mutations; although these may be associated with certain clinical features, their presence does not yet affect clinical management. The most common mutations are those of the potassium channel encoded by the *KCNJ5* gene; these are present in approximately 40% of patients with APA. Mutations are thought to trigger calcium influx into glomerulosa cells, resulting in aldosterone secretion and cellular proliferation. Phenotypically, they are more prevalent in females and are associated with larger tumours and higher aldosterone levels, but are not associated with adrenal hyperplasia. In contrast, less common variants, including somatic mutations in the *ATP1A1, ATP2B3, CACNA1D* and *CTNNB1* genes, exhibit a stronger male preponderance.

Bilateral adrenal hyperplasia (idiopathic hyperplasia)

Traditionally thought to result from diffuse hyperplasia of the zona glomerulosa, the pathophysiology of bilateral adrenal hyperplasia and its drivers remain poorly understood. More recently, aldosterone-producing cell clusters with a high prevalence of somatic mutations in the *CACNA1D* l-type calcium channel gene have been identified in the adrenal cortex of patients with bilateral hyperplasia and these 'micro-APAs' have been cited as the putative cause.

Familial hyperaldosteronism types I–IV

These rare genetic variants of PA are all inherited in an autosomal dominant fashion (50:50 chance that offspring of an affected individual will inherit the disorder).

FH type I or glucocorticoid-remediable aldosteronism (GRA) arises as a result of a *CYP11B1/CYP11B2* chimeric gene and presents with (typically normokalaemic) hypertension when the patient is in their early twenties. The chimeric gene leads to ACTH-dependent aldosterone secretion and is treated by administering physiological doses of glucocorticoids, which suppress ACTH release. Thus treatment is always medical.

FH types II–IV (caused by germline *CLCN2* pathogenic variants, *KCNJ5* pathogenic variants and *CACNA1H* pathogenic variants, respectively) all result in early-onset PA within affected kindreds. Type II FH may lead to APAs or bilateral adrenal hyperplasia; type III massive bilateral adrenal hyperplasia; and type IV developmental disorder with bilateral adrenal hyperplasia. Genetic testing for these disorders is in evolution and, currently, it is recommended that treatment should be as for patients with sporadic PA.

Clinical presentation

Aside from hypertension, patients may be asymptomatic unless they are hypokalaemic, in which case muscle weakness, cramps and fatigue may be present. Hypokalaemia-induced palpitations after initiation of diuretic therapy or polyuria and polydipsia from nephrogenic diabetes insipidus are also described. Physical signs include hypertension, associated bruits and retinopathy. It is worth noting that the following presentations might also warrant screening for PA: drug-resistant hypertension, hypertension and obstructive sleep apnoea, hypertension with incidentaloma, patients with first-degree relatives with PA, and a family history of early-onset hypertension or stroke.

Diagnosis

Biochemical

Although routine tests may reveal hypokalaemia and/or metabolic alkalosis, the diagnosis depends on the presence of non-suppressed plasma aldosterone (pmol/L) and a suppressed plasma renin activity (nmol/L/h). The two are combined to give a plasma ARR: if >850 this is suggestive of PA; if >1700 it is very likely to be PA. Because most, if not all, patients will be prescribed antihypertensives, it is important to stop agents that might interfere with interpretation of the ARR. Although

Jerome William Conn, 1907–1981, Professor of Internal Medicine, University of Michigan, Ann Arbor, MI, USA.

most can be continued, predictably, those that interfere with the renin–angiotensin system, i.e. ACE inhibitors, angiotensin receptor blockers, direct renin inhibitors and aldosterone antagonists (spironolactone and eplerenone), should be stopped for 2 weeks beforehand. More severe biochemical disease is more likely to be due to an APA.

Radiological

Once a biochemical diagnosis is secure, the primary objective is to determine whether it is due to a unilateral APA (or, rarely, carcinoma) or bilateral hyperplasia. High-resolution (2- to 3-mm slices) adrenal CT is the initial investigation of choice and APAs typically appear as a hypodense (<10 HU) unilateral 1- to 2-cm adrenal nodule; carcinomas are heterogenous and >60 mm; and bilateral hyperplasia presents as bilateral bulky adrenal enlargement.

Diagnosis of a unilateral APA on CT alone is controversial: tumours are often small and this, combined with the increasing preponderance for adrenal nodules with advancing age, means that a missed contralateral nodule could be the underlying cause. For this reason, adrenal vein sampling (AVS) is considered the gold standard for confirming unilateral secretion. Surgery based on biochemistry and a unilateral adrenal lesion on imaging alone is effective in those younger than 35 years, leaving AVS for patients older than 35 years or with negative imaging or bilateral nodules. PET scanning with ^{11}C-metomidate, an 11β−hydroxylase (CYP11B1) and aldosterone synthase (CYP11B2) inhibitor, has been compared with AVS and found to be 86% specific and 76% sensitive for lateralising PA; it is therefore a useful adjunct in patients with failed or equivocal AVS results (***Figure 57.3***) (see ***Further reading***).

Treatment

Medical

Prior to surgery, hypertension and hypokalaemia should be adequately corrected. The preoperative response to aldosterone receptor antagonist (spironolactone/eplerenone) therapy is a useful surrogate for predicting likely success. In general, the shorter the time to diagnosis, the better the likely outcome from surgery.

Surgical

Unilateral APA should be managed by minimally invasive adrenalectomy, which results in resolution of hypertension and hypokalaemia or a reduction in antihypertensive requirement in the vast majority of patients.

Bilateral disease

Unless hyperplasia is marked, with dominant nodules >40 mm that are indeterminate, patients with bilateral disease should be managed medically with aldosterone antagonists and other antihypertensives. If this is unsuccessful, lateralising investigations may be used to determine if one side is dominant, in which case excision of that side may improve medical control.

Familial hyperaldosteronism

These disorders are extremely rare and are best managed in a multidisciplinary fashion in conjunction with tertiary

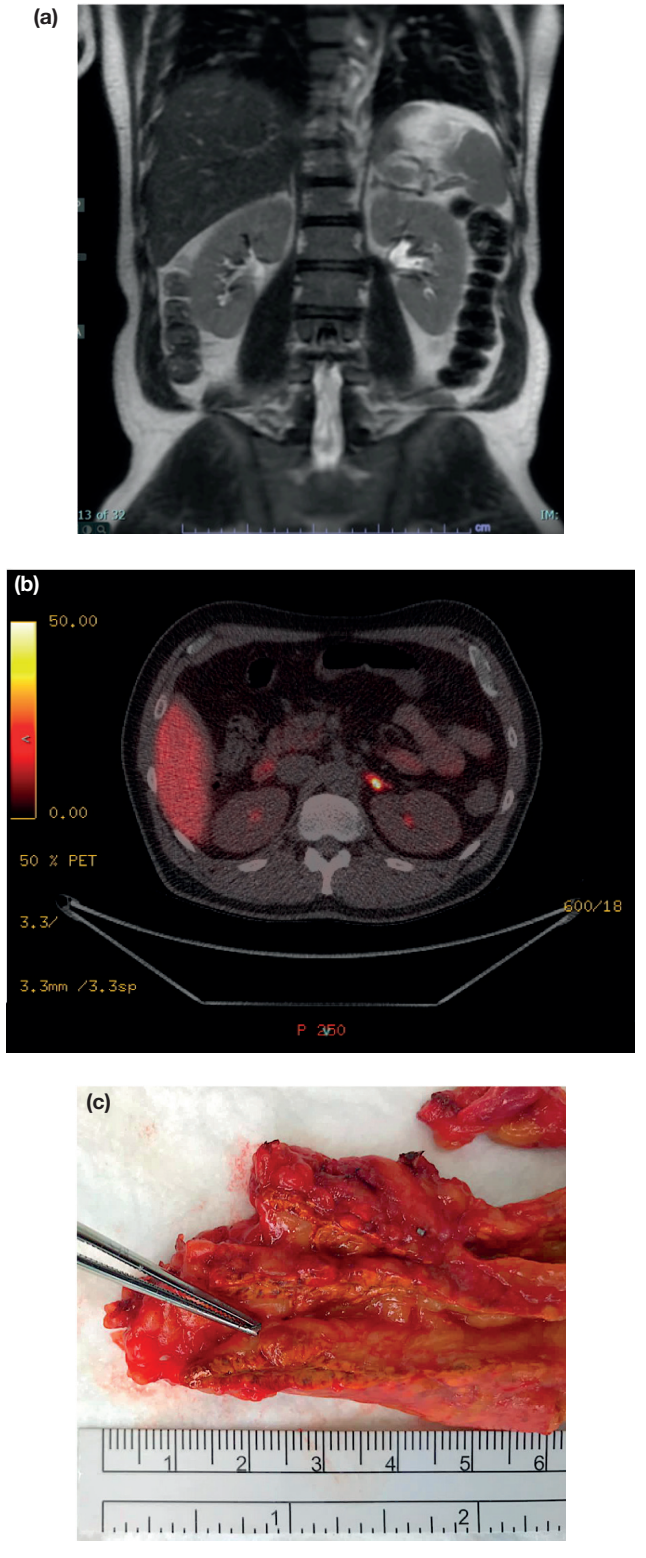

Figure 57.3 A patient with confirmed Conn's syndrome. Magnetic resonance imaging **(a)** failed to demonstrate a lesion but a 30-SUV-max lesion was demonstrated on a ^{11}C-metomidate positron emission tomography (PET)–computed tomography (CT) scan **(b)**. **(c)** Surgical specimen sliced to reveal a 6-mm aldosterone-producing adenoma in the medial limb. The patient's hypertension resolved with laparoscopic left adrenalectomy (PET-CT image courtesy of Mark Gurnell, Addenbrooke's Hospital, Cambridge). SUVmax, maximum standard unit value.

endocrinology input. However, surgery should be considered if a unilateral secreting lesion is found to be the cause.

Cushing's syndrome

Definition

Hypercortisolism may arise as a result of excess ACTH secretion (termed pituitary dependent; Cushing's disease), ectopic ACTH secretion from a non-pituitary tumour, exogenous corticosteroid therapy or autonomous secretion of endogenous glucocorticoids from cortical tumours of the adrenal glands (pituitary independent; Cushing's syndrome). ACTH-secreting pituitary tumours account for 70–80% of cases, whereas ectopic ACTH production from foregut neuroendocrine tumours and small cell lung tumours are the cause in 10%. In the remaining 10–15%, Cushing's syndrome arises from unilateral cortisol-secreting adenomas and occasionally ACCs or bilateral nodular adrenal hyperplasia. Left untreated, hypercortisolism leads to a fivefold increase in the risk of death from cardiovascular disease. The principal aim therefore is to determine and treat the underlying cause, while avoiding, if possible, long-term hormonal deficiency or dependence on medication.

Incidence

Iatrogenic Cushing's syndrome is likely to be most prevalent as a result of the widespread use of corticosteroids for other diseases but this is poorly documented. The incidence of pituitary-dependent disease is around six or seven per million per year, whereas the incidence of ectopic ACTH syndrome is around one per million per year. Although adrenal tumours are extremely common, 99% do not present with endocrine disease and so adrenal Cushing's syndrome is also quite uncommon (one or two per million per year). Both ACTH-dependent and -independent Cushing's have a strong female preponderance (four to six times), whereas ectopic ACTH syndrome is twice as common in men. The incidence increases significantly from age 50.

Pathology

Similar to PA, the most common cause of adrenal Cushing's (syndrome) is an adrenocortical adenoma, although it can arise in the setting of bilateral nodular hyperplasia or less commonly ACC (see ***Adrenocortical carcinoma***).

Adrenal adenoma

Tumours are well circumscribed, nodular in appearance and composed of polygonal eosinophilic and lipidised cells in a nested pattern. The resulting hypercortisolism leads to suppressed ACTH, which causes atrophy of fasciculata and reticularis, not glomerulosa, in the residual or opposite adrenal gland.

Primary bilateral macronodular adrenal hyperplasia

Primary bilateral macronodular adrenal hyperplasia (BMAH) is a relatively uncommon cause of Cushing's syndrome. It may present as bilateral adrenal incidentalomas and is characterised by the presence of bilateral non-pigmented adrenal nodules ranging from 10 to 40 mm in size. It may also present with subclinical Cushing's.

Clinical presentation

Because of the pleiotropic actions of cortisol, the clinical features of Cushing's syndrome are broad and multisystem (***Summary box 57.2***). The typical patient is characterised by a facial plethora, a buffalo hump and a moon face in combination with hypertension, diabetes, central obesity and proximal muscle-wasting, traditionally referred to as the 'lemon on sticks' appearance (***Figures 57.4 and 57.5***). Clinical signs can be minimal or absent in patients with subclinical Cushing's syndrome.

Summary box 57.2

Clinical features of Cushing's syndrome

Clinical feature	Incidence (%)
Obesity	90
Hypertension	85
Facial plethora	70
Hirsutism	75
Glucose intolerance/diabetes	75
Hyperlipidaemia	70
Abdominal striae	50
Acne	35
Easy bruising	35
Osteoporosis	80
Proximal myopathy	65
Depression/mania/psychosis	85
Menstrual disorders	70
Decrease libido/impotence	85
Renal stones	50

Adapted from Raff H, Sharma ST, Nieman LK. Physiological basis for the etiology, diagnosis, and treatment of adrenal disorders: Cushing's syndrome, adrenal insufficiency, and congenital adrenal hyperplasia. *Compr Physiol* 2014; **4**: 739–69.

Diagnosis

Biochemical

It is important to exclude iatrogenic Cushing's due to ingested steroid therapy, including potent inhaled corticosteroids. Investigations should then determine **if** hypercortisolism is present **and** whether it is ACTH dependent or independent. Imaging should not be pursued until the diagnosis is secure. Endocrine Society 2008 guidance states that two of the following tests should be abnormal for diagnosis:

- late-night salivary cortisol (two measurements): raised levels signify a loss of diurnal rhythm;
- 24-hour urinary free cortisol (UFC) excretion (two measurements): more than three times the upper limit signifies overspill into the urine;

Figure 57.4 A 34-year-old patient with Cushing's syndrome whose symptoms included thickening of the face, weight gain and acne. Today patients with Cushing's syndrome rarely have the full-blown appearance shown in older textbooks.

Figure 57.5 Discrete central obesity, ecchymosis and fragile skin in a patient with Cushing's syndrome.

- overnight 1-mg DST (dexamethasone suppression test): non-suppressed morning cortisol >50 nmol/L;
- raised serum ACTH signifies pituitary-dependent disease; if it is adrenal in origin, the ACTH is suppressed (<5 pg/mL).

Radiological

These tests should determine the causative lesion. The ACTH result will determine which diagnostic pathway is taken.

- **ACTH raised**: pituitary MRI and inferior petrosal sinus sampling to exclude pituitary microadenoma. If both are negative, this suggests ectopic ACTH syndrome, which warrants CT imaging of the thorax, abdomen and pelvis. Functional imaging with ^{68}Ga-SSTR PET-CT is a useful adjunct and is 75–80% sensitive in confirming the source of ectopic ACTH.
- **ACTH suppressed**: dedicated adrenal CT or MRI to determine if unilateral adenoma or bilateral nodular hyperplasia (or rarely adrenocortical cancer) are present. Benign lesions are typically hypodense and <10 HU on non-contrast CT.

Treatment

Medical

Metyrapone or ketoconazole therapy reduces steroid synthesis and secretion by CYP11B1 inhibition and can be used to prepare patients with severe hypercortisolism preoperatively or as primary therapy if surgery is not possible. In patients who are critically ill with Cushing's syndrome, intravenous etomidate infusion (even at non-hypnotic doses) can reduce serum cortisol levels to normal within 24 hours, providing a suitable window for surgery. This requires monitoring in an intensive care unit setting.

Surgical

ACTH-producing pituitary tumours are treated by transsphenoidal resection and/or radiotherapy. Resection of ectopic ACTH-secreting tumours will also correct hypercortisolism. Patients who have undergone failed pituitary surgery or those with an unresectable or unlocalised ectopic ACTH-secreting tumour may require bilateral adrenalectomy to control hormone excess. This will render them steroid dependent. Unilateral adenoma should be treated by minimally invasive adrenalectomy provided adrenocortical cancer is not suspected. In cases of bilateral ACTH-independent disease (***Figure 57.6***), the extent of adrenalectomy is contentious; bilateral adrenalectomy should be employed in severe Cushing's and equally enlarged adrenals. In asymmetric disease, excision

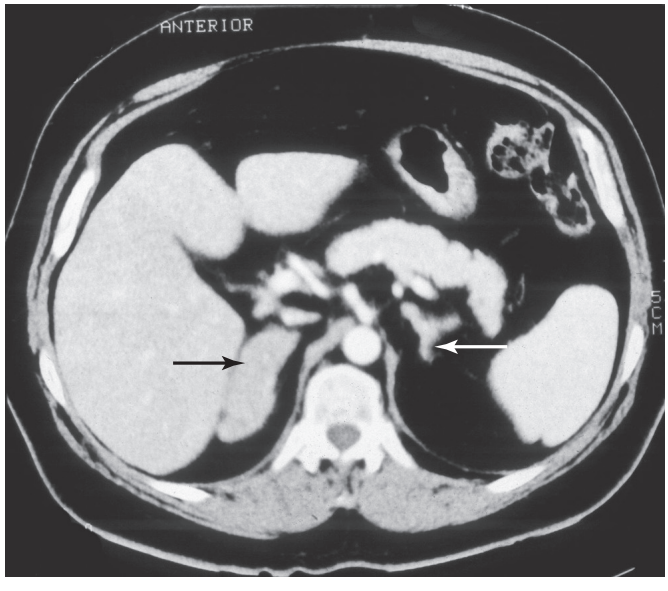

Figure 57.6 Bilateral asymmetrical hyperplasia of the adrenal glands (arrows) in a patient with Cushing's syndrome.

of the larger gland may be curative with a low risk of recurrence. In cases of subclinical Cushing's syndrome and a unilateral adenoma, unilateral adrenalectomy is indicated if the tumour is >4 cm or <4 cm with features of the metabolic syndrome.

Preoperative management. Cushing's syndrome predisposes patients to increased risk of venous thromboembolism, cardiac events, infection and poor wound healing. Patients should therefore receive chemical and mechanical thromboprophylaxis as well as perioperative broad-spectrum antibiotics. Accompanying diabetes should also be adequately controlled. As unilateral or bilateral adrenalectomy in the setting of Cushing's syndrome will result in steroid deficiency in the postoperative period, patients should receive intraoperative corticosteroids (50–100 mg intravenous hydrocortisone) and close liaison with the endocrinology team is strongly advised to guide postoperative management.

Postoperative management. After unilateral adrenalectomy the contralateral gland will be suppressed and so all patients should be commenced on 15–25 mg daily of hydrocortisone. In total, 15 mg/h is required parenterally for the first 12 hours followed by a daily dose of 100 mg for 3 days, which is gradually reduced thereafter. After unilateral adrenalectomy, the contralateral suppressed gland may need up to a year to recover adequate function. A synacthen test is used to confirm adequate adrenal function prior to stopping hydrocortisone supplementation. In 10% of patients with Cushing's disease who undergo a bilateral adrenalectomy after failed pituitary surgery, the pituitary adenoma causes Nelson's syndrome owing to continued ACTH secretion at high levels, resulting in hyperpigmentation due to uncontrolled secretion of pro-opiomelanocortin (POMC). POMC is cleaved to produce ACTH and melanocyte-stimulating hormone, excess of the latter resulting in hyperpigmentation.

Adrenocortical carcinoma

Definition

ACC is a rare aggressive malignancy that arises from the adrenal cortex. The prognosis is variable but is generally poor, in part owing to its tendency to present at a late stage. Although most ACCs are sporadic, a minority occur as part of genetic tumour syndromes such as multiple endocrine neoplasia type 1 (MEN 1), familial adenomatous polyposis and the Li–Fraumeni and Lynch syndromes. Optimal surgery remains the best way of curing the patient and so preoperative diagnosis and planning are key in ensuring this outcome.

Incidence

Estimated incidence is one or two cases per 1 000 000 population per year and, in keeping with benign adrenocortical tumours, a female predominance is observed (1.5:1). ACCs can occur at any age but the peak incidence is in the fourth and fifth decades.

Pathology

Tumours are often large (>10 cm) with a cut surface that ranges from orange to brown (***Figure 57.7***). Necrosis is usually present. Distinguishing between benign and malignant adrenocortical tumours may be difficult, with the presence of local invasion or distant metastasis being the only definitive criteria. If neither are present, the modified Weiss histopathological system may be used to guide management. It comprises five criteria: >6 mitoses/50 high-power fields, ≤25% clear tumour cells in cytoplasm, abnormal mitoses, necrosis and capsular invasion. If a criterion is absent, it is scored 0; if present, it scores 2 for the first two criteria and 1 each for the last three. A total score ≥3 is suggestive of malignant behaviour. More recently the use of the Ki-67 proliferation index has been advocated, with increasing count suggesting poorer prognosis.

Clinical presentation

Patients may present with hormonal excess (50–60%) or symptoms of an abdominal mass such as abdominal or back pain (30–40%). Around one in six ACCs present as adrenal incidentalomas. Those that are hormonally active usually cause Cushing's syndrome or a mixed picture of Cushing's and virilisation in women. Mineralocorticoid excess is rare, as is feminisation in male patients.

Diagnosis

Although radiological investigations are critical in diagnosis, the presence of autonomous secretion of glucocorticoids, sex hormones and steroid precursors should also be carefully evaluated. Phaeochromocytoma (PCC) must also be excluded.

Lawrence M Weiss, contemporary, pathologist, Aliso Viejo, Ca, USA.

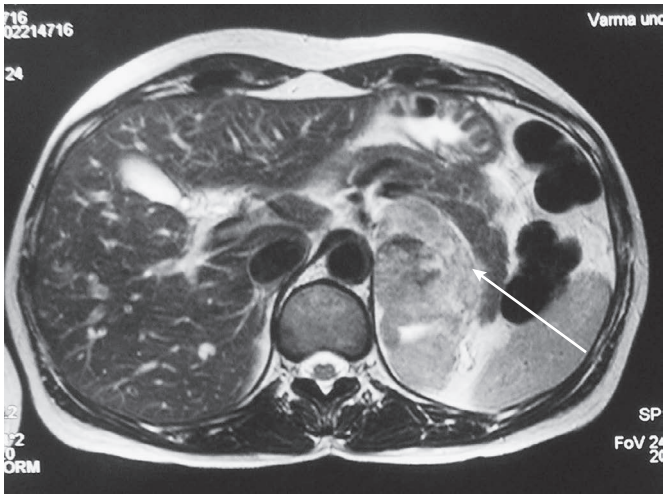

Figure 57.8 Magnetic resonance imaging of adrenocortical carcinoma (arrow) in a patient with cortisol and testosterone excess.

Radiology

ACC is often readily diagnosed on CT or MRI (***Figure 57.8***), where size (>6 cm), heterogeneous appearance and presence of necrosis are suggestive and local invasion and metastatic disease are diagnostic. Common sites of metastases are the lungs and liver, so staging should include the thorax. FDG-PET scanning is complementary and is advised to exclude occult metastatic disease in suspicious lesions. A maximum standard unit value (SUVmax) >40 or 1.5 times higher than the liver both suggest malignant tumours. The use of ^{11}C-metomidate PET may improve diagnostic accuracy but is not widely available. In terms of tissue diagnosis, adrenal biopsy is discouraged and fine-needle aspiration cannot distinguish benign from malignant tumours. Biopsy may have a role in patients with widespread metastatic disease at presentation to guide palliative systemic treatment.

Biochemistry

Glucocorticoid excess should be excluded by careful history and examination, followed by low-dose overnight DST. Serum levels of adrenal androgens (DHEAS, androstenedione, testosterone, 17-hydroxyprogesterone) and serum oestradiol in men and postmenopausal women should also be measured. In patients who are hypertensive, the aldosterone–renin ratio should be measured along with the serum potassium. Steroid precursors can be measured in 24-hour urine collections and may demonstrate a particular pattern on mass spectrometry although use is not widespread at present. Lastly, 24-hour urine or plasma metanephrines should be measured in all patients to exclude PCC.

Treatment

Surgery

Successful R0 resection of the tumour should be the aim of surgery and offers the best chance of cure for the patient. Preoperative assessment should therefore focus on determining whether any adrenal tumour is potentially malignant as this will guide the operative strategy. Treatment should take place in a multidisciplinary setting in a unit with experience of treating this rare disease. Patients with cortisol excess should be given perioperative hydrocortisone. At presentation, there are three common scenarios:

- **Indeterminate or probably malignant tumour <6 cm**: laparoscopic adrenalectomy may be feasible in this situation, but if there is evidence of local invasion on imaging or suspicion of it at laparoscopy open surgery is mandated.
- **Indeterminate or probably malignant tumour >6 cm**: laparoscopic surgery is not advised. In this scenario open radical resection must be undertaken, if necessary *en bloc* with involved adjacent organs (see ***Surgery of the adrenal glands***).
- **Indeterminate or probably malignant tumour <6 cm with synchronous metastatic disease**.

For **limited metastatic disease**, open resection of the tumour and intra-abdominal metastases is advised. For distant disease, resection of the primary followed by adjuvant systemic or surgical treatment of metastases is appropriate.

For **widespread metastatic disease**, initial surgery is no longer routinely advised. Instead, palliative treatment with mitotane with or without chemotherapy should be pursued. If there is significant disease regression after 3–6 months, surgery may then become an option.

More rarely, patients present with locally advanced disease with tumour extension into the great vessels. In this situation, it is recommended that such patients are referred to centres with experience of treating these cases.

Oncological treatment

Patients at high risk of recurrence (size >5 cm, Ki-67 >10%, tumour rupture at surgery, tumour thrombus) and those with metastatic disease should commence mitotane therapy as soon as possible (for up to 5 years) as this has been shown to improve disease-free and overall survival. Palliative EDP (etoposide–doxorubicin–cisplatin) chemotherapy may also be an option if there is disease progression despite mitotane therapy. Unless there is ongoing steroid excess, all patients treated with mitotane should receive oral hydrocortisone replacement therapy.

According to the European Network for the Study of Adrenal Tumours (ENSAT) classification, the 5-year, disease-specific survival rates for ACC are: 82% in stage I (tumour <5 cm; T1N0M0), 61% in stage II (tumour size >5 cm; T2N0M0), 50% for stage III (tumour of any size with at least one of the following factors: tumour infiltration in surrounding tissues [T3], tumour invasion into tumour thrombus in the vena cava or renal vein [T4], positive lymph nodes [N1] but no distant metastases) and 13% for stage IV (distant metastases) (see ***Further reading***).

Metastases

Definition

Adrenal metastases are not uncommon and often portend disseminated incurable disease. Primary tumours that commonly spread to the adrenals include lung, renal, gastric, breast and colorectal cancers.

Diagnosis

The decision regarding surgical intervention must be multidisciplinary and in conjunction with the patient, following careful diagnostic work-up to determine whether it is an isolated adrenal metastasis (seen most often with renal, lung and colorectal primaries) or a more widespread metastatic picture. Patients should therefore undergo CT thorax, abdomen and pelvis and PET-CT to exclude disease at other sites. They should also be screened for catecholamine and cortisol excess to exclude a coincident hormonally active tumour.

Treatment

If disease is widespread, metastasectomy will not usually be appropriate and systemic or palliative treatment should be the norm. Adrenal metastasis diagnosed at presentation (synchronous disease) should be removed if ipsilateral to a renal cell cancer (radical nephrectomy). In the case of other primary tumours, it should be observed with interval scanning at 3–6 months; if the lesion remains stable and isolated, resection should be considered. If adrenal metastasis arises more than 6 months after initial treatment (metachronous), PET-CT should be performed to exclude widespread disease; if the lesion is solitary, excision can be considered.

Surgery

Laparoscopic adrenalectomy is the preferred surgical option. Metastases often induce a significant desmoplastic reaction that can make excision more difficult, particularly when lesions are >4 cm. If there is evidence of local invasion, but the surgery is likely to improve survival, open surgery and *en bloc* excision may be appropriate. Note that, in the setting of previous nephrectomy with adrenalectomy, excision of an affected contralateral adrenal gland will render the patient steroid dependent.

Congenital adrenal hyperplasia (adrenogenital syndrome)

Virilisation and adrenal insufficiency in children are pathognomonic of congenital adrenal hyperplasia (CAH). This is an autosomal recessive disorder caused by a variety of enzymatic defects in the synthetic pathway of cortisol and other steroids from cholesterol. The most frequent defect (95%) is the 21-hydroxylase deficiency, which has an incidence of 1 in 5000 live births. Excessive ACTH secretion secondary to the loss of cortisol leads to an increase in androgenic cortisol precursors and to CAH. CAH may present in girls at birth with ambiguous genitalia or as late-onset disease at puberty. Hypertension and short stature, caused by the premature epiphyseal plate closure, are common signs. Affected patients are treated by replacement of hydrocortisone and fludrocortisone. Large hyperplastic adrenals may need to be removed if symptomatic.

ADRENAL INSUFFICIENCY

Adrenal insufficiency may be primary, secondary or tertiary. Primary insufficiency (Addison's disease) is due to adrenocortical disease, whereas secondary and tertiary insufficiency arise from pituitary and hypothalamic pathology, respectively. Addison's disease most commonly occurs when there is autoimmune (70–90%) or tuberculous destruction of the adrenal cortex and results in glucocorticoid and mineralocorticoid insufficiency. This is in contrast to secondary disease (lack of ACTH) and tertiary disease (lack of CRH secretion), where

TABLE 57.1 Causes and classification of adrenal insufficiency.

Cause of adrenal insufficiency	Pathophysiology	Type of AI
Autoimmune adrenalitis (polyglandular autoimmune syndromes)	Serum antibodies against the steroidogenic enzymes	Primary AI
Infective tuberculous disease	Caseating granulomatous destruction	
Bilateral adrenal infarction	Severe bacterial sepsis in children, e.g. meningococcal septicaemia[a]	
Bilateral adrenal haemorrhage	Traumatic obstetric delivery	
Malignancy	Infiltration by secondary cancers	
Congenital adrenal hyperplasia (adrenogenital syndrome)	Genetic disorders of steroidogenesis	
Pituitary destruction	Infarction, trauma, haemorrhage or infiltration, e.g. craniopharyngioma	Secondary AI
Cessation of chronic glucocorticoid therapy	Zona fasciculata and reticularis atrophy owing to long-term CRH suppression by exogenous corticosteroids	Tertiary AI
Treatment of Cushing's syndrome and Cushing's disease	CRH suppression following removal of ACTH-secreting or cortisol-secreting tumours	
Hypothalamic disorders	Trauma, stroke, tumour infiltration, radiation, infection	

ACTH, adrenocorticotropic hormone; AI, adrenal insufficiency; CRH, corticotropin-releasing hormone.
[a]Waterhouse–Friderichsen syndrome.

Thomas Addison, 1795–1860, physician, Guy's Hospital, London, UK, described the effects of disease of the suprarenal capsules in 1852.
Rupert Waterhouse, 1873–1958, physician, Royal United Hospital, Bath, UK, described this syndrome in 1911.
Carl Friderichsen, 1886–1979, Medical Superintendent, Sundby Hospital, Copenhagen, Denmark, gave his account of the syndrome in 1918.

only glucocorticoid deficiency ensues and aldosterone secretion (under control of the renin–angiotensin system) is spared. The causes are summarised in ***Table 57.1***.

Acute adrenal insufficiency (adrenal or Addisonian crisis)

This is a medical emergency. Owing to its non-specific features (shock with some or all of the following: fever, nausea, vomiting, abdominal pain, hypoglycaemia and electrolyte imbalance), it can be difficult to diagnose. It is also rapidly fatal unless prompt and appropriate treatment is instituted early in its course. Typically there is a precipitating illness that may unmask longstanding adrenal insufficiency or a history of trauma or severe sepsis that result in adrenal haemorrhage or infarction (Waterhouse–Friderichsen syndrome), respectively. Because intestinal symptoms and fever are frequent, Addisonian crisis may often be misdiagnosed as an acute abdominal emergency.

Chronic adrenal insufficiency

Patients with chronic adrenal insufficiency may also be difficult to diagnose because symptoms appear insidiously over time. They may experience anorexia, weakness and nausea and, in the case of primary adrenal insufficiency, hyperpigmentation of the skin and oral mucosa because of the loss of negative feedback on secretion of ACTH and POMC. Hypotension, hyponatraemia, hyperkalaemia and hypoglycaemia are commonly observed due to the deficiency of mineralocorticoids.

Diagnosis

The diagnosis of adrenal insufficiency relies on demonstrating cortisol deficiency and then determining whether this is ACTH dependent or independent by performing an ACTH stimulation test (synacthen test). Blood is drawn for basal ACTH and cortisol. If both are low, the diagnosis is secondary or tertiary adrenal insufficiency. If the ACTH is high and the cortisol is low, the cause is adrenal disease (primary adrenal insufficiency). Synacthen testing is used because it is the quickest way to determine if there is any adrenal function; adrenal function is present for some after the onset of pituitary or hypothalamic disease, whereas there will be no response when the adrenal glands are diseased.

Treatment

If acute adrenal insufficiency is suspected, treatment must be commenced immediately while the results of confirmatory testing are awaited. Blood should be drawn for plasma ACTH, serum cortisol, plasma renin activity and aldosterone and therapy with intravenous saline and hydrocortisone should be commenced. A typical regime would consist of a 100-mg bolus of intravenous hydrocortisone followed by 50 mg intravenous hydrocortisone 6-hourly and 2–3 litres of 0.9% saline in 6 hours, with careful cardiovascular monitoring to prevent fluid overload. Concomitant infections, which are frequently present, should also be treated. Fluids and steroids are then tapered as the patient stabilises.

Chronic adrenal insufficiency is treated by replacement therapy with daily oral hydrocortisone (15–25 mg orally in two or three divided doses) and fludrocortisone (0.05–0.2 mg each morning orally). Patients must be advised about the need to take lifelong glucocorticoid and mineralocorticoid replacement therapy. To prevent an Addisonian crisis, patients must be aware of the need to double the dose in cases of illness or stress ('sickness day rules'). If patients with adrenal insufficiency are scheduled for surgery, appropriate steroid cover must be administered.

ADRENAL HAEMORRHAGE

Definition

Adrenal haemorrhage is a serious condition that can result in adrenal insufficiency, shock, acute adrenal crisis and mortality if not managed with adequate treatment. The adrenal glands are, per weight of tissue, one of the most vascular tissues in the body. A number of factors predispose to haemorrhage, including infection (sepsis), myocardial infarction, anticoagulants, trauma, surgery and antiphospholipid syndrome. Clinical presentation can vary from non-specific abdominal pain to adrenal insufficiency or hypovolaemic shock.

Investigation

CT scanning is the most common way to diagnose the condition (***Figure 57.9a***).

Management

Most adrenal bleeds are successfully managed conservatively. Anticoagulation therapy should be stopped temporarily. Rarely, interventional radiology may be necessary to staunch the bleed (***Figure 57.9b***). In cases of bilateral haemorrhage, the possibility of adrenal insufficiency should be considered.

DISORDERS OF THE ADRENAL MEDULLA AND DIFFUSE NEUROENDOCRINE SYSTEM

Phaeochromocytoma and paraganglioma

Definition

Tumours that arise from the neuroectodermal tissue of the adrenal medulla are termed phaeochromocytomas (PCCs) and those arising from the extra-adrenal parasympathetic and sympathetic ganglia are termed paragangliomas (PGLs). PCCs and PGLs are collectively abbreviated to PPGL.

PGLs are either parasympathetic or sympathetic. Parasympathetic PGLs are sited mainly in the head and neck (HNPGLs) and 95% do not secrete catecholamines or other hormones. The common types of HNPGL are carotid body, vagal and jugulotympanic. Sympathetic PGLs usually secrete catecholamines.

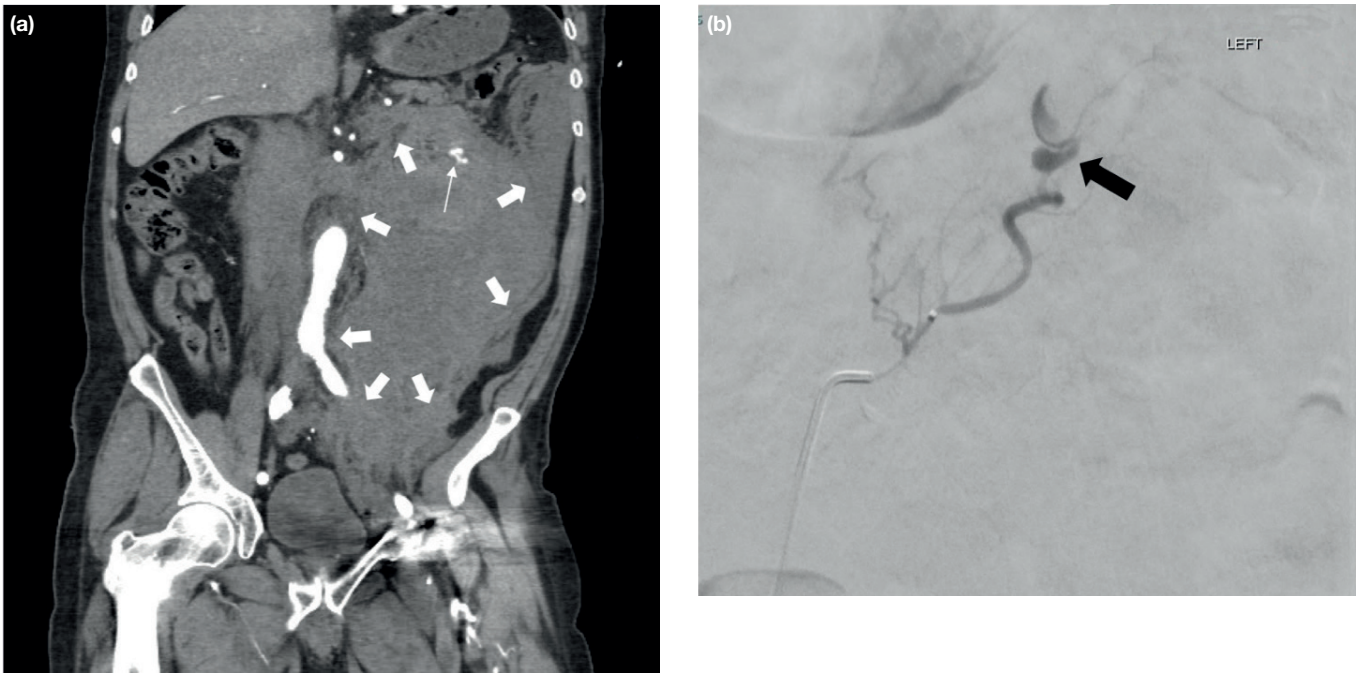

Figure 57.9 (a) Massive left retroperitoneal haematoma (edges outlined by wide white arrows) secondary to left adrenal haemorrhage (contrast extravasation marked by thin white arrow). **(b)** Selective catheterisation of the left middle adrenal artery demonstrating extravasation (seen in **(a)**). The bleeding was arrested with injection of gel foam and coils.

Incidence

The incidence of PCC is about 0.6 in 100 000 and 75% are thought to be sporadic. The incidence of sporadic PGL is not known, but is less common than PCC, and the association with hereditary conditions is more common. Overall, about 70% of PPGLs are sporadic and the rest occur as part of inherited endocrine tumour syndromes, which include:

- hereditary PPGL syndromes
- MEN 2
- von Hippel–Lindau disease (VHL)
- neurofibromatosis type 1 (NF1)

Hereditary PPGL syndromes

These are associated with germline mutations in genes, including succinate dehydrogenase (SDH) subunits, Myc-associated protein X (MAX) and transmembrane protein 127 (TMEM127) (***Table 57.2***). Loss-of-function mutations in SDH lead to accumulation of Krebs cycle precursors, which act as oncometabolites. Loss-of-function TMEM127 and MAX mutations result in PPGL development through cell death escape and enhanced survival. *SDHB* gene variants account for the majority of secreting PGLs whereas *SDHD* mutations account for the majority of non-secreting HNPGLs. Affected individuals are regularly surveilled with annual blood tests and 3-yearly MRI (neck and or abdomen).

von Hippel–Lindau disease

An autosomal dominant disease characterised by central nervous system and retinal haemangiomas (60–80%), renal cysts (50–70%), clear cell renal cell carcinoma (30%), pancreatic neuroendocrine tumours (P-NETs) (8–17%), PPGL (20%), endolymphatic sac tumours (6–15%) and epididymal/broad ligament cyst adenoma (50%). VHL is defined by its genotype as type I (deletions) without PPGL and type II (missense mutations), which is associated with PPGL. Patients develop PCC much more frequently than PGL. VHL tumours overproduce only noradrenaline.

Neurofibromatosis type 1

This is a syndrome characterised by the development of café-au-lait spots (100%), axillary freckling (90%), neurofibromas (84%), Lisch nodules of the iris (70%), typical osseous lesions (14%) and optic glioma (4%). PPGL (PCC 96%) are found in 7% of affected patients. *NF-1* is a tumour-suppressor gene and loss-of-function mutations lead to cell proliferation and cancer development.

Pathology

PCCs are greyish-pink on the cut surface and are usually highly vascularised. Areas of haemorrhage or necrosis are often observed. Microscopically, tumour cells are polygonal but the configuration varies considerably. Approximately 10% of

TABLE 57.2 Hereditary PPGL syndromes.

Gene	Distinguishing clinical features				
	PGL versus PCC	Bilateral PCC or multiple PGL	Biochemical phenotype	Malignancy risk	Mode of inheritance
MAX	PCC	• 60% bilateral	Mixed	25%	Possibly paternal
SDHA	PGL, PCC	Single	Mixed	Low	AD
SDHAF2	HNPGL	• 90% multiple	Unclear	Low	Paternal[a]
SDHB	PGL	• 20% multiple	Noradrenaline/ normetanephrine	34–97%	AD
SDHC	PGL	• 20% multiple	Noradrenaline/ normetanephrine	Low	AD
SDHD	HNPGL and PGL	• 50% multiple	Noradrenaline/ normetanephrine, often silent	<5%	Paternal[a]

AD, autosomal dominant; HNPGL, head and neck paraganglioma; PCC, phaeochromocytoma; PGL, paraganglioma; PPGL, collective term for PCCs and PGLs.
[a]Only mutations inherited from the father will result in the development of tumours.

PCCs are malignant. The differentiation between malignant and benign tumours is difficult, except when metastases are present. An increased PASS (phaeochromocytoma of the adrenal gland scale score), a high number of Ki-67-positive cells, vascular invasion or a breached capsule all lean more towards malignant rather than benign.

PCCs may also produce calcitonin, ACTH, vasoactive intestinal polypeptide (VIP) and parathyroid hormone-related protein (PTHrP). In patients with MEN 2, the onset of PCC is preceded by adrenomedullary hyperplasia, sometimes bilateral. PCC is rarely malignant in MEN 2 (3–5%) but often malignant with *SDHB* mutations (50%).

Clinical presentation

Functioning PPGLs typically present with symptoms and signs of catecholamine excess, and these are typically intermittent (***Table 57.3***). In total, 90% of patients with the combination of headache, palpitations and sweating in the presence of an adrenal tumour have a PCC. Paroxysms may be precipitated by physical training, induction of general anaesthesia and numerous drugs and agents (contrast medium, tricyclic antidepressant drugs, metoclopramide and opiates). Hypertension may occur continuously, be intermittent or absent.

HNPGLs present with the side effects arising from their local mass effect (e.g. neck mass, dysphonia or tinnitus).

TABLE 57.3 Range and incidence of symptoms from PPGL.

Symptoms	Prevalence (%)
Hypertension	80–90
Paroxysmal	50–60
Continuous	30
Headache	60–90
Sweating	50–70
Palpitation	50–70
Pallor	40–45
Weight loss	20–40
Hyperglycaemia	40
Nausea	20–40
Psychological effects	20–40

PPGL, collective term for phaeochromocytomas and paragangliomas.

Diagnosis

Biochemical

The diagnosis of PPGL is confirmed by elevated catecholamine metabolites (metanephrines) in plasma and/or raised 24-hour urinary excretion of fractionated metanephrines. Metanephrines are produced as a result of intratumour conversion of catecholamines by the enzyme catecholamine-*O*-methyltransferase. Measurement of plasma and urinary metanephrines is more sensitive (99% and 97%, respectively) than plasma and urinary catecholamine measurement (86% and 84%, respectively). Measurements of one or more of these substances that are four times greater than the upper limit of the reference range are 100% diagnostic. Plasma dopamine can be regarded as a marker of tumour burden in malignant PPGL.

Radiological

Once a biochemical diagnosis is established, imaging by CT or MRI is undertaken to determine tumour location and assess its size and risk of malignancy. Size is not a predictor of malignancy for PCC. Malignant PPGLs are diagnosed by the presence of local invasion or metastatic disease. Tumours appear vascular and frequently possess cystic areas or central necrosis (***Figure 57.10***). If initial imaging is negative or reveals extra-adrenal disease, functional investigation with ^{123}I-MIBG (meta-iodobenzylguanidine; 80–90% sensitive) or ^{111}In-octretide scanning (50–70% sensitive) is undertaken

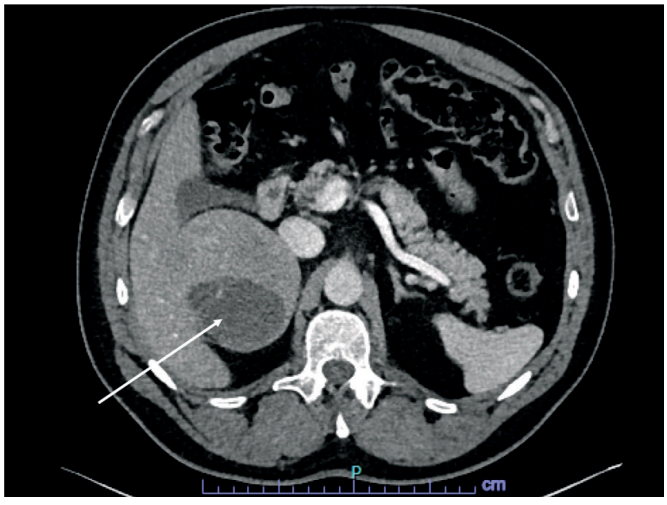

Figure 57.10 A cross-section computed tomography scan of a large phaeochromocytoma showing characteristic central necrosis (arrow).

(*Figure 57.11*). Routine use is not advocated in well-localised adrenal lesions. More recently, 6-[^{18}F]fluorodopamine PET scanning has shown promise, particularly in the setting of PGLs, where conventional imaging and MIBG scanning are negative.

Medical management

Biochemical diagnosis and localisation of PPGLs should be followed by medical preparation to control blood pressure and prompt surgical excision.

Preoperative control of blood pressure

Once a PCC has been diagnosed, an α-adrenoceptor blocker (phenoxybenzamine) is used to block the effects of catecholamine excess and its consequences during surgery. With adequate medical pretreatment, the perioperative mortality rate has decreased from 20–45% to less than 3%. A dose of 20 mg of phenoxybenzamine initially should be increased daily by 10 mg until a daily dose of 100–160 mg is achieved and the

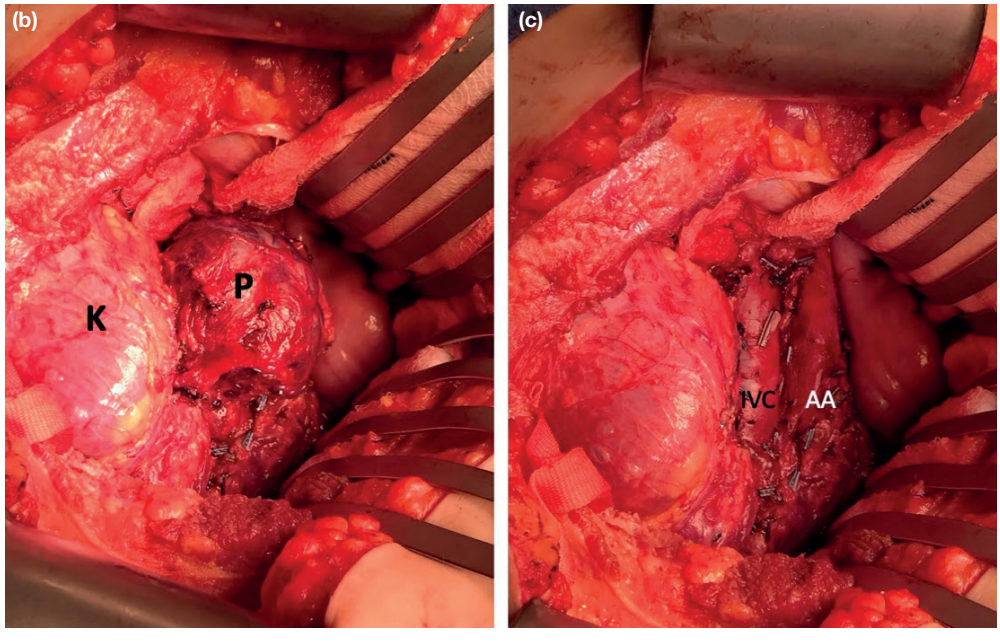

Figure 57.11 (a) A cross-section computed tomography scan showing a paraganglioma anterior to the abdominal aorta (white arrow) and an ^{111}In-octretide scan demonstrating uptake by the tumour (black arrow). Operative photographs before **(b)** and after **(c)** extraction of the tumour. AA, abdominal aorta; IVC, inferior vena cava; K, right kidney; P, paraganglioma.

patient reports symptomatic postural hypotension. Additional β-blockade is required if tachycardia or arrhythmias develop; this should not be introduced until the patient is α-blocked. Other regimens have been described, e.g. α-blockade with doxazosin or prazosin, with and without β-blockade, using calcium channel blockers alone and using the catecholamine synthesis blocker metyrosine in the setting of cardiac failure. However, familiarity and experience with a particular pharmacological regime are probably more important than the regime itself. At this point surgery is safe to proceed.

With adequate α-blockade preoperatively, anaesthesia should not be more hazardous than in patients with a non-functioning adrenal tumour; however, in some patients, dramatic changes in heart rate and blood pressure may occur and require sudden administration of pressor or vasodilator agents. A central venous catheter and invasive arterial monitoring are used. Special attention is required when the adrenal vein is ligated as a sudden drop in blood pressure may occur. The infusion of large volumes of fluid or administration of noradrenaline can be necessary to correct postoperative hypotension in the presence of unopposed α-blockade.

Postoperative care

Patients should be observed for 24 hours as hypovolaemia and hypoglycaemia may occur. Lifelong yearly biochemical tests should be performed to identify recurrent, metastatic or metachronous PCC.

Surgical treatment

PPGLs are excised by either laparoscopic or open surgery.

Adrenalectomy for phaeochromocytoma

Laparoscopic resection is now routine in the treatment of PCC. If the tumour is larger than 10 cm or radiological signs of malignancy are detected, an open approach should be considered.

Surgery for paraganglioma

Tumours along the sympathetic chain can be technically challenging owing to their posterior relationship to the great vessels and visceral arterial branches, which may hide smaller lesions. Furthermore, hereditary PGLs are associated with increased risk of local recurrence. For this reason, minimally invasive surgery may not be feasible; open surgery is the preferred option.

Special circumstances

Malignant phaeochromocytoma. Surgical excision is the only chance for cure. If there is direct invasion, laparotomy and *en bloc* excision of involved adjacent organs offers the best chance of cure. In the presence of metastases, excision of the primary tumour is still recommended to improve symptom control and improve the efficacy of adjuvant radiolabelled MIBG and octreotide therapy. The natural history is highly variable with a 5-year survival rate of less than 50%.

Phaeochromocytoma in pregnancy. PCC in pregnancy may be silent and present as a hypertensive emergency or it may mimic an amnion infection syndrome or pre-eclampsia. Without adequate α-blockade, mother and unborn child are threatened by a hypertensive crisis during delivery. In the first and second trimesters the mother should be scheduled for laparoscopic adrenalectomy after adequate α-blockade; the risk of a miscarriage during surgery is high. In the third trimester, elective caesarean with delayed consecutive adrenalectomy 6 weeks later should be performed. The maternal mortality rate is 50% when a PCC remains undiagnosed.

Neuroblastoma

Definition

Neuroblastoma (NB) is the most common and deadliest solid extracranial malignancy in children. It is derived from the primitive nerve cells (neuroblasts) of the sympathetic nervous system, derived from the neural crest. It is often termed the 'clinical enigma' as the prognosis ranges from spontaneous regression to treatment resistance, metastasis and death.

Incidence

NB accounts for 7% of all childhood cancers, with an incidence of 10 per million children under the age of 15 years.

Pathology

The tumour arises from neuroblasts populating the adrenal medulla and sympathetic ganglia in other sites. Forty per cent of NBs are adrenal in origin. The histopathological diagnosis is established from immunohistochemistry (neurofilaments, synaptophysin and neurone-specific enolase). Biopsy tissue is also analysed for genetic alterations. Genomic amplification of *MYCN* is reported in 25% of tumours and is the strongest predictor of poor prognosis. There are many other chromosome arm-level alterations, notably deletion of 1p and 11q and gain of 17q. There is current interest in the analysis of circulating analytes (so-called 'liquid biopsy'), which is less invasive and can be repeated over the therapeutic course.

Clinical presentation

Most (40%) present under the age of 1 year, 35% between ages 1 and 2 years and 25% older than 2 years. Many present with signs and symptoms related to tumour growth or they may be incidental ultrasonographic findings. Presenting symptoms include malaise and/or pain or obstruction of veins or lymphatics or hydronephrosis. Acute or subacute paraplegia can develop from spinal cord or nerve root involvement. Many children (70%) have metastases at the time of presentation. Rarely the tumour secretes VIP, which results in diarrhoea, dehydration and hypokalaemia.

Diagnosis

NBs may secrete catecholamines, leading to elevated 24-hour urinary metanephrines. Serum lactate dehydrogenase is a useful tumour marker. An unequivocal diagnosis is from histology of either the tumour or bone marrow aspirate. Imaging is undertaken to stage the disease using CT or MRI and MIBG (***Figure 57.12***). In children with regional or metastatic disease, biopsy is necessary for diagnosis and prognostication.

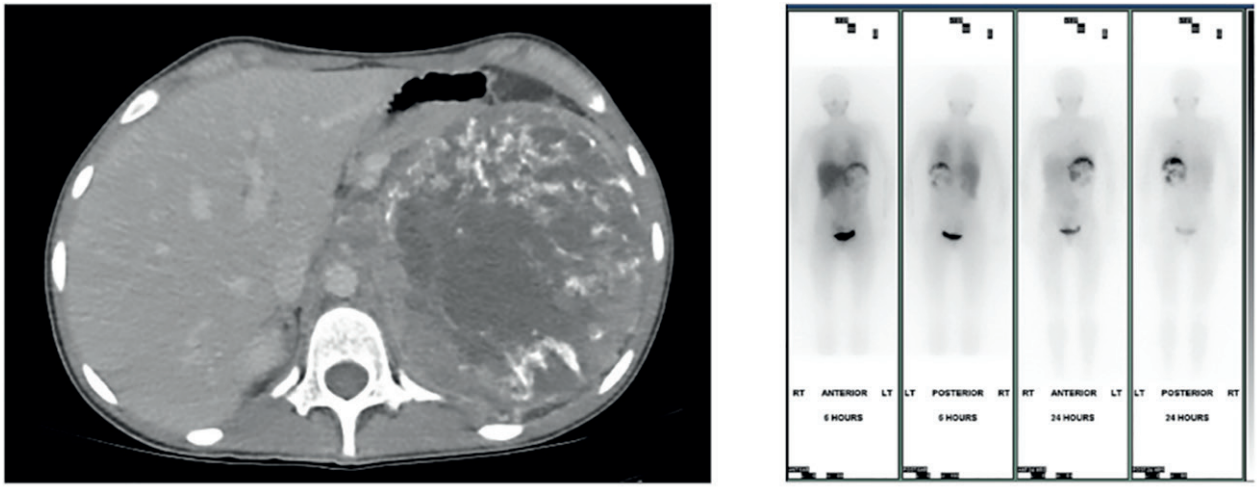

Figure 57.12 Huge left-sided neuroblastoma with central necrosis on computed tomography scan and MIBG (meta-iodobenzylguanidine) scan.

Treatment

Prognosis can be predicted by the tumour stage and the age at diagnosis. Patients are classified as low, intermediate or high risk. Low-risk patients are treated by surgery alone whereas intermediate-risk patients are treated by surgery with adjuvant multiagent chemotherapy. For those patients with localised disease, surgical resection is curative. Postchemotherapy surgery may be performed for complete resection. Patients assigned to the low-risk, intermediate-risk and high-risk groups have overall 3-year survival rates of 90%, 70–90% and 30%, respectively.

Ganglioneuroma

Definition

Ganglioneuromas (GNs) are benign differentiated tumours of neural crest-derived cells in the autonomic nerves.

Incidence

GNs are rare, affecting one per million of the population. Most are sporadic but they can be associated with neurofibromatosis type II and MEN 2B.

Pathology

GNs are benign and are most often located in the mediastinum (20%), retroperitoneum (10%) and adrenal gland (30%). However, GNs can arise anywhere sympathetic nervous tissue is found, such as tongue, bladder, uterus, bone and skin. They are composed of an admixture of ganglion cells and Schwannian stroma/cells.

Clinical presentation

GNs develop in childhood but typically present later as they are non-secreting and slow growing. Two-thirds of patients are under the age of 20 years. They are usually asymptomatic and are identified incidentally. When large, GNs may cause local pressure symptoms such as abdominal pain or bloating. Occasional reports of elevated metanephrines exist and the differential diagnosis is PCC.

Diagnosis

Once a mass is discovered CT and MRI are usually performed to characterise the lesion. They are well defined with a capsule and calcification may be present. GN has a low T1- and a high T2-weighted signal on MRI. Radiology cannot definitively diagnose a GN; histology is required and so preoperative diagnosis can be challenging.

Treatment

Excision is the treatment of choice. A laparoscopic approach is preferred. The prognosis is excellent as recurrences are rare.

SURGERY OF THE ADRENAL GLANDS

Since its description in the 1990s by Gagner, laparoscopic adrenalectomy has become the gold standard in the resection of adrenal tumours, except for tumours with signs of malignancy. Since then, the retroperitoneoscopic modification of the posterior open approach described by Walz has gained popularity. The transperitoneal laparoscopic approach offers a better view of the adrenal region than open surgery and, because the anatomy is more familiar, it is more commonly employed. However, the retroperitoneoscopic approach requires less dissection because it is extraperitoneal; it is most advantageous in patients with small and/or bilateral tumours, e.g. inherited disease. For adrenal surgery as a whole, the mortality rate is less than 0.5% but is higher in the setting of malignant adrenal tumours. The open anterior approach should be undertaken if there are radiological signs of invasion, limited metastases,

Theodore Schwann, 1810–1882, Professor of Anatomy, Leuven, Belgium.
Michel Gagner, b. 1960, Professor of Surgery, Montreal, Canada.
Martin K Walz, contemporary, Professor of Surgery, Essen, Germany.

large tumours (>8–10 cm) or a distinct hormonal pattern to suggest malignancy. To avoid steroid dependence, subtotal adrenalectomy is an option in patients with bilateral tumours provided they are small (<3 cm). It is important to emphasise that these excellent outcomes depend on an experienced surgical team and close liaison with endocrinology colleagues to ensure that any hormonal excess is identified preoperatively, controlled to render surgery safe then supplemented if needed in the postoperative period.

Minimally invasive adrenalectomy

Transperitoneal laparoscopic adrenalectomy

Familiarity with the anatomy of the adrenal region is essential and it should be noted that the approaches for the right and left sides are distinct. Careful haemostasis is essential as small amounts of blood impair the view; direct grasping of the adrenal tissue/tumour should be avoided to reduce the risk of capsular rupture.

Right transperitoneal laparoscopic adrenalectomy

The patient is positioned right side up, with table break. Four ports are used. The liver is retracted cranially and the peritoneal fold between the liver and the tumour is divided from the lateral border of the IVC to the right triangular ligament with the preferred energy device. The peritoneum is then opened caudally along the lateral border of the IVC to the upper renal pole. This allows the tumour to be retracted laterally; the space between it and the IVC is developed, in the process exposing the short right adrenal vein. At this point the posterior abdominal wall (quadratus lumborum) is visible. The vein is clipped and divided and the inferior and lateral attachments are divided and the tumour is removed in a tissue retrieval bag.

Left transperitoneal laparoscopic adrenalectomy

The patient is positioned left side up, with table break. Three ports are used. In the initial phase, the aim is to perform a limited medial visceral rotation of the splenic flexure of the colon, spleen and pancreatic tail. This is achieved by dividing the lateral peritoneal attachments of the colon and the anterior layer of the lienorenal ligament cranially, a distance of 1 cm from the spleen, until the gastric fundus is visible. Further dissection and gravity allow the spleen and pancreatic tail to 'fall' medially to expose the kidney/perinephric fat, covered in Gerota's fascia. The fascia is opened to allow identification of the adrenal vein as it drains into the left renal vein. Once the vein has been clipped and divided, the tumour is retracted away from the renal hilum and resection is completed by mobilising the adrenal gland along its superior, inferior and lateral borders. The inferior phrenic tributary of the adrenal vein may be encountered and is dealt with by clipping. The tumour is then placed in a tissue retrieval bag for removal.

Posterior retroperitoneoscopic adrenalectomy

This technique may be favoured when there has been extensive upper abdominal surgery or for reoperative adrenalectomy (being outside the abdominal cavity affords a better view) as well as for bilateral adrenalectomy. It may not be feasible with larger tumours (>5–6 cm) and in the very obese patient (body mass index >40). The patient is placed prone with the hips and knees flexed to abolish the lumbar lordosis. The first port is placed at the distal end of the 12th rib with a combination of scissor and digital dissection into the retroperitoneum. Gerota's fascia is swept off the posterior abdominal wall and space is made for insertion of the medial (10 mm) and lateral (5 mm) ports, which are inserted with finger guidance. A balloon port is then inserted into the initial port and CO_2 insufflated to 20–25 mmHg; a 30° endoscope is used. Gerota's fascia is opened, avoiding a peritoneal rent laterally. Dissection continues through the perirenal fat to the superior renal pole. The tumour is then mobilised along its lateral and medial borders. The medial border of a right-sided tumour is dissected off the IVC to expose the right adrenal vein, which can then be ligated and divided (***Figure 57.13***). On the left side, the adrenal vein is located at the medial inferior pole of the adrenal gland. After venous ligation, the superior attachments are divided to excise the tumour. The inflation pressure is then reduced to check for haemostasis before tumour extraction with a tissue retrieval bag.

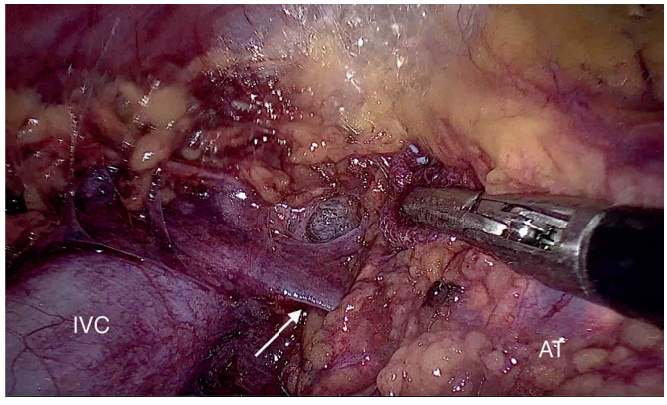

Figure 57.13 View of the right adrenal vein draining (arrow) into the inferior vena cava (IVC) during posterior retroperitoneoscopic adrenalectomy (courtesy of Fausto Palazzo, Hammersmith Hospital, London, UK). AT, adrenal tumour.

Open adrenalectomy

This operation should be performed when a malignant adrenal tumour is suspected, or for very large tumours (>8–10 cm). In the case of adrenocortical cancer, the aim is to remove the tumour in continuity with any invaded adjacent organs *en bloc* and obtain negative resection margins (R0). Consequently, if there is a risk or intention to perform nephrectomy, splenectomy, distal pancreatectomy or limited right hemihepatectomy, the patient should be consented (and, in the case of splenectomy, vaccinated) accordingly. Similarly, a multidisciplinary approach should be employed for tumours that are invading the liver or IVC. Surgical access is via a rooftop incision extending to the appropriate flank, with Mercedes-Benz extension if necessary. On the right, the hepatic flexure of the colon is mobilised, the

The **Mercedes-Benz** sign takes its name from the insignia displayed on the bonnet of a Mercedes-Benz car.

TABLE 57.4 Characteristics of pancreatic neuroendocrine tumours.

Tumour (syndrome)	Incidence (%)	Presentation	Malignancy (%)
Insulinoma	70–80	Weakness, sweating, tremor, tachycardia, anxiety, fatigue, dizziness, disorientation, seizures	<10
Gastrinoma	20–25	Intractable or recurrent peptic ulcer disease (haemorrhage, perforation), complications of peptic ulcer, diarrhoea	60–90
Non-functional tumours	30–50	Obstructive jaundice, pancreatitis, epigastric pain, duodenal obstruction, weight loss, fatigue	60–90
VIPoma	4	Profuse watery diarrhoea, hypotension, abdominal pain	40–70
Glucagonoma	4	Migratory necrolytic skin rash, glossitis, stomatitis, angular cheilitis, diabetes, severe weight loss, diarrhoea	50–80
Somatostatinoma	<5	Cholelithiasis, diarrhoea, neurofibromatosis	>70
Carcinoid	<1	Flushing, sweating, diarrhoea, oedema	60–90
ACTHoma	<1	Cushing's syndrome	>95
GRFoma	<1	Acromegaly	Unknown

ACTH, adrenocorticotropic hormone; GRH, growth hormone-releasing factor; VIP, vasoactive intestinal polypeptide.

duodenum Kocherised and, if the tumour extends cranially, the right liver lobe is mobilised to achieve optimal exposure of the IVC and tumour. Dissection is from lateral to medial and then along the lateral border of the IVC, inferior to and including the kidney if that is involved. On the left side the adrenal gland can be exposed after mobilisation of the splenic flexure of the colon. If invasion of the pancreas is suspected, distal pancreatectomy is performed with or without splenectomy. If not, they are medially rotated as for the transperitoneal laparoscopic operation. The retroperitoneum is then dissected lateral to medial, including the kidney if necessary, and then along the lateral border of the left crura and cranially towards the diaphragm. If pancreatectomy is performed, a drain should be left to manage a potential pancreatic fistula.

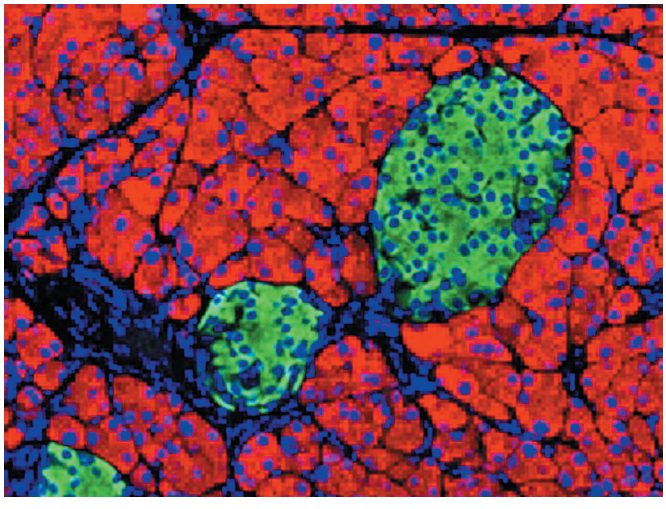

Figure 57.14 Immunofluorescent labelling of endocrine (insulin [green]) and exocrine (amylase [red]) pancreatic cells and the nuclear marker DAPI (4′,6-diamidino-2-phenylindole; blue) (courtesy of Dr Esni, Department of Surgery, University of Pittsburgh, USA).

PANCREATIC NEUROENDOCRINE TUMOURS

Introduction

As with neuroendocrine cells in the intestine, pancreatic neuroendocrine cells are believed to be derived from pluripotent stem cells that differentiate into endocrine cells. From these, tumours may arise that are known as P-NETs. They are a heterogeneous group of tumours with diverse morphologies and behaviour. Non-functioning tumours constitute a substantial proportion of all P-NETs (25–100%). The subtypes of P-NET are listed in ***Table 57.4***. This section focuses on insulinoma, gastrinoma and non-functioning tumours because they represent 90% of all P-NETs.

Physiology of the endocrine pancreas

The endocrine cells of the pancreas are grouped in the islets of Langerhans, which constitute approximately 1–2% of the mass of the pancreas (***Figure 57.14***). There are about 1 million islets in a healthy adult human pancreas and their combined weight is 1–1.5 g. There are four main types of cell in the islets of Langerhans, which can be classified according to their secretions:

1. β cells producing insulin (65–80% of the islet cells);
2. α cells producing glucagon (15–20%);
3. δ cells producing somatostatin (3–10%);
4. pancreatic polypeptide (PP) cells containing polypeptide (1%).

Theodor Kocher, 1841–1917, Professor of Surgery, Berne, Switzerland, awarded the Nobel Prize in Physiology or Medicine in 1909.
Paul Langerhans, 1847–1888, Professor of Pathological Anatomy, Freiberg, Germany.

Insulinoma

Definition

This is an insulin-producing tumour of the pancreas.

Incidence

These are rare tumours with an incidence of four (1–32) per million. Insulinomas have been diagnosed in all age groups, with the highest incidence found in the fourth to the sixth decades. Women seem to be slightly more frequently affected.

Pathology (including prognosis)

The aetiology of insulinomas is unknown. They are equally scattered throughout the pancreas. Tumours are graded according to World Health Organization (WHO) NET criteria (*Table 57.5*). Tumours <2 cm in diameter without signs of invasion are considered benign. More than 90% are both benign and solitary. Approximately 10% are associated with MEN 1.

TABLE 57.5 World Health Organization neuroendocrine tumour (NET) classification of tumour grades.

Grade	Mitoses/10 HPFs	Ki-67 index
Grade 1 NET	<2	<3
Grade 2 NET	2–20	3–20
Grade 3 NET (well differentiated with high proliferative index)	>20	>20
NEC (poorly differentiated NEC)	>20	>20

HPF, high-power field; NEC, neuroendocrine carcinoma.

Clinical presentation

Patients typically develop sporadic symptoms of neuroglycopenia. Classically these manifest while fasting or during exercise, but some (18%) may develop symptoms postprandially and these may be the only symptoms. Some patients develop loss of consciousness and coma. The release of catecholamines produces symptoms such as sweating, weakness, hunger, tremor, nausea, anxiety and palpitations. The diagnosis can be elusive owing to its rarity and it is not uncommon for patients to have been investigated for epilepsy (fitting, loss of consciousness) or drug abuse (altered mental state) before the correct diagnosis is established. It is typical that patients will have put on weight prior to presentation (learning to eat to survive).

Diagnosis (with differential)

The cornerstone of diagnosis remains Whipple's triad:

- symptoms induced by fasting;
- hypoglycaemia at the time of symptoms;
- symptoms relieved by administration of glucose.

The key test is a 72-hour fast looking for documented endogenous hyperinsulinism in association with symptoms and signs of low plasma glucose (<3.0 mmol/L), elevated insulin and high C-peptide. If the test is negative and the suspicion of insulinoma is high, a prolonged oral glucose tolerance test is done.

Differential diagnoses include postprandial syndrome after gastrointestinal surgery, dumping syndrome, factitious hypoglycaemia, ethanol ingestion and pancreatic transplantation. Nesidioblastosis is a rare disorder, mainly encountered in children, that is characterised by replacement of normal pancreatic islets by diffuse hyperplasia of islet cells.

After a positive fast test, a CT or MRI is performed. In only a small percentage (<5–10%) insulinomas are elusive on cross-sectional imaging. In such a situation endoscopic ultrasonography (EUS) is undertaken with a positive detection rate in excess of 90%. Visceral angiography with arterial stimulation venous sampling is reserved for negative EUS studies or when more than one lesion has been identified. Another promising method is scintigraphy with radiolabelled glucagon-like peptide 1, which is often overexpressed by insulinomas. However, this is not universally available. MEN 1 should be considered in younger patients and those with multiple lesions. Chromogranin A is not a useful test for this tumour.

Treatment (medical and surgical)

Patients require treatment because of their symptoms.

Surgery

Most insulinomas are small, sporadic and solitary. In most cases enucleation is possible. Contraindications to enucleation are close proximity to the main pancreatic duct and larger tumours. In most cases a laparoscopic approach is recommended for localised tumours and this achieves a high success rate (98–100%). Postoperatively, blood sugar levels begin to rise in most patients within the first few hours after removal of the tumour. To preserve pancreatic function and reduce the risk of iatrogenic diabetes mellitus, patients in whom tumour localisation is not successful at operation should not undergo blind resection.

For patients with MEN 1, tumours may be multifocal. The classical approach was to enucleate tumours in the 'right' pancreas (dictated by the portal vein) and perform a distal pancreatectomy owing to the high number of non-functioning NETs associated with the mutation. Laparoscopic enucleation of localised tumours has become the procedure of choice.

Medical

All patients undergoing surgery should be treated with diazoxide, which suppresses insulin secretion by direct action on the β cells, and receive frequent small meals to avoid hypoglycaemia. Somatostatin analogue (SSA) therapy may also be useful.

For patients with unresectable or metastatic disease, SSAs and everolimus are effective in controlling hypoglycaemia. Other options include chemotherapy, peptide receptor radionuclide therapy (PRRT) and chemoembolisation.

George Hoyt Whipple, 1878–1976, Professor of Pathology, University of Rochester, Rochester, NY, USA, described this disease in 1907. He shared the 1934 Nobel Prize in Physiology or Medicine with George Richards Minot and William Parry Murphy 'for their discoveries concerning liver therapy against anaemias'.

Gastrinoma

Definition

Zollinger–Ellison syndrome (ZES) is a condition that includes: (i) fulminating ulcer diathesis in the stomach, duodenum or atypical sites; (ii) recurrent ulceration despite 'adequate' therapy; and (iii) non-β islet cell tumours of the pancreas (gastrinoma).

Incidence

This is a rare disease affecting between 0.5 and 4 in a million. Approximately 0.1% of patients with duodenal ulcers have evidence of ZES. Up to 20–25% of ZES is associated with MEN.

Pathology

In sporadic disease the tumours are mostly located in the duodenum (60–80%) and are small (<5 mm) and multiple. In MEN 1, all tumours are in the duodenum. The vast majority (approximately 90%) occur within the 'gastrinoma triangle', an area bounded by the junction of the neck and body of the pancreas medially, the junction of the second and third parts of the duodenum inferiorly and the junction of the cystic and common bile ducts superiorly (***Figure 57.15***). Tumours are graded according to WHO NET criteria (***Table 57.5***). In general, the progression of gastrinomas is relatively slow with a 5-year survival rate of 65% and a 10-year survival rate of 51%. Patients with complete tumour resection have excellent 5- and 10-year survival rates (90–100%). Patients with pancreatic tumours have a worse prognosis than those with primary tumours in the duodenum. There is no established marker to predict the biological behaviour of gastrinoma.

Clinical presentation

Over 90% of patients with gastrinomas have peptic ulcer disease, often multiple or in unusual sites. Diarrhoea is another common symptom, caused by the large volume of gastric acid secretion. Abdominal pain from either peptic ulcer disease or gastro-oesophageal reflux disease remains the most common symptom, occurring in more than 75% of patients. Around 60–95% have a history of high alcohol use, which may be a risk factor. The majority of tumours have metastasised by the time of presentation.

Diagnosis (with differential)

The cornerstone of diagnosing ZES is an elevated fasting serum gastrin (FSG). If elevated, the gastric pH is measured. If the pH is <2 and the FSG is more than 10-fold elevated, the diagnosis is confirmed. If the FSG is less than 10-fold higher, a secretin provocation test should be performed. The diagnosis is becoming more difficult because of unreliability of some commercial gastrin assays and the widespread use of proton pump inhibitors (PPIs), which not only increases the pH of the stomach but also leads to inappropriate elevation of FSG in the presence of hypergastrinaemia when gastric acid secretion is present.

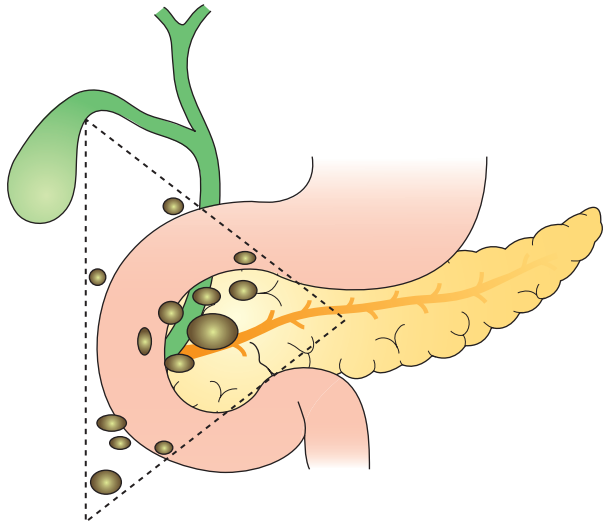

Figure 57.15 The gastrinoma triangle.

Hypergastrinaemia is seen in atrophic gastritis, PPI therapy and *Helicobacter pylori* infections and so all conditions feature in the differential diagnosis. Once a diagnosis is confirmed all patients are screened for MEN 1 (biochemical and genetic).

Localisation studies are then indicated as the tumours are often small and multiple. The majority of gastrinomas have a high density of somatotropin receptors. ^{68}Ga-labelled SSAs with PET-CT have been found to be sensitive and specific. If not available, somatostatin scintigraphy (SRS) and EUS should be done. Chromogranin A is an unreliable test for gastrinoma.

Treatment

Surgery

All patients with sporadic gastrinoma without metastases should have a surgical operation by an experienced surgeon. At the time, the peritumoral lymph nodes should be sampled for histological assessment.

In MEN 1/gastrinoma, surgery is not recommended for patients with tumours <2 cm. Tumours >2 cm are enucleated. Parathyroidectomy reduces gastric acid secretion.

Medical

PPI therapy is the management of choice. Even when patients undergo a surgical cure, most (60%) require continued medical treatment. For patients with advanced locoregional disease or metastases, PPI remains the first-line treatment supplemented with SSA therapy. In refractory cases, locoregional ablative therapy (radiofrequency ablation or chemoembolisation) or PRRT may be effective.

Robert Milton Zollinger, 1903–1992, Professor of Surgery, The Ohio State University, Columbus, OH, USA.
Edwin Homer Ellison, 1918–1970, Professor of Surgery, Marquette University, Milwaukee, WI, USA. Zollinger and Ellison described this condition in a joint paper in 1957 when they were both working at The Ohio State University.

Non-functioning pancreatic neuroendocrine tumours

Definition

P-NETs are clinically classified as non-functioning (NF-P-NET) when they do not cause a clinical syndrome.

Incidence

NF-P-NETs account for 60–90% of all P-NETS.

Pathology

NF-P-NETs cannot be distinguished from functional tumours by immunocytochemistry because they may also express hormones such as gastrin and insulin. They usually stain positively for chromogranin A and synaptophysin. The tumours are usually large (>5 cm) and unifocal except in MEN 1 syndrome. They are distributed throughout the pancreas with a head to body to tail ratio of 7:1:1.5.

Clinical presentation

They are generally diagnosed at a more advanced stage owing to their indolent nature, slow growth and lack of functional secretion causing a delay in the onset of symptoms. Therefore, in contrast to functioning PETs, patients with NF-PETs present with various non-specific symptoms, including jaundice, abdominal pain, weight loss and pancreatitis. In some cases liver metastases are the first presentation.

Diagnosis

Increased levels of chromogranin A and PP are usual. The majority of these tumours are large and are easily identified by transabdominal ultrasonography or CT scanning. Differentiation from the more aggressive pancreatic adenocarcinoma is extremely important (see ***Chapter 72***). Recognition of NF-P-NETs is imperative because of their resectability and excellent long-term survival compared with their exocrine counterparts.

Treatment (medical and surgical)

For grade 1 and 2 unresectable tumours, SSAs may be effective because of their antiproliferative properties. Alternatively novel targeted drugs (everolimus and sunitinib) could be considered. Platinum-based chemotherapy is the treatment of choice for grade 3 and NEC tumours. The algorithm for the management is summarised in ***Figure 57.16***.

NEUROENDOCRINE TUMOURS OF THE STOMACH AND SMALL INTESTINE

Embryology and physiology

The embryology of the intestine is developed from the foregut, midgut and hindgut. The bronchus and lungs are also developed from the foregut. Throughout these tissues are APUD neuroendocrine cells. In the stomach they were described by Kulchitsky and are recognised as neuromodulating cells with serotonin (5-hydroxytryptamine [5-HT]) as their main neurotransmitter. These cells play a crucial role in intestinal motility and secretion. Within the gastric pits are enterochromaffin-like (ECL) cells that secrete histamine. Together with gastrin, these cells are critical in the regulation of gastric acid secretion. All cells of the system secrete different neuroendocrine markers, such as synaptophysin, chromogranin A and neurone-specific enolase, and produce peptide hormones that are stored in granules, e.g. serotonin, somatostatin, PP (pancreatic polypeptide) or gastrin. In clinical practice chromogranin A is utilised as a tumour marker. The main functional test for NETs of the jejunum and ileum (the NETs that are most often encountered) is measurement of the serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) in urine.

Gastrointestinal neuroendocrine tumours (GI-NETs) were formerly divided into foregut (stomach, duodenum and pancreas), midgut (small intestine, appendix and caecum) and hindgut carcinoids (large bowel except caecum and rectum). Nowadays, the definition of NET does not consider the organ of origin; instead, a common definition is used that is based on the tissue of origin and histological factors such as the Ki-67 index or mitotic index and size according to the WHO criteria (*Table 57.5*).

Pathogenesis

Historically, tumours arising from the neuroendocrine cells were referred to as 'karzinoide' (carcinoma-like) tumours by Oberndorfer. Now they are termed neuroendocrine tumours (NETs). NETs can be either benign or malignant.

In the gastrointestinal tract, especially the small intestine, they secrete excess 5-HT, which is rapidly metabolised by the liver. In the presence of liver metastases, NET metastases secrete 5-HT into the IVC, avoiding hepatic first-pass metabolism and leading to symptoms of 5-HT excess, known as **carcinoid syndrome**. The cardinal features are sweating, flushing, bronchospasm and restrictive cardiomyopathy secondary to fibrotic right heart valvular disease (Hedinger syndrome).

The overall incidence of GI-NETs is 2.5–5.0 per 100 000 people per year, with a much higher prevalence of 35 per 100 000. Their relative distribution in the gastrointestinal tract is shown in *Table 57.6*.

TABLE 57.6 Relative distribution of neuroendocrine tumours in different organs.

Site	Distribution (%)
Lung	10
Stomach	5
Duodenum	2
Small bowel	25
Appendix	40
Colon	6
Rectum	15

Stomach

Incidence

These are rare with an incidence of 0.2 per 100 000 population per year.

Pathology

There are three types:

1. Type I polyps: associated with atrophic gastritis with high pH and gastrin levels.
2. Type II polyps/small tumours (<1 cm): arise secondary to small gastrinoma with low gastric pH and high gastrin levels (ZES).
3. Type III: these are larger tumours (>1–2 cm), associated with low gastrin.

Types I and II are derived from ECL cells. Type III are almost always malignant and are treated like gastric adenocarcinoma, although liver metastases are common at the time of presentation.

Clinical presentation

Type I (70–80%) are usually found at gastroscopy in the investigation of vague dyspeptic symptoms. Type II (5%), ZES (see *Pancreatic neuroendocrine tumours*), presents with multiple and complicated peptic ulcers. Type III (15–25%) typically present with bleeding or discomfort.

Diagnosis

Upper intestinal endoscopy is the gold standard with biopsy of identified lesions. EUS is pivotal in measuring tumour depth. Staging is done with CT, SRS or ^{68}Ga-DOTATOC PET.

Treatment

Medical

Type I is managed with vitamin B12 and type II with PPIs with or without endoscopic resection of all visible tumours. Patients are then subjected to annual endoscopic surveillance.

Surgical

Absolute indications for surgery include:

Nikolai Kulchitsky, 1856–1925, Professor of Histology, Kharkov Imperial University, Ukraine.
Siegfried Oberndorfer, 1876–1944, Professor of Pathology, Munich, Germany.
Christoph Hedinger, 1917–1999, pathologist, Zurich, Germany.

- local excision of type I polyps >10 mm;
- a visualised gastrinoma;
- type III gastric NET.

Duodenum

Incidence

These are exceptionally rare tumours, accounting for 1–3% of all GI-NETs.

Pathology

They are usually small (<20 mm) and submucosal. They can be functional (gastrin, somatostatin) or non-secreting. Gastrinoma is often associated with MEN 1.

Clinical presentation

Gastrinoma presents as per type II gastric NETs or as part of MEN 1. Somatostatinoma is associated with NF-1 and gallstones.

Diagnosis (including staging)

Gastrin will be elevated in gastrinoma and low in other cases. Chromogranin A is often elevated for all NETs. Identification and staging is achieved using a combination of endoscopy, EUS, CT and SRS. Patients must be screened for genetic disease.

Treatment (medical and surgical)

PPI therapy successfully manages gastrinoma. In the presence of MEN 1, parathyroidectomy reduces gastric acidity. Duodenal gastrinomas are often elusive and can be successfully managed with PPIs. However, when localised and in the absence of lymph node metastases, resection is the treatment of choice, either endoscopically or by open surgery (see ***Further reading***).

Small intestine

Incidence

Midgut carcinoids are the most common NETs with a peak age of diagnosis at 60–70 years. They are the second most common small bowel malignancy.

Pathology

They arise from the enterochromaffin cells and secrete serotonin and substance P. They are either solitary or multiple (30%) (***Figure 57.17***) and the primary tumour can be small (5–20 mm). They are often indolent but often discovered at an advanced stage when regional (lymph nodes; 36%) and distant (liver; 48%) disease is present. From the latter, the patient may develop carcinoid syndrome.

Clinical presentation

Chronic abdominal pain is the most frequent initial symptom. The carcinoid syndrome is seen in 20–30% of patients with liver metastases. Small bowel ischaemia producing pain and diarrhoea arises from involved lymph node metastases, which constrict the mesenteric vessels. However, up to 20% of patients are diagnosed during the investigation of liver metastases or they may be incidentally found during surgery for another reason (laparotomy or appendicectomy).

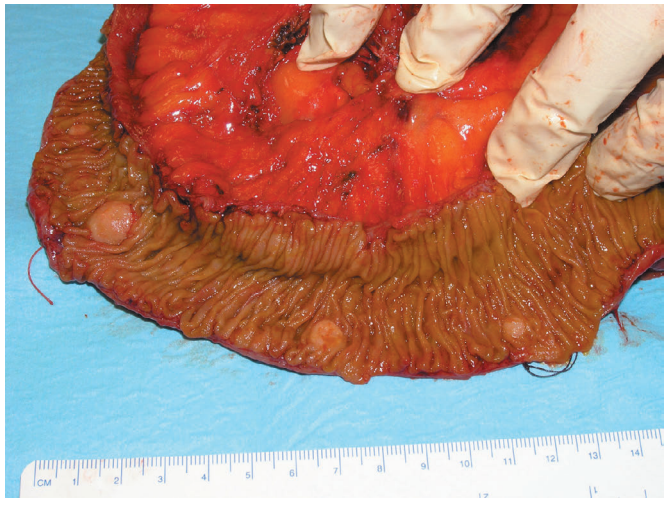

Figure 57.17 Multiple neuroendocrine tumours in the small bowel.

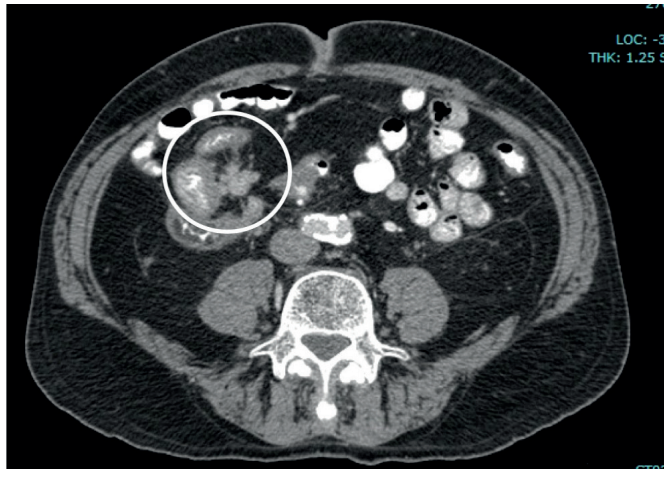

Figure 57.18 Contrast-enhanced (bowel) cross-sectional computed tomography scan with mesenteric lymph node metastasis drawing in the adjacent mesenteric vessels in the desmoplastic reaction (white circle).

Diagnosis

Chromogranin A is often elevated (non-specific) and elevated 24-hour urinary 5-HIAA is specific. Cross-sectional CT or MRI often shows the mesenteric lymph nodes with a characteristic spiralling of vessels trapped in the desmoplastic reaction (***Figure 57.18***) and will demonstrate if liver metastases are present. Biopsy is diagnostic and Ki-67 grading is an important prognostic factor and is mandatory for reporting. This is often via an ultrasound-guided liver biopsy. In the search for a primary tumour, CT and/or MRI is followed by ^{68}Ga-DOTATOC PET, fused with CT.

Patients must be evaluated for the presence of Hedinger syndrome (right heart valve fibrosis). A referral is made to the cardiology department, where transthoracic echocardiography will be carried out.

Summary box 57.3

Stratified treatment of NETs based on stage

Disease status	Localised	Regional	Distant		
Stage	I/II	III (N1)	IV (M1)		
Surgical approach	Radical resection		Radical – curative intent	Palliative resection	No resection
	Resection of • primary • nodes (along mesentery)		Resection of • primary • nodes (along mesentery) • liver metastases	Resection of • primary • nodes (along mesentery) • liver metastases	Due to • irresectable • comorbidities
Aim	R0		R0	To avoid obstructive complications (R1)	

Treatment

ENETS (European Neuroendocrine Tumor Society) has developed an algorithm for the treatment of small intestine NETs (***Summary box 57.3***).

Surgical

Patients without distant metastases (stages I–III) are all potential candidates for curative surgery of the primary tumour and regional nodal metastases. All patients should be discussed in a multidisciplinary team meeting. Surgery is only undertaken if it is thought that an R0 resection can be achieved. The limiting factor is often lymph node involvement around the superior mesenteric artery, especially in the presence of severe desmoplastic reaction. Concomitant cholecystectomy should be considered owing to the risk of gallstone formation secondary to SSAs.

In the presence of stage IV (metastatic disease) surgery is contemplated when the patient has obstructive symptoms (palliative) or if an R0 resection (curative) can be achieved with concomitant liver metastasectomy(ies). In this setting, patients should have peroperative protection with intravenous SSAs to avoid a carcinoid crisis.

When curative intent is not possible, there are a number of locoregional therapies to the liver. Patients are always treated with SSAs to prevent a crisis. Therapeutic options include radiofrequency ablation, embolisation and chemoembolisation. Liver transplantation is only considered in a highly selected population (see also ***Chapters 69 and 74***).

Medical

SSAs are an effective treatment for syndrome control for functional NETs. SSAs may also be used for antiproliferative purposes in stable or progressive disease in tumours up to a Ki-67 index of 10% (grades I and II). Loperamide or other similar agents may be useful in the control of diarrhoea. When SSA treatment fails, a second-line option is PRRT. Currently yttrium- or lutetium-labelled SSAs are most frequently used. For grade III tumours (NEC), cisplatin-based systemic chemotherapy is the treatment of choice.

Appendiceal carcinoid

Incidence

Appendiceal NETs are the commonest neoplasm in the appendix (30–80%). They are diagnosed in 3–5 in 1000 appendicectomies for acute appendicitis.

Pathology

They are classified in the same way as other NETs. Staging is determined by tumour size and involvement of either the subserosa or mesoappendix (T) as well as nodal (N) and distant metastases (M).

Treatment

Tumours <10 mm in size have an excellent prognosis and appendicectomy achieves cure. A right hemicolectomy should be considered in the rare situations of positive or unclear margins or deep mesoappendiceal invasion (>3 mm). An oncological right hemicolectomy should be performed for tumours >20 mm. Low-risk tumours do not require any follow-up (see also ***Chapter 76***).

MULTIPLE ENDOCRINE NEOPLASIA

MEN is a group of heterogeneous disorders characterised by a predisposition of benign and malignant tumours involving two or more endocrine glands. There are four varieties, the most common being MEN 1 and MEN 2.

Multiple endocrine neoplasia type 1

Epidemiology and genetics

MEN 1 is an autosomal dominant inherited disorder. It was originally called Wermer's syndrome. It is rare (1 in 30 000) in the general population but accounts for 10% of primary hyperparathyroidism (PHPT) in patients under 30 years and 30–40% of all cases of gastrinoma. The tumour-suppressor gene *MEN1* encodes for menin, a protein that regulates transcription, cell division and proliferation. The pathophysiology

Paul Wermer, 1898–1975, physician, The Presbyterian Hospital, New York, NY, USA, described this condition in 1954.

consists of a two-hit methodology: a germline mutation followed by a second-hit somatic mutation in the specific tissues. There are many hundreds of germline mutations of *MEN1* on chromosome 11, but there is no genotype/phenotype association.

Clinical presentation

The manifestations of MEN 1 are listed in ***Table 57.7***. Virtually all patients develop PHPT (see ***Chapter 56***). In screening programmes, non-functioning P-NETs are seen in up to 70% of patients. The most common functioning P-NET is gastrinoma, followed by insulinoma. The remainder are extremely rare. Most pituitary tumours are microadenomas and are either non-functioning or secrete prolactin. The latter can be treated medically.

TABLE 57.7 Clinical manifestations of multiple endocrine neoplasia type 1 (MEN 1).

Tumour site	Frequency (%)
PHPT (four-gland disease)	95
Pancreatic islet cell tumours • Gastrinoma • NF-P-NET • Insulinoma • Glucagonoma • VIPoma • Somatostatinoma	30–80
Pituitary tumours • Prolactin (60%) • Growth hormone (25%) • ACTH (5%) • Non-functioning	15–50
Adrenocortical tumours – mainly non-functioning	40–50
NET lung, thymus, stomach	3–10
Lipomas	5–10
MEN 1 is also associated with meningiomas and facial angiofibromas	

ACTH, adrenocorticotropic hormone; NET, neuroendocrine tumour; NF-P-NET, non-functioning pancreatic neuroendocrine tumour; PHPT, primary hyperparathyroidism; VIP, vasoactive intestinal polypeptide.

Surgery

MEN 1 PHPT treatment differs from sporadic disease because it is secondary to four-gland hyperplasia and so the surgical approach is always bilateral neck exploration. Whether to perform subtotal or total parathyroidectomy with autotransplantation is debatable. All patients should receive counselling about the inevitability of recurrent hyperparathyroidism. At the time of cervical surgery, a prophylactic thymectomy is also performed (see also ***Chapter 56***).

Gastrinoma is typically managed medically for tumours <2 cm in diameter. Functioning P-NETs are excised as previously described, but the treatment of NF-P-NET is challenging owing to the widespread distribution of multiple tumours in the pancreas. A balance is sought between tumour resection and the preservation of endocrine function. Functional adrenal tumours in MEN 1 are rare and have to be operated on. Non-functioning tumours should be resected if they reach a size of 4 cm.

Multiple endocrine neoplasia type 2A

Epidemiology and genetics

MEN 2A has a prevalence of 1 in 25 000 people. It is an autosomal dominant condition caused by germline mutations in *RET*, which encodes a transmembrane tyrosine kinase receptor (TKR) that activates pathways involved in proliferation, survival, migration and angiogenesis. Gain-of-function *RET* mutations lead to activation of the TKR and cancer initiation through deregulated proliferation and increased cell survival. The mutation is sited in chromosome 10. There is a strong genotype–phenotype correlation, not seen in MEN 1.

Clinical presentation

The patterns of disease in MEN 2 are shown in ***Table 57.8***. Nearly all patients develop medullary thyroid carcinoma (MTC), which is the determinant of survival in this syndrome. PCCs are more likely to be bilateral, but are rarely malignant. PHPT is usually mild and asymptomatic and may not need surgery. A subtype of MEN 2, known as familial MTC (FMTC), is a variant of MEN 2 in which MTC occurs in isolation. MTC combined with PCC alone is known as Sipple's syndrome.

TABLE 57.8 Genotype–phenotype associations for disorders arising from RET gene mutations.

Syndrome	Frequently affected *RET* gene codons	MTC (%)	PHPT (%)	PCC (%)
MEN 2A	609, 634, 790, 804	90–100	20–30	10–70
FMTC	533, 630, 768, 844	90–100	–	–
MEN 2B	883, 918	100	–	10–60

FMTC, familial medullary thyroid carcinoma; MEN, multiple endocrine neoplasia; MTC, medullary thyroid carcinoma; PCC, phaeochromocytoma; PHPT, primary hyperparathyroidism.

Multiple endocrine neoplasia type 2B

Epidemiology and genetics

This has a prevalence of 0.2 in 100 000. MEN 2B is also caused by *RET* mutations, half of which are *de novo*.

Clinical presentation

A variant of MEN 2 characterised by an aggressive and early-onset form of MTC (100%), PPGL (59%), marfanoid habitus and ganglioneuromatosis of the oral mucosa and gut (***Figure 57.19***). MTC is associated with rapid growth and a poor prognosis.

John H Sipple, b. 1930, physician, The State University of New York, Syracuse, NY, USA.

Figure 57.19 Ganglioneuromatosis of the oral mucosa in multiple endocrine neoplasia type 2B.

Surgery for MEN types 2A and 2B

Kindred of known MEN 2 patients are tested for the presence of a mutation. MEN 2B infants should undergo a thyroidectomy in the first year of life. Children who carry *MEN2* mutations are screened for calcitonin, which can detect the presence of the precursor to MTC – C-cell hyperplasia. This allows a thyroidectomy to be undertaken before invasive MTC has developed (so-called prophylactic thyroidectomy) (see also ***Chapter 55***). Owing to the strong genotype–phenotype relationship, the specific mutations guide clinicians with regard to the timing of prophylactic surgery (***Table 57.9***).

TABLE 57.9 Risk of medullary thyroid carcinoma and genetic mutations in multiple endocrine neoplasia syndromes.

Risk level, codon	Age of *RET* testing	Age of required first calcitonin	Age of prophylactic surgery
D, 918; 804	As soon as possible, within first year of life	6 months if not already done	As soon as possible, within first year of life
C, 634	<3–5years	>3–5years	Before 5 years
B, 609, 611, 618, 620	<3–5years	>3–5years	Consider before 5 years, may delay
A, 833, 819, 891, 912	<3–5years	>3–5years	Between 10 and 15 years

Multiple endocrine neoplasia type 4

Described in 2006, this is an exceptionally rare autosomal dominant syndrome consisting of *MEN1*-associated tumours (parathyroid and pituitary) in association with tumours of the kidney, adrenal glands and reproductive organs. P-NETs have also been described. The disease is thought to be due to mutations in *CDNK1B*. Treatment is the same as for MEN 1.

PART 8 | Endocrine and breast

CHAPTER

58 The breast

Learning objectives

To understand:

- Appropriate investigation of breast disease
- Aberrations of Normal Development and Involution (ANDI) concept and management of benign breast disease
- Types and management of mastitis
- Modern management of breast cancer

COMPARATIVE AND SURGICAL ANATOMY

The breast in adult females overlies the pectoral region, extending from the second rib above to the sixth rib or inframammary crease below. Medially it extends to the lateral border of the sternum and laterally it reaches the anterior axillary line or the mid-axillary line. In adult males the breast tissue is rudimentary and about 2 cm in diameter; it lies deep to the areola and extends up to the areolar edge. The anatomy of the breast is illustrated in *Figure 58.1 and* 58.1.

The axillary tail of the breast is palpable in some women and can be seen in the premenstrual period or during lactation. A well-developed axillary tail is sometimes mistaken for a mass of enlarged lymph nodes, a breast mass or a lipoma.

The **breast parenchyma** consists of ductolobular and supportive tissue. The terminal ductule together with the lobule constitute the **t**erminal **d**uctal **l**obular **u**nit, which is referred to by the acronym TDLU. The TDLU is the most active part of the breast tissue and responds to a number of hormones: namely, oestrogen, progesterone, prolactin and growth hormone. There are five to nine major lactiferous (milk) ducts carrying milk from the lobes. Approximately 10–100 lobules empty via ductules into a lactiferous duct. Each lactiferous duct is lined with a spiral arrangement of contractile myoepithelial cells.

Most diseases of the breast arise from the TDLU. About 50% of the ductolobular tissue is located in the upper outer quadrant and about 20% in the central region. Hence, during breast examination particular attention must be paid to the upper outer quadrant, retroareolar region and the nipple–areola complex.

The **supportive tissue** of the breast comprises fibrous tissue in the form of suspensory ligaments of Cooper, adipose

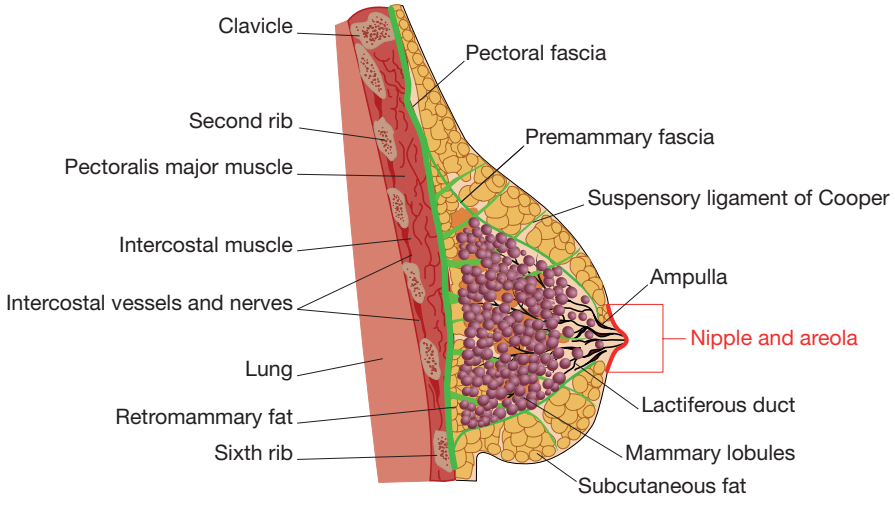

Figure 58.1 Cross-sectional anatomy of the breast.

tissue, blood vessels, nerves and lymphatics. The **ligaments of Cooper** are attached to the undersurface of the dermis superficially and to the pectoral fascia deeply.

The **areola and nipple** contain involuntary muscle arranged in concentric rings as well as radially in the subcutaneous tissue. The circular muscle fibres constitute Sappey's muscle (causes erection of the nipple), whereas longitudinal fibres form the Myerholtz muscle (causes retraction of the nipple). The areolar epithelium contains numerous sweat glands and sebaceous glands; the latter enlarge during pregnancy and serve to lubricate the nipple during lactation (Montgomery's tubercles).

The nipple is covered by thick skin with corrugations. Near its apex lie the orifices of the lactiferous ducts.

The lymphatics of the breast drain predominantly into the axillary and internal mammary lymph nodes. The axillary nodes receive approximately 85% of the lymph from the breast and are arranged in the following groups:

- lateral nodes along the lower border of the axillary vein lying lateral to the thoracodorsal vascular pedicle;
- anterior or pectoral nodes between the lateral borders of pectoralis major and pectoralis minor and the lateral thoracic vessels; these are the sentinel lymph nodes in most patients;
- posterior along the subscapular and thoracodorsal vessels just anterior to the latissimus dorsi muscle;
- a central or medial group of nodes embedded in fat in the centre of the axilla;
- interpectoral or Rotter's nodes – a few nodes lying between the pectoralis major and minor muscles;
- apical nodes that lie above and medial to the pectoralis minor tendon and lateral to the first rib; the apical nodes receive the efferent lymphatic channels from all the axillary nodes.

The apical nodes are in continuity with the supraclavicular nodes and drain into the subclavian lymph trunk, which enters the great veins directly or via the thoracic duct or jugular trunk. Surgically the axillary lymph nodes are classified into three levels:

- **level I**, below and lateral to the lateral border of the pectoralis minor muscle (the majority);
- **level II**, in front of and behind the pectoralis minor muscle (including Rotter's nodes);
- **level III**, above and medial to the medial border of pectoralis minor.

The internal mammary nodes lie along the internal mammary vessels deep to the plane of the costal cartilages and just superficial to the parietal pleura. These drain the medial half of the breast.

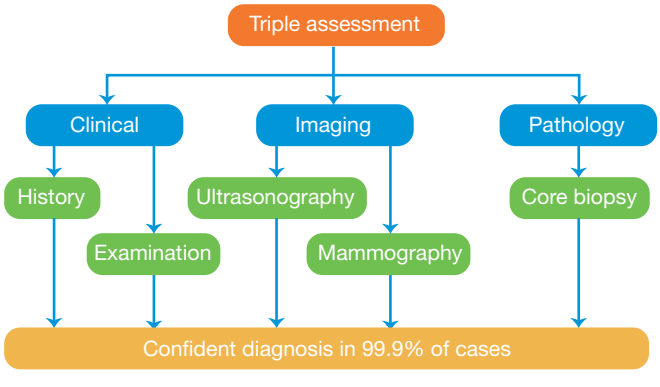

Figure 58.2 Triple assessment.

INVESTIGATIONS FOR BREAST SYMPTOMS

The assessment of women presenting with symptomatic breast disease is carried out in a systematic manner.

Triple assessment

Patients presenting with a breast lump, nipple discharge or other symptoms are assessed by a combination of clinical examination, radiological imaging and tissue sampling taken for either cytological or histological analysis. This combined approach is called 'triple assessment' (***Figure 58.2***). The positive predictive value and diagnostic accuracy of this combination approach 100%.

The clinical assessment should involve a thorough history and clinical breast examination that includes inspection and palpation (***Figure 58.3 and*** ***58.2***).

Ultrasonography

Ultrasonography is the primary imaging modality in young women with dense breast tissue in whom mammograms are difficult to interpret. Ultrasonography can distinguish cystic from solid lesions. Simple cysts do not require further work-up and follow-up can be avoided. Therapeutic aspiration may be performed for cysts causing pain (***Figure 58.4***). A well-circumscribed, mobile, solid mass in a young woman is suggestive of a fibroadenoma and has an extremely low likelihood of malignancy. Such a finding requires reassurance and imaging follow-up (***Figure 58.5***). Solid masses with an irregular shape and ill-defined margins (indistinct, angular or spiculated) are suspicious for malignancy and require biopsy (***Figure 58.6***). Ultrasonography of the axilla is performed when cancer is diagnosed, with guided percutaneous biopsy of any suspicious lymph glands.

Sir Astley Paston Cooper, 1768–1841, surgeon, Guy's Hospital, London, UK, described these ligaments in 1845.
Marie Philibert Constant Sappey, 1810–1896, French anatomist who published his comprehensive atlas in 1874.
William Fetherston Montgomery, 1797–1859, obstetrician, Dublin, Ireland, described these tubercles in 1837.
Josef Rotter, 1857–1924, German surgeon, described these nodes in the early nineteenth century.

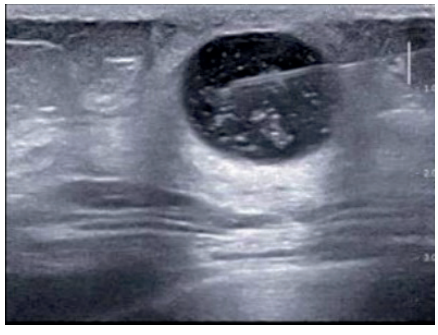

Figure 58.4 Therapeutic aspiration of a complicated cyst. Ultrasonography shows needle aspiration of a sharply defined, anechoic cyst with internal echoes – the floating debris. Breast Imaging Reporting and Data System (BI-RADS) score 2 (***Table 58.1***).

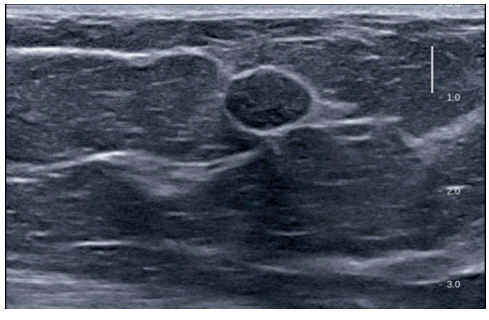

Figure 58.5 Fibroadenoma. Ultrasonography shows a well-circumscribed, solid mass suggestive of fibroadenoma in a young woman. Breast Imaging Reporting and Data System (BI-RADS) score 3 (***Table 58.1***).

Mammography

Mammography in two planes and ultrasonography are the first-line investigations for imaging the breast. Magnetic resonance imaging (MRI) is a valuable adjunctive diagnostic tool because of its high sensitivity for breast pathology. Mammography is also used as an initial screening tool for asymptomatic women in population-based programmes. Radiographs are taken by placing the breast in direct contact with ultrasensitive film and exposing it to low-voltage, high-amperage x-rays. The dose of radiation is approximately 1 mGy per film (***Figure 58.7***). Mammography should be the first investigation in older women who present with breast symptoms. Mammographic features of cancer are shown in ***Figure 58.8***. Ancillary signs of malignancy such as lymphadenopathy, breast oedema and skin or areolar thickening or retraction may be seen in advanced cases. The mammographic and ultrasonographic features are not diagnostic of cancer; biopsy is required for definitive diagnosis in lesions with a Breast Imaging Reporting and Data System (BI-RADS) score of 4 or 5 (***Table 58.1***).

Mammography reporting

The American College of Radiology has developed guidelines – BI-RADS – to achieve uniformity and objectivity in the interpretation and reporting of mammograms and ultrasound. The mammographic assessments are categorised from BI-RADS 0 to BI-RADS 6 (***Table 58.1***).

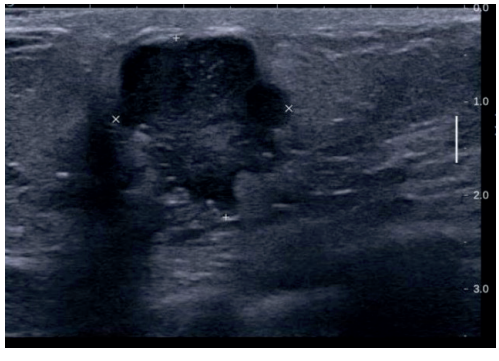

Figure 58.6 Imaging features of breast carcinoma on ultrasonography. This shows a solid, irregular-shaped mass, taller than wider, with angular irregular margins. Breast Imaging Reporting and Data System (BI-RADS) score 5 (***Table 58.1***).

Magnetic resonance imaging

MRI of the breast (***Figure 58.9***) is useful in a number of settings:

- women with dense breasts or discordant or equivocal findings on mammogram/ultrasonography;
- to distinguish scar from recurrence in women who have had previous breast conservation therapy for cancer;

Gy is short for Gray, the SI unit for the absorbed dose of ionising radiation.
Louis Harold Gray, 1905–1965, Director, British Empire Cancer Campaign Research Unit in Radiobiology, Mount Vernon Hospital, Northwood, UK.

TABLE 58.1 Breast Imaging Reporting and Database System (BI-RADS).

Category	Assessment	Probability of malignancy	Follow-up recommendation
0	Assessment is incomplete	Not applicable	Need for additional imaging evaluation and/or prior mammograms for comparison
1	Negative	Essentially 0%	Routine annual screening mammography (for women over age 40)
2	Benign finding(s)	Essentially 0%	Routine annual screening mammography (for women over age 40)
3	Probably benign finding	>0% but ≤2%	Initial short-term follow-up (usually 6 months) examination
4	Suspicious abnormality:		Biopsy should be considered
	4a: Findings needing intervention with a low suspicion for malignancy	>2 to ≤10%	
	4b: Intermediate suspicion of malignancy	>10% to ≤50%	
	4c: Findings of moderate concern, with high suspicion for malignancy	>50% to <95%	
5	Highly suggestive of malignancy	≥95%	Requires biopsy or surgical treatment
6	Known biopsy-proven malignancy	Not applicable	Category reserved for lesions identified on imaging study with biopsy proof of malignancy prior to definitive therapy

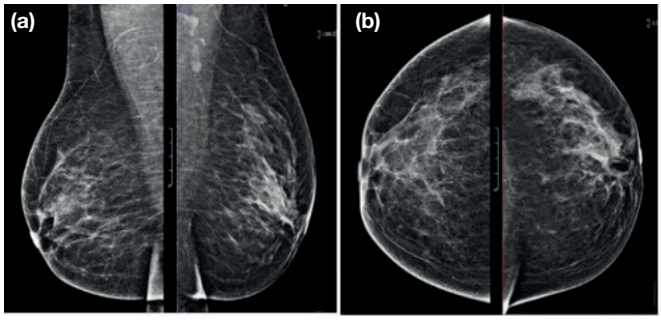

Figure 58.7 Features of a normal mammogram. **(a)** Mediolateral oblique view; **(b)** craniocaudal view.

- to assess multifocality and multicentricity and, in lobular cancer, high-grade ductal carcinoma *in situ* (DCIS);
- women with breast cancer (*BRCA*) gene or other genetic mutations or a strong family history;
- women with breast implants.

MRI-guided biopsy may be performed for lesions not visible on ultrasonography or mammogram.

Positron emission tomography

Positron emission tomography (PET) scans are used as a staging investigation in patients with T3, T4, N2, N3 breast cancer and in patients with T1, T2, N0, N1 breast cancer in the presence of symptoms/signs suggestive of metastasis (***Figure 58.10***). Inflammatory lesions (namely, mediastinal lymphadenopathy and pleuropulmonary lesions due to pulmonary tuberculosis [TB]) may give false-positive results, especially in Asian patients. Moreover, PET is very expensive and insurance policies may not cover its cost.

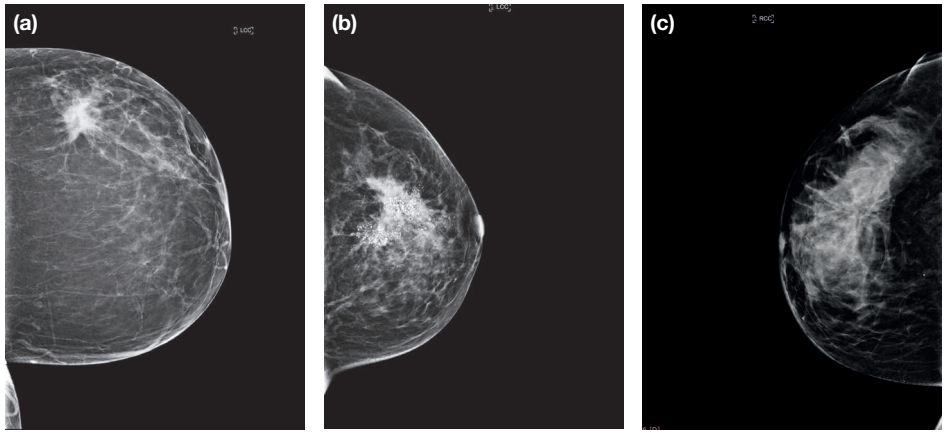

Figure 58.8 Imaging features of breast cancer on mammography (Category BI-RADS 5). **(a)** Irregular, spiculated mass; **(b)** fine pleomorphic microcalcifications; **(c)** architectural distortion.

Otto Heinrich Warburg, 1883–1970, German physiologist, awarded a Nobel prize in 1931 for describing the metabolic dependence of tumour cells on glucose (the Warburg effect). Most primary tumours and metastatic deposits exhibit high uptake of a radiopharmaceutical (^{18}F-fluorodeoxyglucose [^{18}F-FDG]) that may be detected by positron emission tomography.

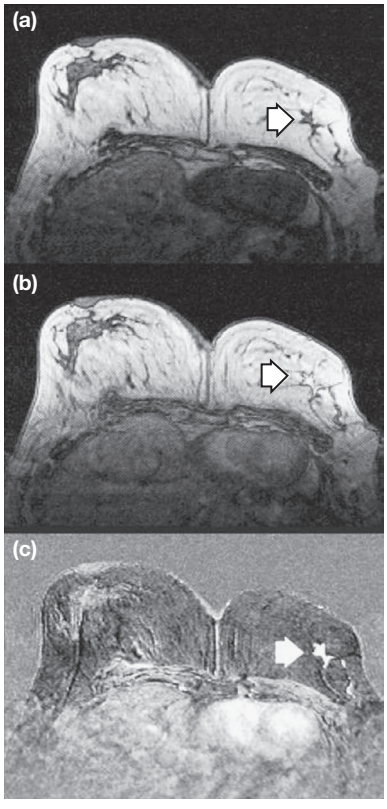

Figure 58.9 Magnetic resonance imaging showing carcinoma of the left breast (arrows). **(a)** Precontrast; **(b)** post gadolinium contrast; **(c)** subtraction image.

Needle biopsy

Tissue for histological examination can be obtained under local anaesthesia using a large-diameter core needle biopsy device (14G for breast tissue and 18G for axillary nodes) (***Figure 58.11***). The core needle biopsy should always be taken under image guidance. The passage of the biopsy needle can be guided by ultrasonography, mammogram or sometimes MRI; the needle tip should be used to take a sample from only the solid part of the mass, avoiding areas of cystic degeneration and blood vessels in and around the lesion.

Figure 58.11 Large-diameter core needle biopsy of the breast.

Vacuum-assisted biopsy

The sampling error decreases as the biopsy volume increases and using 8G or 11G needles allows more extensive biopsies to be taken. This is useful in the management of microcalcifications and removal of benign lumps such as fibroadenoma.

BENIGN BREAST DISEASE

Nomenclature

The nomenclature of benign breast disease in the past has been confusing owing to the use of a variety of terms – namely, fibrosis, adenosis, epitheliosis, fibroadenosis and fibrocystic disease – for clinical patterns of pain, nodularity, benign lumps and nipple discharge. However, such terms do not relate to clinical or histological features. Most benign disorders are derived from minor aberrations of the normal process of development, cyclical hormone-related change and involution. To address this confusion, the concept of Aberrations of Normal Development and Involution (ANDI), developed and described by the Cardiff Breast Clinic in the UK, helps in better understanding and treatment of benign breast disease.

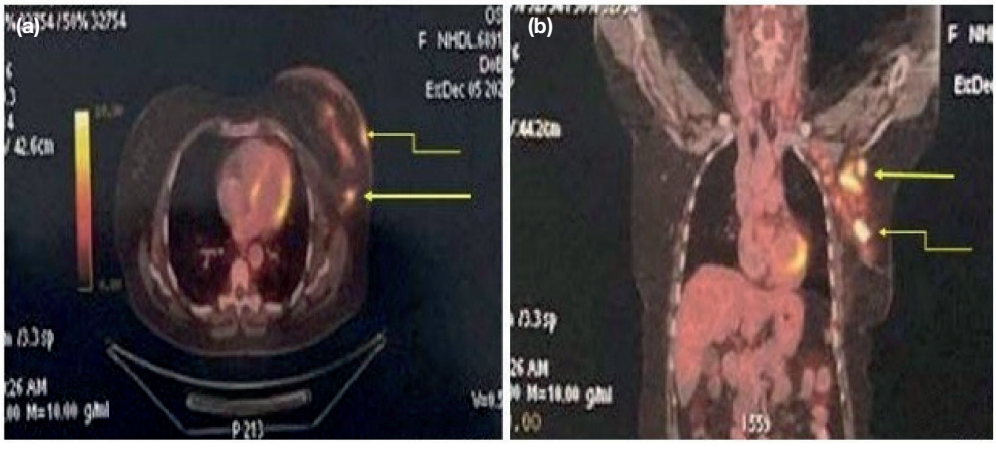

Figure 58.10 Positron emission tomography showing hot spots in the left breast and in axillary lymph nodes in **(a)** transverse and **(b)** coronal view.

Aetiology

The breast is a dynamic structure that undergoes alterations due to the cyclical changes in oestrogen and progesterone in every menstrual cycle. These hormones act as growth factors on the epithelial and stromal cells of the TDLU (*58.1*). The pathogenesis of ANDI involves disturbances in the breast physiology extending from a perturbation of normality to well-defined disease processes.

Pathology

This can be considered in three phases: lobule development at 15–25 years, cyclical changes at 15–50 years and involution at 35–55 years of age. It is believed that lobular proliferation leads to the formation of fibroadenoma and involution leads to cyst formation. Aberration in the above phases may lead to a number of benign conditions.

- **Hyperplasia of the epithelium** is defined as the presence of more than two layers of cells in the lining of the ducts and acini. It may occur with or without atypia. If atypia of epithelial cells is seen, the terms **atypical ductal hyperplasia** (ADH) and **atypical lobular hyperplasia** (ALH) are used. If features of ADH are seen to involve more than two ducts or lesions measure >2 mm in diameter, the term **ductal carcinoma *in situ*** (DCIS) is used.
- **Papilloma**. Localised hyperplasia of the ductal epithelium may produce a papilloma within the ducts. It is composed of a central fibrovascular core and papillary projections of the epithelium and myoepithelial cells. The papillary lesions in a duct are of three types:
  - solitary papilloma (relative risk [RR] for cancer 1.5–2);
  - papillomatosis: five or more papillomas in many ducts with peripheral and often bilateral distribution (RR for cancer 3);
  - juvenile papillomatosis, also called **Swiss cheese disease**, affects young women, who present with multiple firm palpable nodules; microscopically, there are multiple papillomas with/without atypia, apocrine cysts, ductal hyperplasia and sclerosing adenosis. A positive family history of breast cancer increases the lifetime cancer risk.
- **Cyst formation**. Kinking or narrowing of ductules is usually due to involution of the stroma and may result in accumulation of secretions in the lobules, forming a microcyst. Many microcysts may join together to form a macrocyst.

Clinical features

The most common manifestations of ANDI are breast pain and benign nodularity. The breast pain usually follows the menstrual cycle, appearing around day 14 and increasing in severity until day 28, when it becomes severe (cyclical pronounced mastalgia with premenstrual exacerbation). Nodularity or lumpiness may be either localised or spread diffusely throughout the breast; it is often bilateral and is most conspicuous in the upper outer quadrant. The nodularity may be cyclical, appearing 1–2 weeks prior to menstruation and regressing with the onset of the menses. A discrete lump in the breast is commonly a fibroadenoma in the young and a cyst in the middle-aged.

Mastalgia

Approximately 50–70% of women attending any breast clinic present with mastalgia (synonym: mastodynia or mazodynia). True mastalgia (arising from breast tissue) is classified into cyclical and non-cyclical types.

Cyclical mastalgia

The pain usually starts around the middle of the cycle on day 14 and gradually increases in severity (measured on a visual analogue scale [VAS] as 0–10) until day 27 or 28. Usually both breasts are involved. The pain is usually relieved with the onset of menses. Severe forms may lead to loss of sleep and impaired sexual and other activities of daily life. The pain may radiate to the upper arm and may be mistaken for angina pectoris.

The cause is unclear and considerations of hormone imbalance, high caffeine intake, low dietary essential fatty acids, water retention or psychoneurosis are not supported by research. In most patients the basal levels of oestrogen, progesterone and prolactin are in the normal range. However, most patients do respond to treatment with antioestrogen drugs, such as tamoxifen, ormeloxifene, luteinising hormone analogues or danazol, suggesting excessive responsiveness of breast tissue to circulating oestrogen.

Non-cyclical mastalgia

The pain presents at any time of the menstrual cycle, at any location of the breast and may occur both before and after menopause. It is often well localised. Some patients may have duct ectasia or periductal mastitis. Breast palpation may reveal a very tender spot confined to a point called the trigger spot or trigger point. Other causes are musculoskeletal, in the form of Tietze's syndrome: a painful costochondral junction with no radiological anomaly and lateral chest wall pain in the anterior axillary line and over serratus anterior. Trauma, cancer or sclerosing adenosis may also result in breast pain. True breast pain must be distinguished from angina, biliary colic, reflex oesophagitis and cervical spondylosis. In low-/middle-income countries, vitamin D and calcium deficiencies are rampant, leading to bony aches and pains that may present as non-cyclical mastalgia. About 5% of breast cancers exhibit pain at presentation, but this is rarely the sole presenting feature.

Treatment

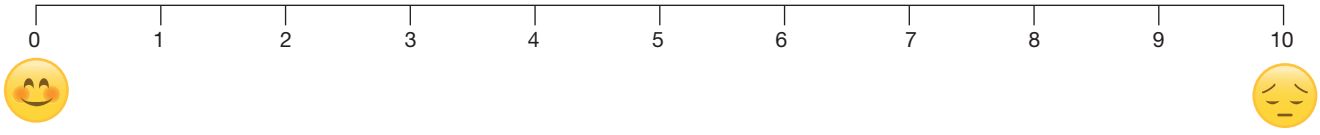
Treatment begins with assessment, including breast examination and imaging. If normal, reassurance that the symptoms are not due to cancer helps the majority of women. The type of pain, cyclical or non-cyclical, should be identified by recording a pain chart for 1 month (*Figure 58.12*). The principles of treatment are outlined in *Table 58.2 and* *58.1*. In patients

Alexander Tietze, 1864–1927, Professor of Surgery, Breslau, Germany (now Wrocław, Poland), described this condition in 1921.

DAILY BREAST PAIN CHART

Patient name: Age: Reg. number:

Date:



Month of visit: 0/1/2/3/4/5/6:

Duration of complaint (first visit only): Right Breast_____ Left Breast_____

Out of ten what was the maximum breast pain score in the last month? Please encircle the number.

(Note: 10 is the maximum pain you ever experienced and 0 is no pain)

On monthly period chart, insert the letter M below the date on days you have menses.

How many days in the last month were painful?

Right breast pain score

Note: Please bring this card with you on each visit

Figure 58.12 Breast pain chart. All India Institute of Medical Sciences modification of the Cardiff Breast Pain Chart.

with non-cyclical pain, musculoskeletal pain and other referred causes should be excluded. Trigger point pain may be relieved by local injection of a long-acting corticosteroid such as triamcinolone in combination with lidocaine at the point of maximum tenderness. This may be repeated at intervals until the pain is controlled.

TABLE 58.2 Treatment of breast pain.

Exclude cancer	
Reassure	Use a VAS breast pain chart to record severity
Adequate support	Tight sports brassiere during the day
Consider medication	
Flax seed 30 g daily or oil of evening primrose	Rich sources of omega 3 fatty acids and γ-linolenic acid, respectively
Topical non-steroidal anti-inflammatory cream (diclofenac or piroxicam) four times a day	Useful in mild to moderate mastalgia
Consider systemic medication if pain score >3 on a VAS of 0-10	
Tamoxifen 10 mg daily	For 3–6 months
Danazol 50–300 mg daily	For 3–6 months
Ormeloxifene 30 mg twice a week	For 3–6 months used in both cyclical and non-cyclical mastalgia and for treating nodularity
LHRH agonist alone or with antioestrogen: tamoxifen or ormeloxifene	Short duration: use for 3 months for recalcitrant pain not relieved by the above medications

LHRH, luteinising hormone-releasing hormone; VAS, visual analogue scale.

Nodular or lumpy breasts

Patients who present with painful tender nodularity with mastalgia should be treated for breast pain, as outlined in *Table 58.2*.

Patients with breast nodularity without pain should undergo triple assessment (*Figure 58.2*). The Cardiff–Lucknow nodularity scale – a five-point ordinal scale that grades the nodularity on a scale of 0 to 4, providing an objective measurement of nodularity – has been developed and validated (*Figure 58.13*). In the absence of a discrete lesion on breast imaging, reassurance may be given. If necessary, treatment with an antioestrogen such as tamoxifen or ormeloxifene (Centchroman) has been found to control nodularity within a few weeks.

Discrete lumps in the breast

The main causes of discrete lumps in the breast are listed in *Summary box 58.1*. Sometimes a lump appears in the breast and within a few days regresses on its own. This is called an **evanescent lump**. It is caused by an inflammatory mass of periductal mastitis; the lump, pain and tenderness all disappear together. Sometimes, a cyst or a galactocele may rupture; the lump disappears but pain and tenderness appear. The cyst fluid or milk leaking in the stroma may induce inflammation, causing pain and tenderness.

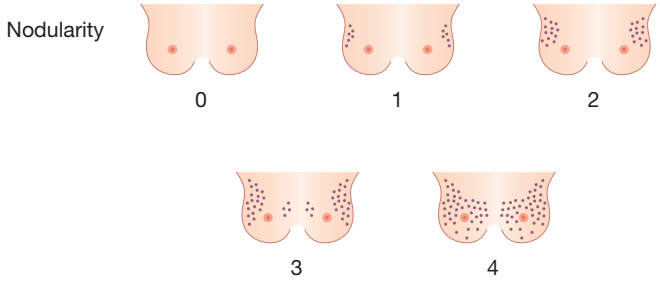

Figure 58.13 The Lucknow–Cardiff breast nodularity scale. A visual analogue scale for nodularity: an ordinal scale. 0, normal or non-nodular; 1, minimal; 2, mild; 3, moderate; 4, severe.

Summary box 58.1

Causes of discrete breast lumps

Benign		Malignant
Non-inflammatory	Fibroadenoma	Carcinoma of the breast (invasive, DCIS)
	Ductal papilloma	Malignant phyllodes
	Phyllodes	
	Hamartoma	
	Galactocele	
	Breast cyst	
	Haematoma	
	Traumatic fat necrosis	
Inflammatory	Breast abscess (acute inflammatory, tubercular)	
	Antibioma	
	Periductal mastitis (evanescent mass)	
	• Granulomatous mastitis • Parasitic: hydatid, filariasis • Fungal: aspergillosis, blastomycosis, *Cryptococcus*, *Histoplasma*	

Breast cysts

Breast cysts are common in the 35- to 55-year-old age group and usually present as a painless lump. Several causative factors contribute as part of ANDI, including lobular involution, increased secretion, ductile obstruction, loss of stroma, hyperoestrogenaemia and hormone replacement therapy. Cysts are often multiple, may be bilateral and can mimic malignancy. They typically present suddenly and cause great alarm; prompt diagnosis by ultrasonography and aspiration under ultrasound guidance provides immediate relief. A smooth-walled cyst without any solid component in its wall is classified as BI-RADS 2 and requires only observation without biopsy. The presence of a solid component in the cyst wall is classified as a **complex cyst** and necessitates a core biopsy to rule out cystadenocarcinoma. This should be distinguished from a **complicated cyst**, which is defined as a cyst containing intracystic floating debris that moves within the cyst with change of posture.

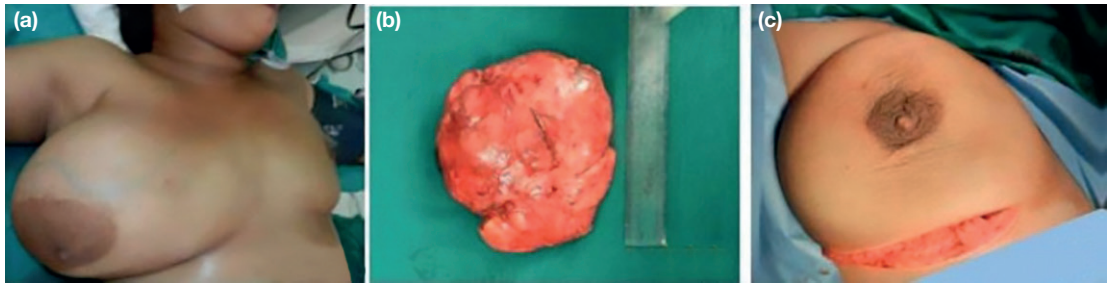

Figure 58.14 Giant fibroadenoma. **(a)** Clinical picture; **(b)** excised specimen; **(c)** submammary (Gaillard Thomas) incision.

Treatment

A solitary cyst or small collection of cysts may be aspirated if associated with pain or inflammation. If the cyst(s) resolve(s) completely, and if the fluid is not bloodstained, no further treatment is required. Cytological examination of cyst fluid is not useful. If there is a residual lump or if the aspirate is bloodstained, a core biopsy or excision for histological diagnosis is advisable. A complicated cyst with associated infection may be treated with a short course of antibiotics.

Galactocele

Galactocele is rare and usually presents as a solitary subareolar milk-filled cyst seen during or just after lactation. It disappears completely and is usually cured by a single aspiration. If it recurs, it may be reaspirated or a nylon strand (2/0) may be passed to clear the blocked duct. Complications of galactocele are non-resolution because of inspissated material and calcification. Surgical excision is rarely indicated. Lactating mothers should be encouraged to continue breastfeeding.

Fibroadenoma

A fibroadenoma is the most common cause of a breast lump in women aged 15–25 years. It arises from hyperplasia of a lobule and usually grows to 2–3 cm in size. It is surrounded by a well-defined capsule. A clinically typical fibroadenoma, confirmed on ultrasonography, may be observed without a biopsy. A biopsy should be obtained if the patient is over 25 or if there are atypical features on ultrasonography. Regression with antioestrogen drugs has been observed with tamoxifen and ormeloxifene (*58.3*).

Giant fibroadenomas occasionally occur during puberty. They are over 5 cm in diameter, often rapidly growing and can be enucleated through a submammary incision (*Figure 58.14*).

The RR of cancer with fibroadenoma ranges from 1.5–1.7 if simple to 3.4–3.7 in the presence of epithelial hyperplasia. Complex fibroadenoma with a family history has an RR for cancer of 3.0–4.0, particularly lobular carcinoma.

Indications for surgical excision are: age over 30 years; suspicious features on imaging, such as microlobulation; atypia on histology; size >5 cm; family history of breast cancer; and the patient's preference. Excision of fibroadenoma in the elderly should include a rim of normal tissue as it may contain malignancy or a phyllodes tumour.

Figure 58.15 Phyllodes tumour of the left breast.

Phyllodes tumour

Previously known as cystosarcoma phyllodes, these benign tumours usually occur in women over the age of 30 years but can appear in younger women and present as a large, sometimes massive, tumour with an unevenly bosselated surface (*Figure 58.15*). Occasionally, the overlying skin is ulcerated owing to pressure necrosis. Despite their size, phyllodes tumours remain mobile on the chest wall and rarely infiltrate the skin until late. It is a true mixed neoplasm comprising both epithelial and mesenchymal elements and resembling a fibroadenoma. Some have a higher mitotic index with infiltrating borders and may rarely metastasise via the bloodstream. Phyllodes tumours are classified according to histological behaviour into benign (mitotic rate <4 per 10 high-power fields [HPF]), borderline (mitotic rate 4–9 per 10 HPF) and malignant (mitotic rate >10 per 10 HPF) tumours.

Treatment

Treatment is by wide local excision (WLE) with a 2-cm margin along with the overlying skin and underlying pectoralis major muscle because of a high incidence of local recurrence.

Theodore Gaillard Thomas, 1831–1903, American gynaecologist, Columbia University College of Physicians and Surgeons, New York, NY, USA.

Figure 58.16 Accessory nipple with congenital inversion of the normal nipple.

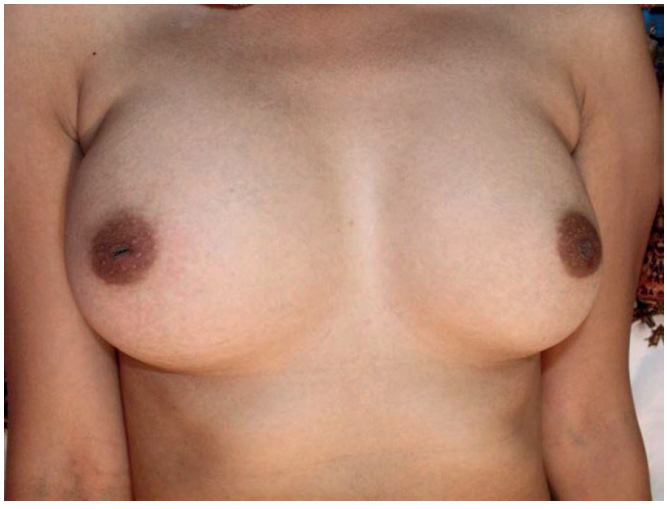

Figure 58.17 Congenital nipple inversion.

Massive tumours, recurrent tumours and those of the malignant type require mastectomy. Postoperative radiotherapy may be offered to women with recurrent or malignant phyllodes tumours. Systemic chemotherapy may be offered for malignant phyllodes.

THE NIPPLE

Absence of the nipple is rare and is usually associated with amazia (congenital absence of the breast). Supernumerary nipples are not uncommon and occur along a line extending from the anterior fold of the axilla to the upper chest (***Figure 58.16***). In the human embryo the milk ridge extends from the axilla to the upper chest only and not to the groin. Rarely, there is duplication of the nipple on a normal areola.

Nipple inversion and retraction

At birth the mammary glands in boys and girls are similar. At around 11–12 years of age, in girls the breast begins to grow. The onset of its growth is called 'the telarche' (1 year before menarche). Initially uniform growth of cells leads to a rounded breast mound. Later elongation of the major milk ducts at age 14–16 years leads to projection of the nipple. Lack of elongation of the major milk ducts leads to failure of the nipple to protrude, called nipple inversion (***Figure 58.17***). An inverted nipple interferes with feeding and may become a source of infection by deposition of debris. It does not predispose to breast cancer.

Nipple retraction is an acquired phenomenon owing to fibrosis in and around the major milk ducts. Retraction of recent onset is always worrisome and may point towards an underlying carcinoma; however, the most common cause of longstanding retraction is periductal mastitis (***Figure 58.18***).

Both nipple inversion and retraction may cause problems with breastfeeding and infection can occur because of retention of secretions. A transverse slit-like or fish mouth-like retraction of the nipple is classically seen in periductal mastitis (***Figure 58.18a***), but circumferential retraction may indicate a carcinoma (***Figure 58.18b***).

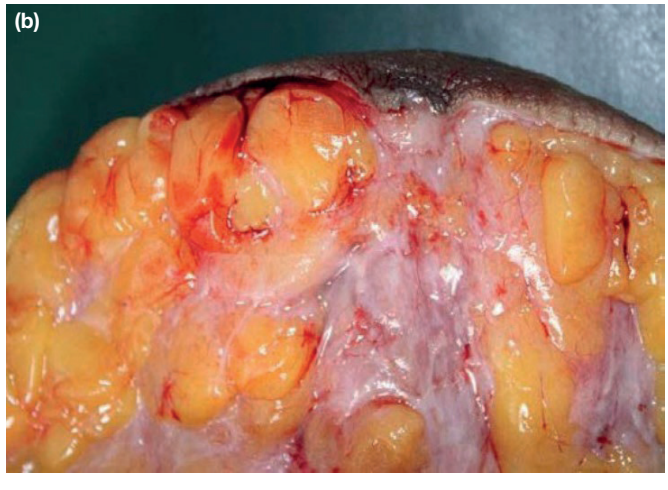

Figure 58.18 Two common causes of retraction of the nipple. **(a)** Slit-like retraction due to periductal mastitis. **(b)** Breast cancer with fibrosis around the major milk ducts.

Treatment

Minor degrees of inversion can be corrected by gently pulling the nipple forward. Surgical correction is fraught with division of milk ducts and loss of nipple sensation and the patient should be fully informed of this risk. Mechanical suction devices have been used to evert the nipple, with some benefit.

Cracked nipple

This is observed in about 10% of nursing mothers and is thought to arise from the strong negative force created by suckling. It initiates as a small blister on the nipple that soon ruptures to give rise to a small ulcer. The crack thus formed is often colonised by bacteria or fungi. The microbes from the crack may enter the milk ducts and may progress to lactational mastitis.

If the nipple becomes cracked during lactation, it should be rested for 48 hours and the breast should be emptied with a breast pump. The sore nipple should be gently washed with warm water and moisturising soap followed by application of an antimicrobial cream (mupirocin).

Papilloma of the nipple

Papilloma of the nipple has the same features as any cutaneous papilloma and should be excised with a tiny disc of skin. Alternatively, the base may be tied with a ligature and the papilloma will spontaneously fall off.

Retention cyst of a gland of Montgomery

These glands, situated in the areola, secrete sebum. If they become blocked a sebaceous cyst forms. Rarely they may become infected and need excision.

Eczema

Eczema of the nipple and areola is a rare condition and is often bilateral; it is usually associated with eczema elsewhere on the body. It is treated with 0.1% betamethasone skin cream by local application and by using moisturising soaps. If the nipple fails to heal, Paget's disease must be excluded by taking a wedge biopsy of the lesion.

Paget's disease

Paget's disease is a unique type of DCIS arising in the nipple. It presents as erosion of the nipple that slowly destroys the nipple and encroaches on the areola (***Figure 58.19***). It may become invasive with metastasis to the axillary lymph nodes. Triple assessment is needed to exclude underlying malignancy. Paget's disease without associated underlying malignancy is treated by central core excision, removing a cone of major milk ducts along with the nipple and areola down to the pectoralis major muscle, followed by radiotherapy. Paget's disease with underlying malignancy is treated by mastectomy and evaluation of the axillary nodal status.

Figure 58.19 Nipple erosion in early Paget's disease.

Discharges from the nipple

Most nipple discharges are caused by physiological aberrations as part of ANDI, may emanate from a single or many milk ducts and may involve one or both sides. The presence of a **s**ingle, **s**erous, **s**anguineous and **s**pontaneous discharge ('**four S**') should be considered pathological and triple assessment should be carried out. Both serous and sanguineous discharges are caused by excessive proliferation of the ductal epithelium, which can be either diffuse or localised or may result from a ductal carcinoma. During pregnancy, the increase in blood flow to the ductolobular tissue may lead to serous or bloody nipple discharge. Hence, a bloody discharge during pregnancy is considered physiological and usually abates spontaneously after childbirth; however, ultrasonography should be performed to rule out malignancy. The clinical significance of the specific colour of the nipple discharge is as follows:

- A clear, serous discharge is commonly caused by ductal papilloma. It is potentially serious and should not be ignored. Multiduct, multicoloured discharge is physiological and the patient may be reassured (***Figure 58.20***).
- A bloodstained discharge may be caused by a duct papilloma, carcinoma or duct ectasia. A duct papilloma is usually single and situated in a major milk duct usually within 5 cm from the nipple.
- A black, green or muddy-coloured discharge is usually the result of duct ectasia.

Galactorrhoea is defined as spontaneous milk discharge from several ducts of both nipples unassociated with childbirth or breastfeeding. It may be associated with a prolactin-secreting adenoma of the pituitary gland. Many drugs can also lead to increased prolactin secretion and galactorrhoea, including haloperidol, chlorpromazine, amitriptyline, metoclopramide and H_2 receptor antagonists (cimetidine).

Sir James Paget, 1814–1899, surgeon, St Bartholomew's Hospital, London, UK, described this disease of the nipple in 1874.

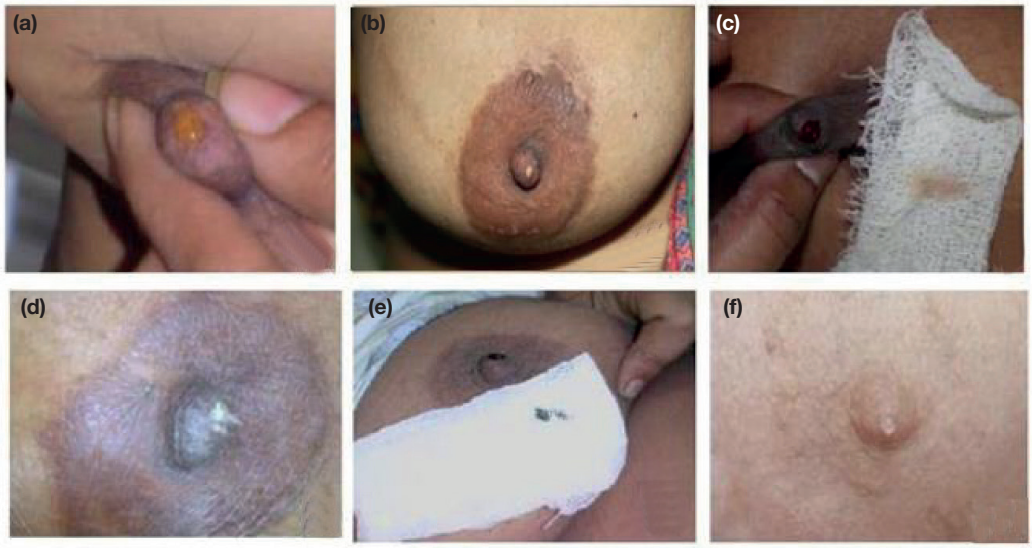

Figure 58.20 Different types of nipple discharge. **(a)** serous; **(b)** pus; **(c)** bloody; **(d)** cheesy; **(e)** greenish; **(f)** watery.

Summary box 58.2

Discharges from the nipple

Discharge from a single duct

- Bloodstained
  - Intraduct papilloma
  - Intraduct carcinoma
  - Duct ectasia
- Serous (sticky translucent fluid)
  - Duct papilloma
  - Ductal hyperplasia
  - Duct ectasia
  - Ductal carcinoma (*in situ* and invasive)

Discharge from more than one duct

- Bloodstained
  - Carcinoma
  - Duct ectasia
- Black, green or muddy
  - Duct ectasia
- Purulent
  - Periductal mastitis

Milk

- Lactation
  - Galactorrhoea
  - Rare causes: hypothyroidism, pituitary tumour
- Discharge from the surface (not from within nipple)
  - Paget's disease
  - Skin diseases (eczema, psoriasis)
  - Rare causes (e.g. chancre)

Management

Triple assessment to exclude carcinoma should be carried out. Ultrasonography may reveal dilated subareolar ducts and a filling defect indicating a duct papilloma with a diagnostic accuracy of 85%.

Ductoscopy (inspection of the internal structure of the duct system) using microendoscopes is technically feasible. Ductography is currently not practised in most centres because of the poor diagnostic yield. Most breast clinics have abandoned the cytological examination of nipple discharge as it has a poor yield for cancer.

Non-bloody discharge

Simple reassurance may be sufficient. However, if the discharge is profuse (wetting of the clothes causing social embarrassment) an operation to remove a 1.5- to 2-cm length of the affected major milk duct (microdochectomy) or ducts (major duct excision) can be performed.

Blood or serous discharge

The risk of cancer is related to the patient's age. Patients below 40 years with a bloody discharge and normal triple assessment may be reassured and followed up with annual imaging. Patients over the age of 40 years should be offered microdochectomy for single-duct discharge or Hadfield's major mammary duct excision for multiduct discharge. A segment of major milk ducts 5 cm in length from the nipple is usually removed as most duct papillomas are located up to a distance of 5 cm from the nipple (*58.4*).

Congenital abnormalities

Amazia

Congenital absence of the breast may occur on one or both sides. It is sometimes associated with Poland's syndrome, which is characterised by the absence of the sternal portion of the pectoralis major and short webbed fingers (symbrachydactyly) on the side of the involved breast (***Figure 58.21***). The breast may be reconstructed with a latissimus dorsi muscle flap and a silicone breast implant.

Geoffrey John Hadfield, 1923–2006, surgeon, Stoke Mandeville Hospital, Aylesbury, UK.
Alfred Poland, 1822–1872, surgeon, Guy's Hospital, London, UK, described this condition in 1841.

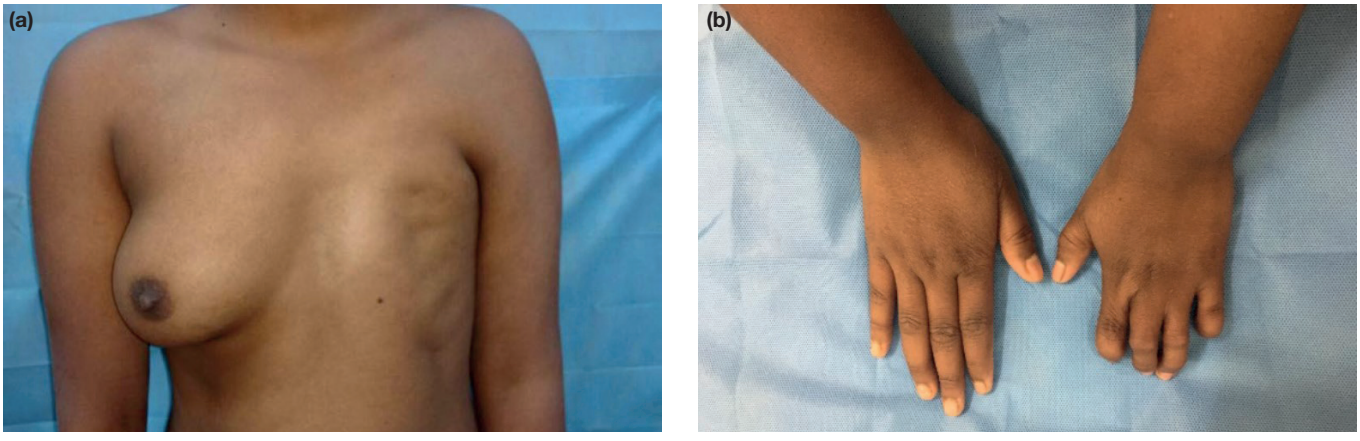

Figure 58.21 Poland's syndrome with congenital absence of the left breast and pectoralis major muscle **(a)** and symbrachydactyly of the ipsilateral hand **(b)**.

Figure 58.22 Polymazia left side.

Polymazia

Accessory breasts (***Figure 58.22***) have been recorded in the axilla (the most frequent site), groin, buttock and thigh. They have been known to fluctuate in response to hormones in a physiological manner, such as pubertal enlargement and lactation. They may also show the same spectrum of pathological diseases observed in normal breasts. Polymazia may be associated with other congenital diseases, such as vertebral anomalies, cardiac arrhythmias or renal anomalies.

Mastitis of infants

Mastitis of infants may occur in both boys and girls. It is uncommon and is predominantly caused by *Staphylococcus aureus*.

Macromastia

Macromastia is a benign disorder characterised by massive enlargement of one or both breasts disproportionate to the body habitus. The aetiology of this condition is multifactorial: it is usually idiopathic or associated with obesity, the presence of excessive endogenous or exogenous hormones or increased sensitivity of the breast tissues to the hormones. The treatment is reduction mammoplasty (***Figure 58.23***) or a subcutaneous mastectomy along with breast reconstruction.

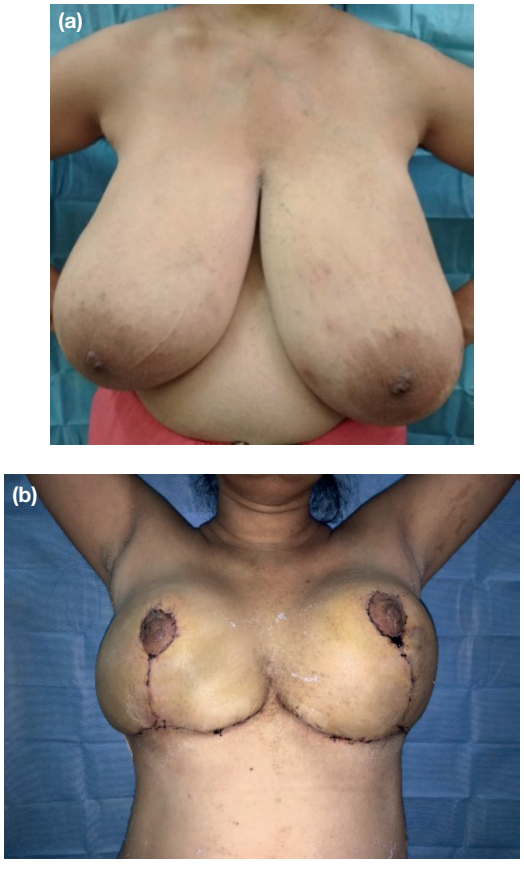

Figure 58.23 Patient with macromastia **(a)** who underwent inferior pedicle reduction mammoplasty **(b)** with removal of 1600 g of tissue from the right breast and 1800 g from the left.

Injuries of the breast

Haematoma

Haematoma, particularly a resolving haematoma, gives rise to a lump that, in the absence of overlying bruising, is difficult to diagnose correctly unless it is biopsied.

Traumatic fat necrosis

Traumatic fat necrosis may be acute or chronic and usually occurs in stout, middle-aged women. Following a blow, a lump, which is often painless, appears. This may mimic a carcinoma, even displaying skin tethering and nipple retraction; biopsy is required for diagnosis. A history of trauma is not diagnostic as this may merely have drawn the patient's attention to a pre-existing lump. In a road traffic accident, a seatbelt may transect or avulse the breast off the underlying pectoral muscles owing to a sudden deceleration injury.

Acute inflammation of the breast

Mastitis refers to inflammation of the breast tissue that may or may not be accompanied by infection. Acute mastitis can occur in lactating as well as non-lactating women, with the former being more common.

Lactational (puerperal) mastitis

The incidence of acute mastitis in lactating mothers varies from 3% to 20%. Most cases are caused by *S. aureus* and, if hospital acquired, may be to be due to methicillin-resistant *S. aureus*.

Aetiology

Mastitis may be bacterial or non-bacterial. Bacteria may enter the nipple through a cracked or retracted nipple. In many cases the lactiferous ducts get blocked by epithelial debris, leading to stasis, which is followed by infection. Once within the ampulla of the duct, staphylococci cause clotting of the milk and then multiply within the clot. Abscess formation is most commonly seen at two stages during lactation: in the first month after the first childbirth owing to inexperience or inappropriate and inadequate breastfeeding; and at weaning owing to engorgement and trauma to the nipple by the baby's teeth.

Clinical features

Initially there is generalised cellulitis, which if left untreated progresses to suppuration and abscess formation. An abscess presents as a fluctuant lump (in a deep-seated abscess fluctuation may be absent) with pain, signs of inflammation, fever, malaise and difficulty in feeding. It may also be associated with enlarged tender axillary nodes. Ultrasonography reveals cellulitis (seen as an area of increased echogenicity) and liquefaction necrosis (pus is seen as a hypoechoic collection with floating debris that changes with posture).

Management

During the cellulitic stage, the patient should be treated with anti-staphylococcal antibiotics such as cloxacillin, flucloxacillin or erythromycin. Breastfeeding from both the breasts should be encouraged 2-hourly, followed by emptying the breast. A breast support garment, cold compression on the breast and analgesia aid in symptomatic relief. Any pus seen on ultrasonography should be aspirated and sent for culture and sensitivity. Contrary to the practice of incision and drainage, in a breast abscess ultrasound-guided drainage gives an excellent cosmetic result, does not hamper breastfeeding and can be done as a day-care procedure with a high rate of success. Furthermore, incision and drainage may result in a non-healing milk fistula.

In abscesses >3 cm in diameter or those containing more than 30 mL of pus (assessed on ultrasonography), a vacuum suction catheter is inserted under ultrasound guidance to drain the pus (***Figure 58.24 and*** ***58.5***). The patient should be reviewed on alternate days by clinical examination and ultrasonography. Any residual collection should be aspirated. The antibiotics are modified according to the microbiological culture report. In patients with a suction drain, the catheter is irrigated with cold normal saline (cold to reduce pain) on each visit until complete resolution. Antibiotics should be continued for 14 days.

Subacute and chronic inflammation of the breast

Non-lactational mastitis

Non-lactational mastitis may be defined as inflammation of the breast tissue in a nulliparous woman or occurring after a minimum of 6 months after cessation of lactation. Various forms of non-lactational mastitis include periductal mastitis, idiopathic granulomatous mastitis (IGM) and tubercular mastitis.

Periductal mastitis

This is a chronic non-lactational inflammation around the major milk ducts. The pathogenesis is obscure and thought to be autoimmune in nature. The condition is much more common in smokers.

It may progress to a subareolar inflammatory mass that may suppurate, forming a subareolar abscess. Thick areolar muscles do not allow the abscess to perforate through the areola so the pus follows the path of least resistance, rupturing the skin at the areolar edge and forming a mammary or milk duct fistula (***Figure 58.25***). In some cases, a chronic indurated mass forms beneath the areola, which mimics a carcinoma. Fibrosis in and around major milk ducts causes nipple retraction.

The patient presents with central non-cyclical pain, pus discharge from the nipple and a subareolar tender mass/abscess or mammary duct fistula. The examination reveals a tender, firm subareolar lump or abscess, purulent nipple discharge, thickened tender major milk ducts and a transverse slit-like nipple retraction looking like a fish's mouth (***58.6***).

Ultrasonography shows thickened major milk ducts with surrounding inflammation or abscess. A lump should be biopsied under ultrasound guidance to confirm the diagnosis. Any pus discharge should be sent for culture sensitivity and GeneXpert® *Mycobacterium tuberculosis* complex and resistance to rifampicin (MTB/RIF) testing to rule out TB. The most common organisms isolated are staphylococci, enterococci, anaerobic streptococci and sometimes *Bacteroides* and mycobacteria.

Many cases of periductal mastitis resolve with a course of antibiotics, combined with needle aspiration of an abscess. However, surgical treatment by major milk duct excision is needed in patients with a subareolar abscess or sepsis and a mammary duct fistula. A 1.5- to 2-cm length of the ductal cone

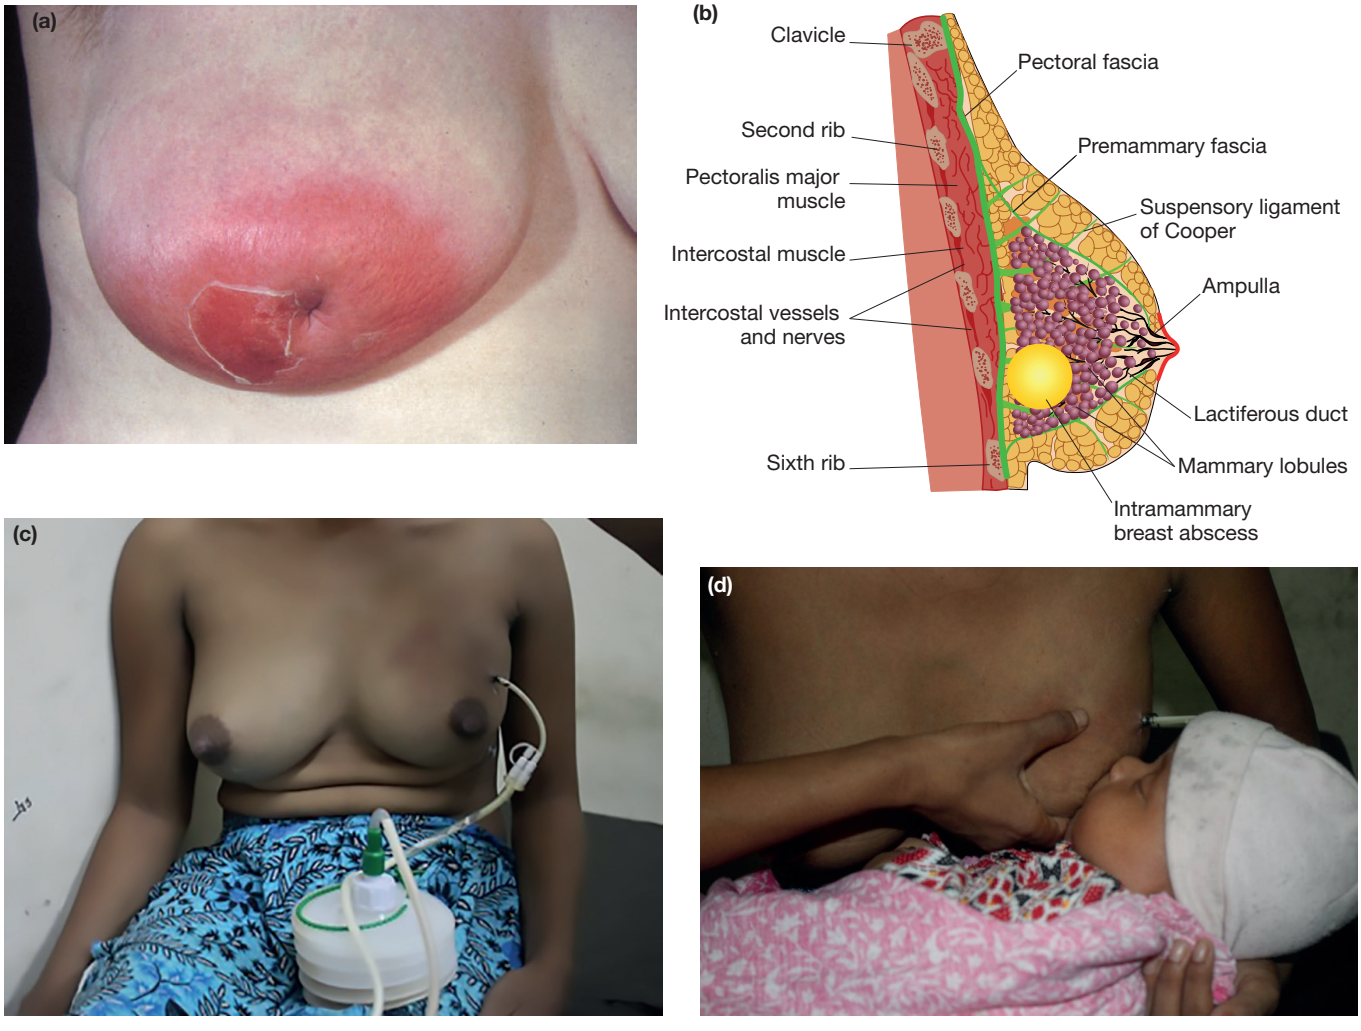

Figure 58.24 (a) Breast abscess; **(b)** diagrammatic representation; **(c)** closed suction drainage; **(d)** breastfeeding while a drainage catheter is in place.

should be excised. Smoking cessation must be encouraged to prevent recurrence.

Idiopathic granulomatous mastitis

This is a benign, self-limiting, inflammatory breast disease of unknown aetiology. It occurs most commonly in young parous women within the first few years after pregnancy. An association between IGM and *Corynebacterium kroppenstedtii* infection has been postulated. IGM may present as single or multiple central or peripheral inflammatory breast masses, with or without abscess formation. IGM may be associated with skin ulceration, nipple retraction, sinus formation, peau d'orange and axillary lymphadenopathy. These findings may mimic cancer.

A needle biopsy of a solid mass establishes the diagnosis of IGM. The tissue/aspirate should also be sent for Gram stain and culture, acid-fast bacilli (AFB) stain and culture and fungal stain and culture. Histologically IGM shows a non-caseating granuloma with chronic inflammation. The differential diagnoses include TB, foreign body reaction and sarcoidosis.

In symptomatic patients and in those with infection, treatment with non-steroidal anti-inflammatory drugs and antibiotics with or without drainage is indicated. In countries where TB is endemic, care should be taken to avoid administering anti-tuberculous therapy as a blanket treatment to all patients with granulomatous mastitis. Anti-tuberculous treatment should only be given to patients with evidence of TB on imaging, histopathology or microbiological analysis and GeneXpert® MTB/RIF. In cases of persistent symptoms or progression, treatment with prednisolone (oral or topical) with or without methotrexate has helped in regression of IGM. A major milk duct excision is indicated in patients with a mammary duct fistula. Excision of chronic abscess cavities is performed in patients with recurrence.

Hans Christian Joachim Gram, 1853–1938, Professor of Pharmacology (1891–1900) and of Medicine (1900–1923), Copenhagen, Denmark, described this method of staining bacteria in 1884.

Tuberculosis of the breast

TB of the breast is uncommon. It is caused by spread from the axillary or internal mammary lymph nodes or osteitis of the rib or sternum. Sometimes infection may reach the breast from the pleural cavity. Uncommon sources of infection can be entry from a cracked nipple or a haematogenous route. It presents with multiple chronic abscesses and sinuses with a typical bluish discoloration of the surrounding skin. The diagnosis rests on bacteriological and histological examination. Tubercular mastitis results in epithelioid cell granuloma with caseating necrosis. AFB can be seen occasionally in the pus/aspirate from caseation necrosis. Any pus or tissue should be sent for Ziehl–Neelsen staining, GeneXpert® MTB/RIF testing and mycobacterial culture. A computed tomography (CT) scan of the chest and abdomen aids in diagnosis by detecting other foci of present or past TB. A Mantoux test may be done; however, it is of little value in countries where TB is endemic. Treatment consists of anti-tuberculous chemotherapy for 6–9 months. Healing is usual, although often delayed with puckered scars (***Figure 58.26***).

Duct ectasia

Duct ectasia is defined as dilated major milk ducts. It is considered a disorder of involution as part of ANDI. Abnormally dilated ducts are filled with debris. This acts as an irritant and can lead to periductal inflammation and subsequent fibrosis, leading to nipple retraction. Patients usually present with toothpaste-like or coloured (such as brown, green or mud coloured) nipple discharge. The clinical findings of duct ectasia can mimic malignancy as well as benign conditions such as mastitis. Ultrasonography reveals dilated major milk ducts >3 mm in diameter.

Treatment

Triple assessment should be followed by antibiotic therapy if inflammation/infection is present. Co-amoxiclav, flucloxacillin,

Franz Ziehl, 1859–1926, German bacteriologist and a professor in Lubeck, Germany.
Friedrich Carl Adolf Neelsen, 1854–1898, German pathologist and professor at the Institute of Pathology, University of Rostock, Germany.
Charles Mantoux, 1877–1947, physician, Le Cannet, Alpes Maritimes, France, described the intradermal tuberculin skin test in 1908.

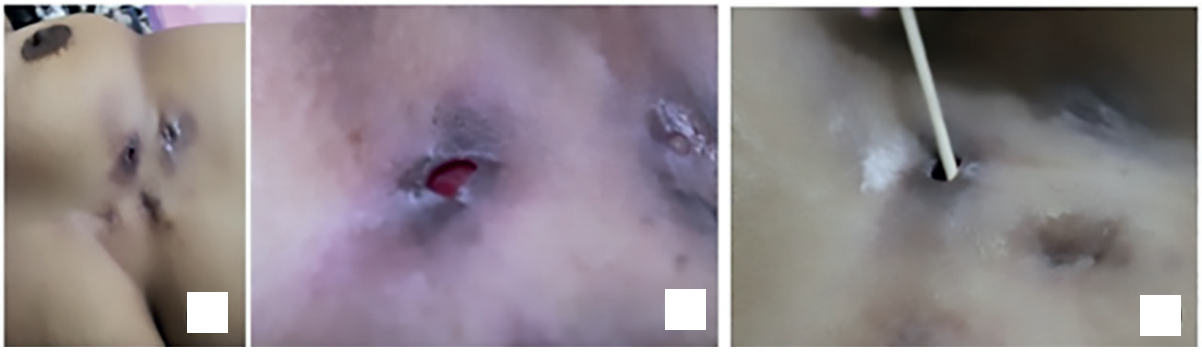

Figure 58.26 Tuberculosis of the breast. **(a)** Multiple pus-discharging sinuses from the lower part of the breast and lower chest wall. **(b)** Bluish discoloration of the skin around the tubercular sinus. **(c)** Undermined edge of a tubercular ulcer.

ciprofloxacin or cefixime along with anti-anaerobic cover with metronidazole or tinidazole for 2–3 weeks is recommended. In patients with profuse nipple discharge or subareolar abscess, major mammary duct excision is performed.

Actinomycosis

Actinomycosis of the breast is very rare. It is caused by anaerobic *Actinomyces* bacteria. The lesions present with multiple chronic, pus-discharging, non-healing sinuses over the breast. The pus demonstrates typical black granules and the specific pathogen on microbiology. The condition requires long-term penicillin injections along with curettage of necrotic granulomas and sinuses.

Mondor's disease

Mondor's disease is thrombophlebitis of the superficial veins of the breast and anterior chest wall.

In the absence of injury or infection, the cause of thrombophlebitis is obscure. The pathognomonic feature is a tender thrombosed subcutaneous cord, usually attached to the skin. When the skin over the breast is stretched by raising the arm, a narrow, shallow, subcutaneous groove alongside the cord becomes apparent (***Figure 58.27***). The differential diagnosis is lymphatic permeation from an occult carcinoma of the breast. The only treatment required is to restrict arm movements. The condition usually subsides within a few months without recurrence, complications or deformity.

CARCINOMA OF THE BREAST

Breast cancer is the most frequent cancer among women, with an estimated 2.3 million new cases diagnosed worldwide in 2020, representing about 25% of all cancers in women. Incidence rates vary widely across the world, from 27 per 100 000 in Middle Africa and East Asia to 92 per 100 000 in North America. In western Europe approximately one in nine women will develop breast cancer, accounting for 3–5% of all deaths in women. In resource-poor countries 1 in 28 women will develop breast cancer in her lifetime and for every 2 women diagnosed with breast cancer 1 dies of cancer.

Risk factors

There are several factors known to increase the RR for developing breast cancer. These are called the risk factors and can be divided into modifiable (those that can be modified by adopting a healthy diet and lifestyle) and non-modifiable risk factors. The events increasing the oestrogenic exposure of the breast are said to be risk factors for breast cancer, such as early menarche, late menopause, nulliparity, late first pregnancy and hormone replacement with high oestrogen therapy. These are listed in ***Table 58.3***.

Figure 58.27 Mondor's disease in the lateral aspect of the right breast.

Henri Mondor, 1885–1962, Professor of Surgery, Paris, France.

TABLE 58.3 Risk factors for breast cancer.

	Remarks
Modifiable risk factors	
Obesity: BMI >30	Increased risk in postmenopausal women: RR = 1.29
Parity	Increased risk in nulliparous women or first pregnancy after 35 years of age
Breastfeeding	It is protective for breast cancer and >12 months of breastfeeding by women has a greater protective effect than shorter duration
Age at first childbirth	Early: less risk, <20 years Late: high risk, >35 years
Use of HRT	Use for >10 years increased risk: RR = 1.2
Tobacco use	RR = 1.14 for smoking 25 or more cigarettes/day; RR = 1.07 for smoking for 20 years or more
Alcohol consumption	RR = 1.05 for light drinking (<1 drink/day); RR = 1.32 for moderate drinking (3 or 4 drinks/day); RR = 1.46 for heavy drinking (>4 drinks/day)
Radiation exposure	RR = 6
Non-modifiable risk factors	
Age	Increasing age is a risk factor. While the median age at presentation is around 60 years in the West (UK, USA), it is around 48 years in low-/middle-income nations such as India
Sex	Female sex is a risk factor as only 0.5–1% of all breast cancers occur in males
Ethnicity	American white, African American (age <45 years), Ashkenazi Jew, Parsi in India
Family history of breast cancer	One first-degree relative (mother, sister or daughter) with breast cancer: RR = 2; two first-degree relatives with breast cancer: RR = 3
Genetic predisposition	5–10% of all breast cancers are hereditary; *BRCA1* and *BRCA2* mutations account for up to 70% of hereditary breast cancers
Early menarche (<12 years)	Breast cancer risk increases by around 5% for each year earlier menstruation begins: RR = 1.19 for age <11 years
Late menopause (>55 years)	Breast cancer risk increases by about 3% for each year later menopause begins: RR = 1.12 for menopause at 55 years versus menopause at 45 years
High-risk breast lesions	Proliferative conditions without atypia: RR = 1.8–2 Complex fibroadenoma: RR = 3 Papillomatosis: RR = 3 Proliferative diseases with atypia: atypical ductal and lobular hyperplasia: RR = 4–5 Lobular carcinoma *in situ*: RR = 8–10

BMI, body mass index; *BRCA*, breast cancer; HRT, hormone replacement therapy; RR, relative risk.

Pathology of breast cancer

Breast carcinoma arises from the milk ducts in 90% (ductal carcinoma) or from the lobule in 10% (lobular carcinoma) of patients. The disease may remain confined to the epithelium of the duct or lobule with no breach in the basement membrane; this is called ***in situ* disease**. Infiltration of the surrounding tissue through a breach in the basement membrane leads to 'invasive or infiltrative' ductal or lobular carcinoma. The tumour may be well differentiated, moderately differentiated or poorly differentiated. The modified Bloom–Richardson scoring system for tumour grade includes the sum of individual scores for three variables (percentage of tumour cells with tubule formation, nuclear pleomorphism and the size and number of mitoses/HPF), each of which is assigned from 1 to 3 points according to the degree of deviation from normal breast epithelium. A total score of 3–5 defines grade I; 6 or 7 grade II; and 8 or 9 grade III.

Invasive carcinoma is usually of **no special type** (NST), which represents the most common variety of breast cancer. Rare histological variants, usually carrying a better prognosis, include colloid or mucinous carcinoma, whose cells produce abundant mucin; medullary carcinoma, with solid sheets of large cells often associated with a marked lymphocytic reaction; and tubular carcinoma. The papillary type of carcinoma (both *in situ* and invasive) is a rare type of breast cancer accounting for 0.5–1% of all neoplasms. The lesion is characterised by papillomas with a fibrovascular core and surface covered by epithelial and myoepithelial cells. It usually carries a better prognosis and rarely spreads to lymph nodes and the bloodstream. The tumour cells may overexpress oestrogen receptors (ER positive), progesterone receptors (PR positive), human epidermal growth factor receptor 2/neu (HER2/neu positive) and androgen receptors (AR positive). The degree of mitosis can be detected by the Ki-67 mitotic index.

Gene array analysis has identified five major subtypes: luminal A, luminal B, basal, HER2/neu receptor enriched and a normal-like group (***Table 58.4***). In the absence of gene array testing such as prediction analysis of microarray-50 (PAM-50), immune histochemical receptor staining serves as a surrogate marker of molecular subtypes.

TABLE 58.4 Molecular classification of breast cancer.

Classification	Hormone receptor	HER2/neu	Others
Luminal A	Positive (either or both ER/PR)	Negative	Ki-67 low
Luminal B	Positive (either or both ER/PR)	Negative	Ki-67 high
Basal type (triple negative)	Negative	Negative	Ki-67 usually high
HER2/neu enriched	Negative	Positive	Ki-67 high
Claudin low	Negative	Negative	Claudin low

ER, oestrogen receptor; HER2/neu, human epidermal growth factor receptor 2/neu; PR, progesterone receptor.

Harris JG Bloom, 1923–1988, radiation oncologist, Royal Marsden Hospital, London, UK.
William W Richardson, 1915–2005, pathologist, Middlesex Hospital, London, UK, published a paper with Bloom on the natural history of breast cancer in 1957.

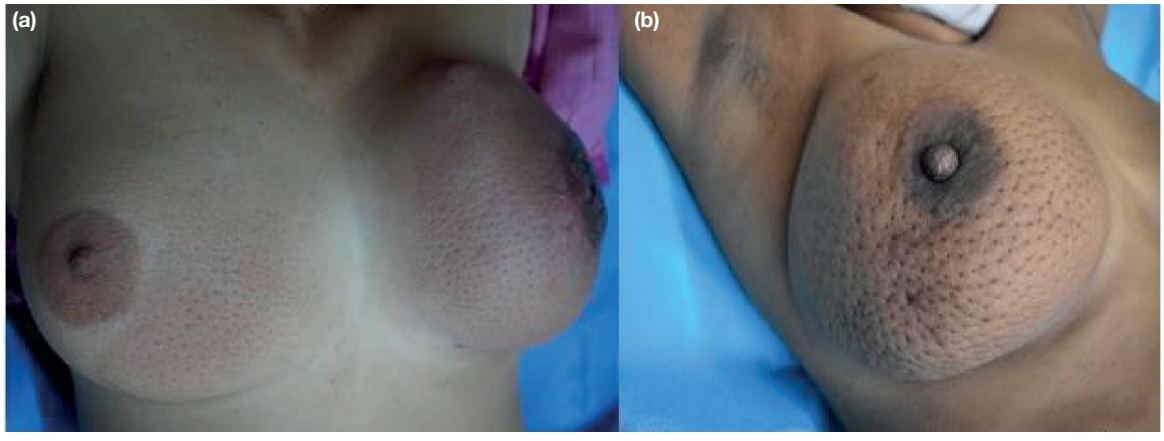

Figure 58.28 (a) Diffuse redness (erythema) and skin oedema involving more than one-third of the breast, with an enlarged left breast – features of inflammatory carcinoma. **(b)** Peau d'orange refers to the orange peel appearance of the skin of the breast and is a sign of locally advanced disease. Note that in people with darker skins the erythema takes on a brownish hue.

Spread of cancer

Local spread

The tumour increases in size and invades adjacent breast parenchyma. It may involve the skin, leading to ulceration and satellite nodules, and/or involve pectoralis major, serratus anterior and even the chest wall. The tumour cells release a number of growth factors; namely, fibroblast growth factor (FGF), transforming growth factor (TGFα and TGFβ) and vascular endothelial growth factor (VEGF). FGF induces mitosis of adjacent fibrocytes, which convert to fibroblasts and lay down collagen (desmoplastic reaction). Contraction of collagen leads to shortening of Cooper's ligament, pulling the skin inwards and giving rise to the telltale signs of dimpling (shortened single Cooper's ligament), puckering or tethering (many Cooper's ligaments shrunken) or nipple retraction.

Lymphatic metastasis

This occurs mainly to axillary lymph nodes. Tumours from the inner half of the breast may also spread to the internal mammary nodes. Involvement of the contralateral lymph nodes in the absence of a contralateral primary represents metastatic disease (***Table 58.5***).

TABLE 58.5 Causes of contralateral axillary lymph node involvement in breast cancer.

- Haematogenous spread from the contralateral primary
- Spread of cancer from one breast to another via subdermal lymphatics in front of the sternum
- Spread of cancer from one breast to the other via the ipsilateral internal mammary nodes → interconnecting lymphatics behind the sternum → the contralateral internal mammary nodes → the other breast → the opposite axillary nodes
- Tumour developing in an epithelial embryonic cell rest trapped in a lymph node during embryonic development of a node (rare)
- Primary tumour of the opposite breast

Haematogenous spread

At a tumour size of 1–2 mm (10^5 cells) neoangiogenesis occurs. The onset of angiogenesis ushers in rapid growth, invasion and metastatic potential. Haematogenous metastasis occurs to the skeletal system (in order of frequency: lumbar vertebrae, neck of femur, thoracic vertebrae, rib and skull). The bony metastasis is generally osteolytic, although osteosclerotic and mixed types may be seen. Haematogenous metastasis may also occur to the liver, lungs and brain and, occasionally, the adrenal glands and ovaries. In limbs these deposits occur above the elbow and above the knee (haematopoietic vascular bone marrow is confined to the axial skeleton and in limbs above the elbows and the knees). Extensive bone marrow replacement by tumour cells may result in release of immature blast cells in the peripheral blood, giving rise to 'leukoerythroblastic anaemia'. Peripheral blood samples for circulating cell-free tumour deoxyribonucleic acid (cf-DNA) and circulating tumour cells are being studied as potential prognostic markers to predict disease recurrence.

Clinical presentation

A discrete lump in the breast is the most common presentation, and the most common tumour site is the upper outer quadrant of the breast (50% of TDLUs lie there). Other symptoms include nipple retraction, nipple discharge (blood or serous), skin changes such as ulceration, peau d'orange (***Figure 58.28***), satellite nodules or dimpling/tethering. Peau d'orange is a sign of locally advanced disease due to obstruction of cutaneous lymphatic drainage of the breast, by infiltration of either subdermal lymphatics or axillary lymph nodes by tumour cells. **Cancer en cuirasse** (***Figure 58.29***) is due to extensive tumour infiltration of the skin of the breast, chest (in cases of postmastectomy recurrence), upper limb and abdomen.

Few breast cancers in high-income countries present with either locally advanced disease or symptoms of metastatic

Alfred Armand Velpeau, 1795–1867, anatomist and surgeon, Tours, France, described cancer en cuirasse in 1838.

Figure 58.29 Cancer en cuirasse: advanced breast cancer with extensive tumour infiltration of the skin of the breast, upper limb and abdomen.

disease; however, the incidence is much greater in resource-poor countries, where up to 60% of women still present late. Enquiry should be made for the presence of any swelling in the neck or armpit and for the presence of any symptoms due to distant metastasis (bony pain, cough, breathlessness, haemoptysis, headache, visual disturbances, neurological deficit, epileptic fits, abdominal distension, jaundice, anorexia, weakness, weight loss, hypercalcaemia, etc).

Staging of breast cancer

Staging refers to the process of finding out the extent of tumour. The eighth edition of the Union for International Cancer Control (UICC)–American Joint Committee on Cancer (AJCC) TNM staging system is currently used (***Table 58.6***).

In addition to anatomical staging, the eighth edition of the AJCC TNM staging system includes the histological grade, the ER, PR, HER2/neu and Ki-67 assessment, multigene testing with Oncotype DX® and the response to neoadjuvant chemotherapy to refine the prognostic information. The key points in the eighth edition of the AJCC TNM staging system are listed in ***Summary box 58.3***.

Summary box 58.3

Key points of the eighth edition of the AJCC TNM staging system

- Lobular carcinoma *in situ* (LCIS) is a high-risk benign lesion not a cancer
- The T categorisation of multiple synchronous tumours is documented using the (m) modifier
- The prefix (y) is used to denote the post-neoadjuvant therapy status
- Satellite nodules in the skin must be separate from the primary tumour for it to be categorised as T4b
- Pathological complete response (pCR) denotes the absence of tumour cells in the breast and axillary nodes in surgical specimens
- Inflammatory carcinoma remains classified as inflammatory carcinoma after NACT, even after complete remission
- Microinvasive (T1mi) carcinomas are defined as invasive tumour foci ≤1.0 mm
- Tumours >1 mm and <2 mm should be reported as rounded to 2 mm
- Tumour size should be measured to the nearest millimetre

Work-up for metastatic breast cancer

Contrast-enhanced CT of the chest, abdomen and pelvis and an isotope bone scan are needed for patients with locally advanced breast cancer (T3, T4 or N2, N3 disease). Patients with early breast carcinoma (T1, T2 and N0, N1 disease) need metastatic evaluation only if they present with symptoms to suggest metastatic disease or raised serum alkaline phosphatase. A PET-CT scan with ^{18}F-fluorodeoxyglucose (^{18}F-FDG) tracer may be used for metastatic work-up.

Treatment of breast cancer

The treatment of breast cancer is multimodal (includes surgery, systemic treatment [chemotherapy, targeted therapy, hormonal therapy] and radiotherapy); hence, specialist breast centres employ a **multidisciplinary team** (MDT) that should include the surgeon, radiologist, pathologist, radiation oncologist, medical oncologist, plastic surgeon and allied health professionals, such as a breast care nurse, psychological counsellor and preferably a genetic counsellor (***58.7***).

While some patients with low disease burden and low biological aggressiveness can be treated with surgery followed by adjuvant therapy, others require downsizing of disease with neoadjuvant systemic therapy or primary systemic therapy.

Neoadjuvant systemic therapy (NAST) consists of **neoadjuvant chemotherapy** (NACT), targeted therapy or hormonal therapy prior to surgery. It aims to downsize the disease and enable clinicians to know the *in vivo* response of the tumour to therapy. The indications for NACT are as follows:

1. Locally advanced breast cancer T3, T4/N2, N3 disease: to downsize the tumour.
2. Select cases of early breast cancer:
   - **a** to downsize the tumour to facilitate breast conservation surgery (BCS);
   - **b** HER2/neu-positive tumours;
   - **c** triple-negative breast cancer (TNBC);
   - **d** premenopausal women (age <50 years);
   - **e** patients with axillary node metastasis.

- **Neoadjuvant targeted therapy** (trastuzumab, pertuzumab) is administered for HER2/neu-positive tumours >5 mm in diameter.
- **Neoadjuvant hormonal therapy** is offered to elderly or frail women (with ER and/or -, PR-positive advanced tumours) who are deemed unfit to receive systemic chemotherapy. Neoadjuvant hormonal treatment takes longer (around 3–6 months) for the response to become clinically evident.
- **Response assessment and timing of surgery**: the patient is examined 3 weeks after administration of

TABLE 58.6 Union for International Cancer Control–American Joint Committee on Cancer TNM staging system (eighth edition) for breast cancer.

T category	T criteria
Tx	Primary tumour cannot be assessed
T0	No evidence of primary tumour
Tis(DCIS)	Ductal carcinoma *in situ* (DCIS)
Tis(Paget's)	Paget's disease of the nipple **not** associated with (Paget's) invasive carcinoma and/or carcinoma *in situ* (DCIS) in the underlying breast parenchyma. Carcinomas in the breast parenchyma associated with Paget's disease are categorised based on the size and characteristics of the parenchymal disease, although the presence of Paget's disease should still be noted
T1	Tumour ≤20 mm in greatest dimension
T1mi	Tumour ≤1 mm in greatest dimension
T1a	Tumour >1 mm but ≤5 mm in greatest dimension (round any measurement >1.0–1.9 mm to 2 mm)
T1b	Tumour >5 mm but ≤10 mm in greatest dimension
T1c	Tumour >10 mm but ≤20 mm in greatest dimension
T2	Tumour >20 mm but ≤50 mm in greatest dimension
T3	Tumour >50 mm in greatest dimension
T4	Tumour of any size with direct extension to the chest wall and/or to the skin (ulceration or macroscopic nodules); invasion of the dermis alone does not qualify as T4
T4a	Extension to the chest wall; invasion or adherence to pectoralis muscle in the absence of invasion of chest wall structures does not qualify as T4a
T4b	Ulceration and/or ipsilateral macroscopic satellite nodules and/or oedema (including peau d'orange) of the skin that does not meet the criteria for inflammatory carcinoma
T4c	Both T4a and T4b are present T4a + T4b = T4c
T4d	Inflammatory carcinoma; peau d'orange and redness involving >1/3rd of the surface of the breast with or without a breast lump
cN category	**cN criteria**
cNx	Regional lymph nodes cannot be assessed (e.g. previously removed)
cN0	No regional lymph node metastases (by imaging or clinical examination)
cN1	Metastases to movable ipsilateral level I, II axillary lymph node(s)
cN1mi	Micrometastases (approximately 200 cells, >0.2 mm, but none >2.0 mm)
cN2	Metastases in ipsilateral level I, II axillary lymph nodes that are clinically fixed or matted; **or** in ipsilateral internal mammary nodes in the absence of axillary lymph node metastases
cN2a	Metastases in ipsilateral level I, II axillary lymph nodes fixed to one another (matted) or to other structures
cN2b	Metastases only in ipsilateral internal mammary nodes in the absence of axillary lymph node metastases
cN3	Metastases in ipsilateral infraclavicular (level III axillary) lymph node(s) with or without level I, II axillary lymph node involvement; **or** in ipsilateral internal mammary lymph node(s) with level I, II axillary lymph node metastases; **or** metastases in ipsilateral supraclavicular lymph node(s) with or without axillary or internal mammary lymph node involvement
cN3a	Metastases in ipsilateral infraclavicular lymph node(s)
cN3b	Metastases in ipsilateral internal mammary lymph node(s) and axillary lymph node(s)
cN3c	Metastases in ipsilateral supraclavicular lymph node(s)
M category	**M criteria**
M0	No clinical or radiographic evidence of distant metastases
cM0(i+)	No clinical or radiographic evidence of distant metastases in the presence of tumour cells or deposits <0.2 mm detected microscopically or by molecular techniques in circulating blood, bone marrow or other non-regional nodal tissue in a patient without symptoms or signs of metastases
cM1	Distant metastases detected by clinical and radiographic means

c, clinical.

the second cycle of NACT. Response evaluation criteria in solid tumours (RECIST) are used for reporting the response to NAST. The four RECIST categories are:

- complete response (CR) (lesion not detectable on clinical palpation and imaging);
- partial response (PR) (≥30% reduction in the maximal diameter);
- stable disease (SD) (<30% reduction in maximal diameter);
- progressive disease (PD) (≥20% increase in the maximal diameter).

For patients with CR and PR, the entire chemotherapy regimen may be delivered prior to surgery. If the patient is being planned for BCS, a radio-opaque clip or magnetic marker such as Magseed® is placed under image guidance in the epicentre of the tumour to allow identification at the time of surgery should there be a complete response to NACT. If the facility for clip placement is unavailable, in place of the metal clip a 0.5-cm piece of silicone or a polyvinylchloride (PVC) catheter tip may be inserted through a small skin incision just anterior to the tumour. This catheter tip remains palpable even after complete regression of the tumour and helps the surgeon in performing removal of the index area for BCS, excising 2 cm of tissue all around this catheter. For patients showing stable or progressive disease, after the initial two cycles of chemotherapy, the patient should undergo surgery and be given second-line chemotherapy after surgery.

Surgical management

Surgery plays a central role in the management of breast cancer. There has been a general de-escalation towards more conservative techniques, backed up by clinical trials and meta-analyses showing equal efficacy in locoregional cancer control and survival between mastectomy and WLE/BCS followed by radiotherapy.

The aim of surgery is to remove all disease in the breast and axilla with negative margins. The pathologist reports the distance of the tumour to the nearest excision margin in the breast specimen. Indelible India ink is applied on the specimen surfaces. There should be no tumour cells on the cut edge or 'inked margins' of the tumour for invasive cancer. However, in patients with DCIS a minimum of 2 mm is considered a safe margin.

Early breast cancer (stages 0, I, II)

The surgical options for the primary tumour include mastectomy or BCS.

Mastectomy is indicated for large tumours (in relation to the size of the breast), multicentric disease, diffuse microcalcification on a mammogram indicative of DCIS, *BRCA*-positive cancers, local recurrence following BCS or the patient's preference. It entails removal of the entire breast tissue, including the skin over the tumour, the nipple–areola complex and the axillary tail. The breast tissue usually extends to a point where the anterior premammary fascia fuses with the posterior pectoral fascia. Therefore, the surgeon should remove the breast to the point of fusion between these two fasciae, which usually extends to the level of the second rib above, to the parasternal edge medially, to the inframammary crease below and to the anterior border of latissimus dorsi laterally. This is different from the traditional view of raising flaps up to the inferior border of the clavicle superiorly and 2–3 cm below the inframammary crease (or up to the upper fibres of the external oblique muscle/rectus abdominis) inferiorly. The radical mastectomy (Halsted) included excision of the breast, all the axillary lymph nodes and both the pectoralis major and minor muscles. It is rarely indicated as it causes excessive morbidity owing to the limitation in movement at the shoulder joint, extensive upper limb lymphoedema, pain and chest wall deformity with no survival benefit compared with less radical surgery. The modified radical mastectomy (MRM) entails mastectomy along with removal of the level I, II and III axillary lymph nodes.

Skin- and nipple-sparing mastectomy is an option in DCIS and early breast cancers where a mastectomy is indicated and the tumour is >1 cm away from the skin and >2 cm away from the nipple. The breast may then be reconstructed using autologous tissue flaps/fat or a silicone breast implant.

Breast conservation surgery (BCS) is aimed at removing the tumour along with a 1-cm margin of normal breast tissue. It is important to orient the surgical specimen with sutures: long lateral ('L' for 'lateral') and short superior ('S' for 'superior'). This is important if one or more margins is positive on histological examination. Patients with involved margins should have a revision of margins called a 'cavity shave'. All patients with BCS receive radiotherapy. BCS together with radiotherapy is called **breast conservation therapy** (BCT): BCS + RT = BCT. BCS is, however, best avoided in patients with a multicentric tumour, diffuse microcalcifications on a mammogram, a large tumour-to-breast ratio, two times positive surgical margins after re-excision, a history of previous breast or chest wall radiation, systemic lupus erythematosus or other collagen vascular disease (these patients have a high risk of a radiation reaction), or ankylosing spondylitis; it is also best avoided in those with severe orthopnoea (as the patient cannot lie on the radiation table).

Wide local excision (WLE) of up to 20% of the breast volume can be achieved by excision of the tumour with adequate margins and closure of the defect by approximation of the breast tissue with absorbable sutures. Volume loss greater than 20% or an unfavourable breast-to-tumour ratio requires an **oncoplastic procedure** to fill the defect so created by mobilising the breast tissue.

Oncoplasty is defined as tumour excision with wide margins followed by repair of the defect by local rearrangement/replacement of the breast tissue and the nipple–areola complex to maintain shape and symmetry. This may be achieved by **volume displacement** (level 1) (***Figures 58.30 and 58.31***) or by **volume replacement** using a distant or local flap (level 2) (***Figure 58.32***) (***Summary box 58.4***).

William Stewart Halsted, 1852–1922, Professor of Surgery, Johns Hopkins Medical School, Baltimore, MD, USA

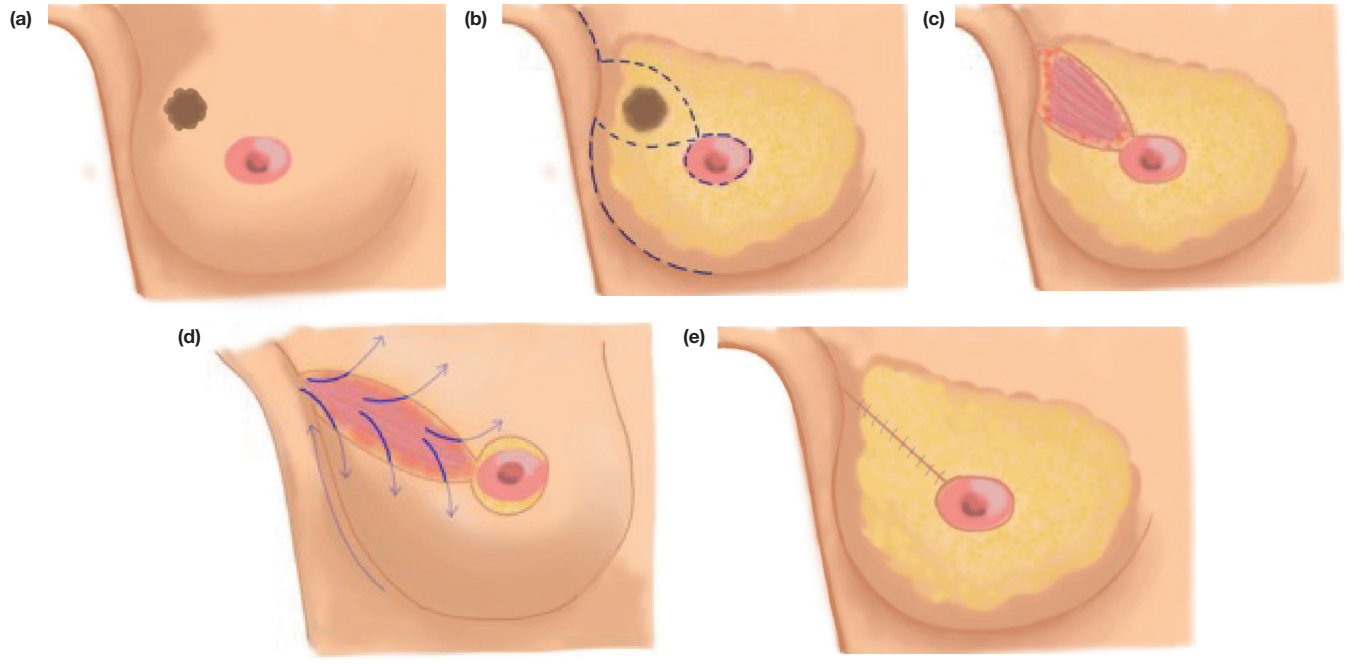

Figure 58.30 Volume displacement oncoplasty for an upper outer quadrant tumour **(a)**. Skin incision markings extending to the periareolar and the lateral mammary crease **(b)**. Full-thickness excision of the tumour with 1-cm margins **(c)**. Dermoglandular pillar mobilisation from the lower outer quadrant of the breast to fill the defect cavity **(d)**. Final sutured wound **(e)**.

Figure 58.31 A patient with volume displacement with round-block oncoplasty for a right breast tumour.

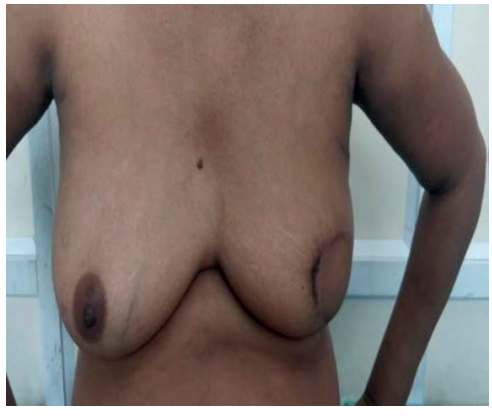

Figure 58.32 A patient with volume replacement oncoplasty with a muscle-sparing latissimus dorsi muscle flap reconstruction for a left breast tumour.

Surgery for the axilla

The role of axillary surgery is to stage the patient (sentinel lymph node biopsy [SLNB]) and to treat disease by axillary lymph node dissection (ALND) for patients with positive axillary nodes (*58.8)*.

Sentinel lymph node biopsy. Sentinel means 'a guard'. Like a guard, the first echelon/level of axillary lymph nodes is located at the gateway of the axilla and provides information about the status of axillary node metastasis. The sentinel lymph node refers to the first echelon lymph node in the axilla draining the breast. The sentinel lymph node is identified by the injection of a blue dye (patent blue or methylene blue) and radioisotope technetium-99m-labelled albumin/sulphur colloid/antimony in the breast. The fluorescent dyes fluorescein or indocyanine green can be used if radioisotope is not available. The combination of fluorescein and methylene blue can detect sentinel nodes with >90% identification. Indocyanine green can detect sentinel nodes with 95–100% identification. The dye may be injected into the peritumoral tissue or the periareolar, subareolar or intradermal plane. The tracer(s) passes through lymphatics to the sentinel node and is detected visually as a blue-coloured node and/or a hot node (radioactive) with a handheld gamma ray detection probe or as a fluorescent node with blue light (480 nm for fluorescein) or infrared light (780 nm for indocyanine green) (***Figure 58.33***). The *ex vivo* count of the hot lymph node(s) is noted. All lymph nodes with >10% of the *ex vivo* count of the hottest node and blue lymph nodes are removed and sent for histological confirmation of nodal metastasis. This may be done with

Summary box 58.4

Surgical techniques used to treat breast cancer

Modified radical mastectomy	Mastectomy + level I, II, III axillary lymph node dissection: pectoralis minor muscle is removed in Patey/Madden, retracted in Auchincloss and is divided but not removed in Scanlon modifications
Simple or total mastectomy	Mastectomy including axillary tail without axillary surgery
Skin-sparing mastectomy	Mastectomy: breast skin envelope is preserved, nipple–areola complex removed
Skin + nipple/areola-sparing mastectomy	Mastectomy: breast skin envelope and nipple–areola complex are preserved
WLE (synonyms lumpectomy; breast conservation surgery, BCS)	Removal of tumour with a three-dimensional clearance of a 1-cm margin of normal tissue
Quadrantectomy	Removal of the tumour-containing quadrant of the breast
Level I oncoplasty	Volume displacement technique involves dual-plane mobilisation of the breast parenchyma (i.e. the dermoglandular plane and the plane between breast parenchyma and pectoralis muscle) to close the defect created after WLE
Level II oncoplasty	More complex procedures that involve skin excision and glandular mobilisation to allow major volume resection, usually more than 20% of breast volume

frozen-section analysis, touch imprint cytology or by molecular methods (GeneSearch Breast Lymph Node Assay™). These methods involve homogenising the node and detecting a gene expression of cytokeratin 19 or mammaglobin by RT-PCR.

Frozen-section evaluation of sentinel nodes has a false-negative rate of 10–12%. Wherever the facility for frozen section is not available, the sentinel node should be sent for formalin-preserved paraffin section processing and haematoxylin and eosin staining.

SLNB is contraindicated in patients with inflammatory breast cancer and in those with T4 disease or a history of previous breast or chest wall surgery, breast scarring (burns) or radiotherapy.

Axillary lymph node dissection. This is indicated for staging and local disease control in patients with axillary lymph node-positive tumours that are clinically and/or biopsy-proven non-palpable nodes and those with three or more sentinel lymph nodes that are positive for macrometastasis.

ALND requires careful anatomical dissection to protect the axillary vein, thoracodorsal vessels, medial and lateral pectoral nerves, intercostobrachial nerves and the long thoracic and thoracodorsal nerves. The intercostobrachial nerve may be divided in the presence of heavy nodal burden to achieve oncological clearance. Level I and II nodes are routinely removed (***Figure 58.34***). Level III axillary dissection is reserved for patients who have enlarged level I and II lymph nodes.

Breast reconstruction

Immediate breast reconstruction offers the advantage of women waking up after surgery with a breast mound. Some women may prefer to undergo delayed reconstruction 6–12 months after completion of their adjuvant treatment.

Immediate reconstruction can be performed using silicone gel breast implants or autologous tissue. Silicone gel implants can be placed superficial to (prepectoral) or underneath

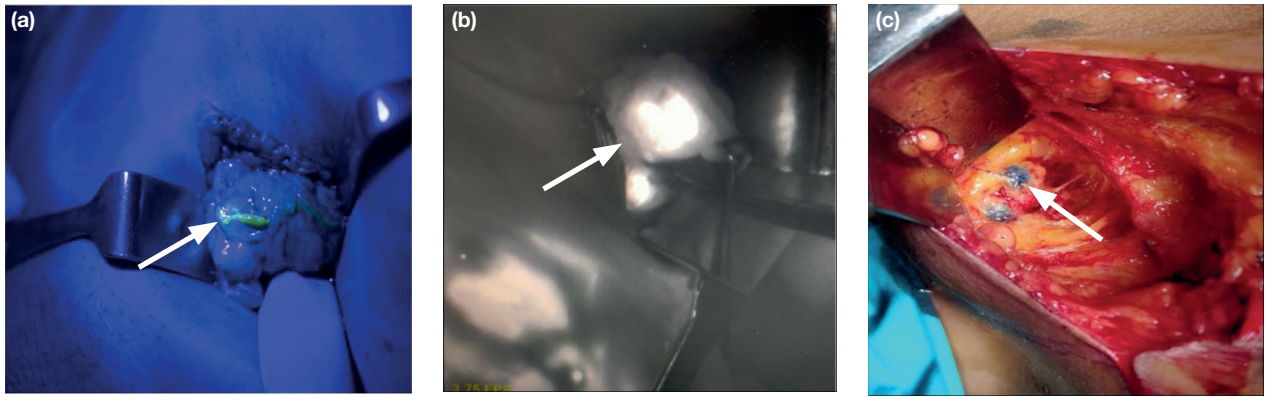

Figure 58.33 Sentinel lymph node biopsy done using **(a)** fluorescein dye – the fluorescent sentinel lymph node is seen with blue light; **(b)** indocyanine green – the fluorescent sentinel lymph node is seen using infrared imaging with a 'spy camera'; **(c)** blue dye (methylene blue) – blue sentinel lymph nodes and lymphatics are seen in the axilla. Sentinel lymph nodes are marked with an arrow.

Hugh Auchincloss, 1915–1998, surgeon, Columbia College of Physicians and Surgeons, New York, NY, USA.
Edward F Scanlon, 1919–2008, surgeon, Evanston, IL USA.

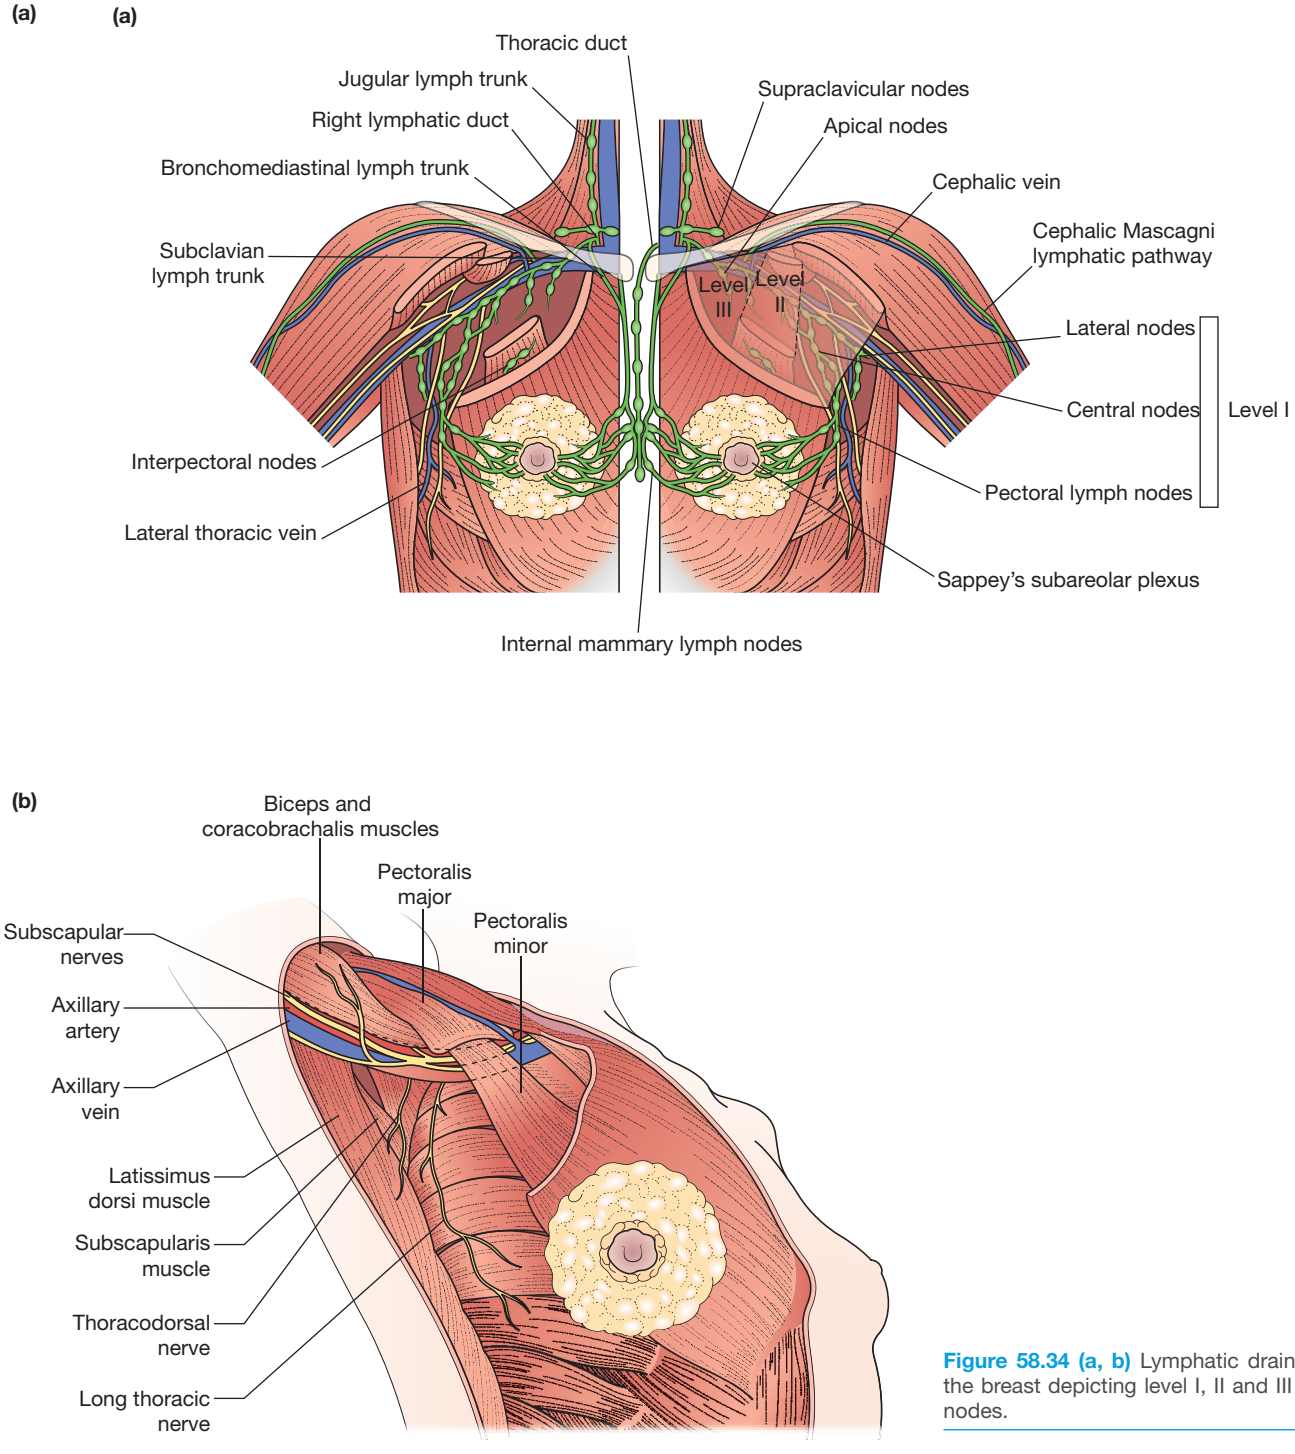

Figure 58.34 (a, b) Lymphatic drainage of the breast depicting level I, II and III lymph nodes.

(subpectoral) the pectoralis major muscle. The tissue flaps commonly used include the latissimus dorsi (***Figure 58.35***), the transverse rectus abdominis myocutaneous (TRAM) (***Figure 58.36***), the anterolateral thigh and the deep inferior epigastric perforator (DIEP) free tissue transfers (***Figure 58.37***). The DIEP flap is commonly used in the UK. It requires microvascular surgical skills and an operative time of about 4 hours. The treatment algorithm for breast reconstruction is set out in ***Figure 58.38***.

Radiotherapy after insertion of a silicone prosthesis often leads to a high incidence of capsular contracture and unacceptable results.

To achieve symmetry after breast reconstruction or BCS, the opposite breast may require a cosmetic procedure such as

Paolo Mascagni, 1755–1815, Italian physician and anatomist, published the first complete description of the lymphatic system.

Figure 58.35 Reconstruction with latissimus dorsi flap.

Figure 58.36 Transversus abdominus muscle flap.

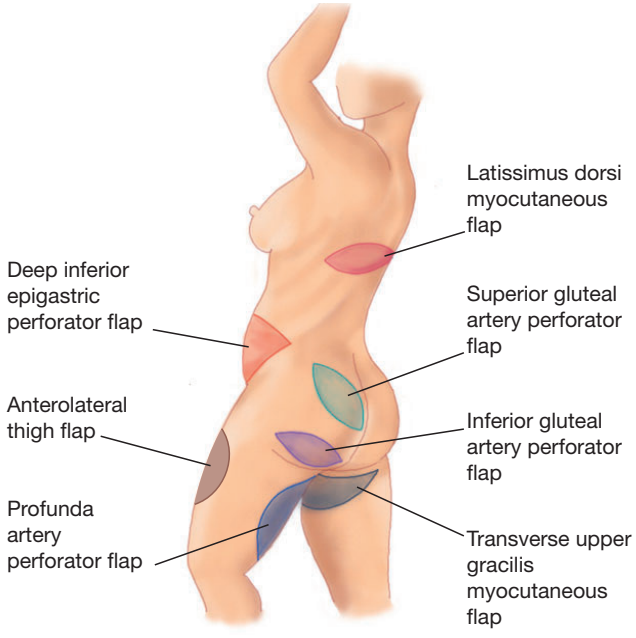

Figure 58.37 Autologous tissue options for breast reconstruction.

reduction or augmentation mammoplasty or mastopexy. The patient needs to be informed that she may require more than one procedure for **symmetrisation**.

Surgical options for locally advanced breast cancers (stages IIIA, IIIB)

Following NACT patients should be offered the option of mastectomy or BCS, if suitable (***Figure 58.38***). Patients with initial skin or chest wall involvement and those with inflammatory carcinoma should undergo MRM (***58.9***).

The role of SLNB in patients with cT3N0 disease and those who become N0 after NACT is currently being studied in a number of trials. A high false-negative rate (>10%) has been reported; this can be reduced if at least three sentinel nodes are removed using dual tracers or using 'targeted SLNB'. In the targeted technique, a metal clip or permanent India ink is applied to a positive node prior to NAST. During surgery after NAST, the node containing the clip or India ink is removed along with SLNB.

Adjuvant treatment

Radiotherapy

Radiotherapy is shown to decrease the risk of locoregional and systemic recurrence and improve survival. The indications include the following:

- patients with locally advanced breast cancers T3, T4, N1, N2, N3 disease;
- following BCS;
- after mastectomy if:
  - tumour size ≥5 cm; skin or chest wall involvement; lymphovascular invasion (LVI), grade 3;
  - axillary lymph node positive for metastasis.

In pathologically lymph node-negative tumours, radiotherapy after BCS is given to the breast only as a dose of 45–50.4 Gy (with or without a boost) delivered in 25 fractions or of 40–42.5 Gy delivered in 15 or 16 fractions (hypofractionation). In patients after mastectomy (T3N0M0), chest wall radiotherapy is given if the sentinel lymph nodes are negative. In patients with lymph node-positive disease locoregional radiotherapy is given covering the chest wall, supraclavicular region, internal mammary nodes and the axilla. The axilla should not be irradiated after axillary node dissection as this increases the risk of lymphoedema.

Accelerated partial breast irradiation (APBI) is a modality of radiotherapy for selected patients meeting the following

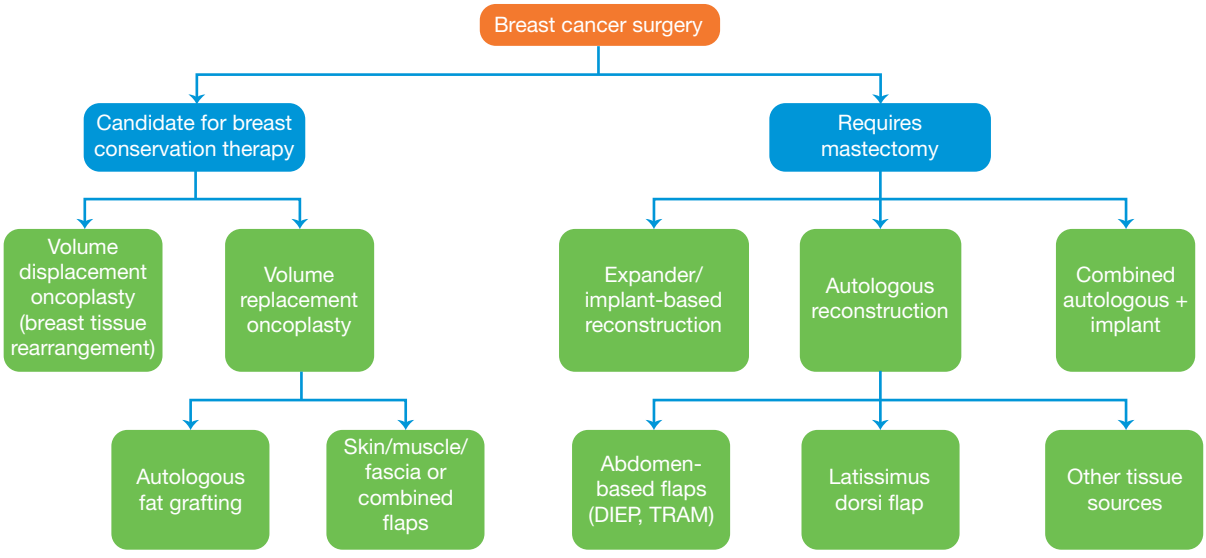

Figure 58.38 Surgical options in women undergoing breast-conservating surgery and reconstructive options for women requiring mastectomy. DIEP, deep inferior epigastric perforator; TRAM, transverse rectus abdominis myocutaneous.

criteria (American Society for Radiation Oncology ABPI guidelines, 2016):

- women 50 years or older with T1 disease and negative resected margins with a margin width of ≥2 mm, invasive ductal carcinoma, no LVI, ER positive, *BRCA* negative and sentinel node negative;
- women 50 years or older with low-risk DCIS (screen detected, low/intermediate nuclear grade, tumour size ≤2.5 cm, negative resected margin widths ≥3 mm).

The tumour bed is irradiated along with a narrow rim of surrounding tissue so as to avoid the potentially harmful effects of irradiation on healthy tissue. It is delivered twice daily for 5 days.

Adjuvant systemic therapy

The purpose of adjuvant systemic therapy is to control putative micrometastases, delay relapse and prolong survival. The results of many international clinical trials, including National Surgical Adjuvant Breast and Bowel Project (NSABP) trials and the Oxford overview meta-analyses by the Early Breast Cancer Trialist Collaborative Group (EBCTCG), demonstrate the benefit of chemotherapy in improving relapse-free survival by approximately 30% and overall survival by 10% at 15 years.

Chemotherapy. This is the most common systemic treatment for breast cancer. The following regimens are used:

- cyclophosphamide (C), methotrexate (M) and 5-fluorouracil (F) (CMF);
- anthracycline-based regimens: CAF (A, Adriamycin [doxorubicin]), CEF (E, epirubicin);
- taxane (docetaxel, paclitaxel)-based regimens.

Adjuvant chemotherapy is indicated for all invasive carcinomas >1 cm in diameter, tumours >0.5 cm with poor prognostic factors (presence of LVI, high grade, HER2/neu positive, TNBC) and node-positive tumours. Currently, decisions to administer chemotherapy as well as to choose a particular regimen are based on tumour stage, tumour biology and discussion with the patient and/or care giver in an MDT.

Gene signature panels help in assessing the benefit of chemotherapy in low-risk tumours, i.e. ER-positive, HER2/neu-negative and node-negative tumours. The risk of recurrence (ROR) scores include Oncotype Dx® (21-gene recurrence score), Prosigna® PAM-50 (breast cancer prognostic gene signature) and MammaPrint® (70-gene breast cancer recurrence assay). Oncotype Dx® is the most widely used ROR score and measures the expression of 16 cancer-related genes and five reference genes on paraffin-embedded tumour tissue. The assay classifies the ROR score as low (<18), moderate (19–30) or high (>30). In patients with a low ROR score, chemotherapy can be avoided.

In patients with endocrine-responsive breast cancer, those with **luminal A tumours** may avoid chemotherapy if they have a low-risk score on Oncotype Dx® and/or clinical risk assessment online tools (e.g. https://breast.predict.nhs.uk/tool); however, patients with a high clinical and genomic risk should be considered for chemotherapy with an anthracycline (epirubicin) or taxane-based therapy. Patients with **luminal B tumours** should receive an anthracycline and/or taxane-based therapy because of the greater risk of relapse. Those with **HER2/neu-positive tumours** should receive trastuzumab+pertuzumab along with chemotherapy (taxane + anthracycline), while those with **triple negative tumours** should receive chemotherapy (taxane + anthracycline). Carboplatin-based regimens may be beneficial for tumours with aggressive biology.

Targeted therapy. The monoclonal antibody trastuzumab (Herceptin®) is effective against the HER2/neu receptor. It is used along with pertuzumab to treat HER2/neu-positive

tumours along with chemotherapy. The cytotoxic agent T-DM1 is used in HER2/neu-positive disease: a chemotherapy agent, emtansine, is conjugated to trastuzumab to allow targeted delivery of the chemotherapy to HER2-positive cells.

Hormone therapy. The selective oestrogen receptor modulator tamoxifen and aromatase inhibitors (anastrozole, letrozole, exemestane) are used for hormonal therapy in breast cancer. In premenopausal patients only tamoxifen is used for 5 years in low-risk patients and for 10 years in patients with a high risk of relapse (node positive, tumour >5 cm, LVI).

Aromatase inhibitors are used in postmenopausal women; in an adjuvant setting they have shown beneficial effect compared with tamoxifen in terms of relapse-free survival and overall survival. They are more expensive than tamoxifen and their use is associated with bone density loss and risk of fracture. A bone density scan is advised prior to commencement of treatment with aromatase inhibitors. Bisphosphonates with vitamin D and calcium are used to restore bone loss and may also reduce the risk of recurrence.

Follow-up of operable breast cancer

Follow-up after initial therapy routinely includes clinical examination every 3 months for 2 years, followed by every 6 months for the next 3 years. Thereafter the follow-up is scheduled yearly. A mammogram is also scheduled yearly. Patients with an implant and those with *BRCA* or other genetic mutations need contrast breast MRI annually. Development of any new symptom or sign during follow-up merits detailed clinical evaluation and relevant investigation. Patients presenting with metastatic disease and those with a local/systemic recurrence are seen more frequently depending on the clinical condition.

Metastatic carcinoma of the breast (stage IV)

Treatment of metastatic cancer is aimed at palliating symptoms, improving quality of life, preventing potential disabling complications and attempting to prolong life.

Endocrine therapy for hormone receptor-positive disease is preferred for patients with bony metastasis and limited visceral metastasis. Systemic chemotherapy is preferred for patients with hormone receptor-negative cancers, hormone-refractory metastases and patients with visceral crisis. Oral low-dose metronomic chemotherapy has cytostatic and antiangiogenic effects and may help in improving quality of life.

Patients with bony metastasis should receive palliative radiotherapy to lesions in weight-bearing areas (e.g. vertebra, femur) and to painful bony deposits, along with bisphosphonates. Symptomatic pleural effusions are palliated by intercostal chest drainage and pleurodesis. Surgical resection of metastatic lesions may be indicated in solitary visceral metastasis in patients with good performance status and favourable tumour biology.

Management of local recurrence

The local recurrence should be biopsied as a change in receptor status may occur and influence further therapy. Whole-body MRI or PET-CT scan should be performed to detect metastasis. Systemic chemotherapy should be followed by surgical excision. Most surgeons perform a mastectomy for recurrence; however, second BCS and re-radiotherapy may be considered.

Hereditary and familial breast cancer

Hereditary breast cancer (HBC) runs in families, affecting several close relatives, and is associated with an identifiable genetic mutation. **Familial breast cancer** (FBC) affects several members of a family but is not attributable to any known genetic mutation. HBC accounts for 5–10% and FBC for 20–30% of all breast cancers. HBCs are more aggressive, present at an earlier age and are more often multicentric and bilateral. High-penetrance mutations are found in *BRCA1*, *BRCA2*, Li–Fraumeni syndrome, Cowden syndrome, Peutz–Jeghers syndrome and hereditary gastric cancer syndrome.

BRCA1 (17q21) is associated with a 50–85% lifetime risk of developing breast cancer and up to a 40% risk of ovarian cancer. The breast cancers in *BRCA1* are mostly TNBC. ***BRCA2*** (13q12.3) is associated with an up to 50–60% lifetime risk of breast cancer and a 20% risk of ovarian cancer. It is also associated with cancer of the prostate, colon, gallbladder, bile duct, stomach and pancreas. *BRCA* mutation is more common in males with breast cancer. Genetic risk evaluation should be considered in high-risk individuals (***Summary box 58.5***).

Women with a *BRCA* mutation may be offered a bilateral risk-reducing mastectomy with immediate breast reconstruction. This reduces the risk of breast cancer by 90%. Chemoprophylaxis with tamoxifen or anastrozole may reduce the risk to 50%. Premenopausal women may be offered bilateral salpingo-oophorectomy after they have completed their family at around 35–40 years of age.

Breast cancer in pregnancy

Pregnancy is associated with aggressive tumour biology such as TNBC. Ultrasonography of the breast, mammogram and chest radiograph with abdominal shielding of the fetus may be considered. In cases where bone or brain metastasis is suspected or other investigations are inconclusive, MRI without gadolinium contrast should be used. CT and PET-CT should be avoided (high radiation dose). Genetic counselling should be offered. Surgery can be performed in any trimester.

Frederick Pei Li, 1940–2015, Dana–Farber Cancer Institute, Boston, MA, USA, and **Joseph F Fraumeni Jr**, b. 1933, National Institutes of Health, Washington, DC, USA, in 1969 identified four families with increased susceptibility to cancer. This led to the discovery of mutation in the tumour suppressor gene *p53*.

Cowden syndrome was named after Rachel Cowden, in whom the features were first recognised.

Jan Peutz, 1886–1957, Dutch physician, documented the eponymous condition.

Harold Joseph Jeghers, 1904–1990, Boston, MA, USA, recognised the eponymous syndrome.

Summary box 58.5

Indications for genetic risk evaluation

- An individual at any age with a known pathogenic/likely pathogenic variant in a cancer susceptibility gene within the family
- Breast cancer diagnosed age ≤50 years
- TNBC diagnosed age ≤60 years
- Two breast cancer primaries
- Breast cancer at any age with one or more relative with breast cancer diagnosed ≤50 years, invasive ovarian cancer, male breast cancer, pancreatic cancer, high-grade or metastatic prostate cancer
- Breast cancer at any age with two or more affected relatives
- Male breast cancer
- An individual with a personal or family history of three or more of the following:
  - Breast cancer, sarcoma, adrenocortical carcinoma, brain tumour, leukaemia
  - Colon cancer, endometrial cancer, thyroid cancer, kidney cancer, dermatological manifestations, macrocephaly or hamartomatous polyps of the gastrointestinal tract
  - Lobular breast cancer, diffuse gastric cancer
  - Breast cancer, gastrointestinal cancer or hamartomatous polyps, ovarian sex chord tumours, pancreatic cancer, testicular Sertoli cell tumours or childhood skin pigmentation

Mastectomy is preferred during the first and second trimester as the delay in administering radiotherapy until delivery may be associated with a higher risk of recurrence in the breast. SLNB with low-dose technetium-tagged sulphur colloid is considered safe for the fetus. Chemotherapy should not be administered during the first trimester (period of organogenesis) but can be safely administered during the second and third trimesters (until 34 weeks to allow haematological recovery at the time of delivery). Anthracyclines and taxanes remain the preferred agents. 5-Fluorouracil should be avoided. Anti-HER2/neu and endocrine therapy should be given after delivery, as indicated.

Carcinoma of the male breast

Carcinoma of the male breast (***Figure 58.39***) accounts for less than 0.5% of cases of breast cancer. The most common symptom at presentation is a painless subareolar lump. Involvement of the nipple–areolar complex and underlying pectoral muscles occurs early. Treatment comprises mastectomy with a 2-cm margin along with a portion of underlying pectoralis major muscle followed by radiotherapy. SLNB should be performed in node-negative patients. Tamoxifen 20 mg daily for 5 years is recommended for those with ER-positive tumours.

Sarcoma

Sarcomas, most commonly fibrosarcoma and angiosarcoma, may arise *de novo* from the mesenchymal tissues of the breast.

Figure 58.39 Carcinoma of the male left breast (courtesy of Professor Mike Dixon).

Summary box 58.6

Prognosis

Disease factors	Patient factors
• Size of tumour[a] • Stage of disease • Axillary lymph node involvement[a] • Grade of tumour[a] • Histopathological variant (metaplastic carcinoma is aggressive): ◦ Her2/neu positive and triple negative ◦ Presence of lymphovascular invasion ◦ Extensive DCIS component ◦ High Ki-67 index	• Younger age • Premenopausal women • *BRCA*-associated tumour • Family history of breast cancer • Prior history of breast cancer • Obesity, sedentary lifestyle • Failure to complete intended treatment

DCIS, ductal carcinoma *in situ*.
[a]The Nottingham prognostic index (NPI) is used to determine prognosis following surgery. It is calculated using tumour size (S), number of involved lymph nodes (N) and tumour grade (G). NPI = (0.2 × S) + N + G. Patients are grouped into four categories according to the NPI score: I (excellent) ≤2.4; II (good) >2.4 but ≤3.4; III (moderate) >3.4 but ≤5.4; and IV (poor) >5.4.

Some genetic conditions (Li–Fraumeni, neurofibromatosis type 1), exposure to alkylating agents, vinyl chloride or arsenic, prior radiotherapy (e.g. for Hodgkin's lymphoma) and chronic lymphoedema are associated with the development of sarcoma.

Angiosarcoma (***Figure 58.40***) is the most aggressive of all breast tumours and arises from the endothelial cell lining of vascular or lymphatic channels. Angiosarcoma is associated with prior radiotherapy and carries a very poor prognosis.

Screening for breast cancer

Screening for breast cancer involves a highly sensitive diagnostic test to detect the disease in either the preclinical detectable phase or a high-risk precancerous lesion. In most

Enrico Sertoli, 1842–1910, Italian physiologist, discovered the Sertoli cells of the testis in 1865.
Thomas Hodgkin, 1798–1866, lecturer in morbid anatomy and curator of the museum, Guy's Hospital, London, UK, described Hodgkin's lymphoma in 1832.

Figure 58.40 Angiosarcoma of the breast in a young woman.

high-income countries population-based mammographic screening achieves very high (90–95%) long-term survival in patients with screen-detected tumours. In the UK, all women aged between 50 and 70 years are invited for mammographic screening every 3 years. In low- and middle-income countries, population-based mammographic screening is not available. In some Asian countries clinical breast examination by a trained healthcare professional along with increasing breast health awareness by breast self-examination is being encouraged as a mode of screening. In India, national screening involves multidisease screening for cancer of the mouth, breast and cervix for all women aged 30–65 years. Clinical breast examination can detect the disease in the early stages while breast self-examination can help women become aware of breast health, detect breast changes and report to the healthcare facility early.

Patients with a suspicious lesion on mammogram are invited for biopsy under image guidance. In small or impalpable lesions a metal clip may be inserted at the site of the lesion. If a carcinoma is found on histology, the metal clip facilitates insertion of a hook wire with its tip near the centre of the lesion to facilitate wire-guided excision. Further therapy is based on histology of the excised specimen after discussion in the MDT.

ACKNOWLEDGEMENTS

The authors are grateful to Professors Smriti Hari and Maneesh Singhal from the All India Institute of Medical Sciences (AIIMS), New Delhi, India, for their assistance in providing illustrations used in the chapter, and to Dr Shivangi Saha of AIIMS, New Delhi, for her contribution to the breast reconstruction section and illustrations. Professor V Seenu of AIIMS critically reappraised the section on sentinel node biopsy. Professor Sandeep Kumar provided insight and critical reappraisal of the section on ANDI and benign breast disease. Dr Deepti Singh helped in the section on mastitis. Professor Manoj Kumar Singh and the team of artists at Virtual Skills Laboratory, AIIMS, designed most of the illustrations and videos for this chapter.

PART 9 | Cardiothoracic

CHAPTER 59

Cardiac surgery

Learning objectives

To provide an overall view of:

- The principles of cardiopulmonary bypass
- Incisions, conduits and valve options in cardiac surgery
- The role of investigation and preoperative assessment in planning surgery
- The management of coronary heart disease
- The role of surgery in valvular heart disease
- The role of surgery in congenital heart disease
- The management of aortic pathology
- The management of pericardial disease
- The principles of cardiopulmonary resuscitation after cardiac surgery

INTRODUCTION

Cardiac surgery has developed at a rapid pace since the first procedures in the 1920s. Driven by trauma innovations during the post-war period, the specialty has seen a massive expansion in the range and complexity of conditions treated.

Initially thought to be inoperable, surgery for both acquired and congenital heart disease is now commonplace. There are a variety of techniques to address both ischaemic heart disease (IHD) and valvular disease. These are often performed in conjunction with cardiology colleagues, and minimally invasive approaches are now complementary to surgical techniques.

Surgical correction of congenital defects has given rise to a specialty in its own right, and many patients who would previously have succumbed to heart disease in infancy now have normal life expectancy.

In addition, there are a range of allied technologies that are improving the survival of both adult and paediatric patients undergoing cardiac surgery. Transplantation, mechanical assistance devices and extracorporeal circuits are continuing to have improved outcomes and ensure that cardiac surgery is becoming accessible to more patients than ever.

HISTORICAL PERSPECTIVE

Prior to 1925, when Sir Henry Souttar reported the first mitral commissurotomy in the British Medical Journal, *heart surgery was thought to be impossible*. Souttar wrote that the heart should be as amenable to surgery as any other organ, and the main problem was maintenance of blood flow, particularly to the brain, during surgery.

The first real advances occurred in the late 1940s and early 1950s, driven by surgeons who gained confidence and experience under the pressures and opportunities provided by war. This was followed by the development of cardiopulmonary bypass (CPB) in the mid-1950s, which permitted longer, more complex surgery. Recently, the outlook of patients with congenital, valvular and degenerative heart disease has improved drastically because of advances in the range, complexity and technical expertise in cardiac surgery.

CARDIOPULMONARY BYPASS

CPB was first used successfully in 1953 by Gibbon and has since revolutionised cardiac surgery. It can be used in any procedure in which the heart and lungs need to be stopped temporarily and their function replaced artificially. Before Gibbon's work, heart surgery was mostly confined to epicardial procedures or crude trauma repair. However, valve surgery under direct vision was not possible, nor were the precise reconstructions needed to treat extensive coronary artery disease (CAD). Much of the success of modern CPB is attributable to the development of new biomaterials and sophisticated oxygenating devices, as well as a greater understanding of the pathophysiological consequences of CPB.

Surgical approach to the heart

Median sternotomy is the main approach during cardiac surgery. An incision is made from the suprasternal notch to the xiphisternum. The sternum is divided in the midline and retracted, exposing the thymus superiorly and pericardium inferiorly. The atrophic thymus remains relatively vascular. The thymus and pleurae are dissected from the pericardium, which is opened. Before cannulation for CPB, the patient is fully heparinised. Other incisions can be used, including limited upper or lower sternotomy and left or right anterolateral thoracotomy (in minimally invasive operations or descending aortic surgery).

Sir Henry Sessions Souttar, 1875–1964, surgeon, The London Hospital, London, UK.
John Heysham Gibbon, 1903–1973, worked at Jefferson University, Philadelphia, PA, USA.

Summary box 59.1

Alternative uses of CPB

- Rewarming in hypothermia
- Resuscitation in severe respiratory failure
- As an adjunct in pulmonary embolectomy
- Single- and double-lung transplantation
- In cardiopulmonary trauma
- Certain non-cardiac surgical procedures (e.g. resection of highly vascular tumours or those invading large blood vessels; e.g. the inferior vena cava in renal tumours)

Initiating cardiopulmonary bypass

Arterial cannulation

Conventionally, a perfusion cannula is inserted into the ascending aorta. Two purse-string sutures are usually placed in the selected area for cannulation after manual or epiaortic scan inspection to ensure that it is clear from severe calcification or atherosclerotic lesions that can prevent safe cannulation or lead to increased risk of postoperative complications such as stroke. The aortic cannula is checked for size and inserted into the aorta between the purse-string sutures and secured by tightening them. Air is excluded and the cannula connected to the bypass circuit. Alternatively, when it is either inadvisable (aortic dissection), impractical (aortic root surgery) or impossible (severe adhesions or porcelain [calcified] aorta) to cannulate the aorta, alternative cannulation sites can be used, such as the femoral or the axillary artery. The axillary approach has recently been gaining more popularity as it provides more physiological blood flow in the aorta (antegrade) than femoral cannulation, in which blood flow is opposite to normal physiological conditions (retrograde), and can be utilised to provide selective cerebral perfusion in complex aortic operations. Axillary cannulation has the theoretical advantage of reducing thromboembolic events compared with femoral cannulation. This is related to the differences in the direction of blood flow as flow in femoral cannulation is from the descending aorta to the heart, which means increasing the chances of mobilising calcified plaques from the aorta to the head and neck vessels.

Venous cannulation

A single purse-string suture is placed around the right atrial appendage and a single 'two-stage' venous cannula is placed to establish venous drainage. The venous pipe has end holes that sit in the inferior vena cava and side holes that sit in the right atrium (to drain from the superior vena cava). Alternatively, the superior and inferior venae cavae may be cannulated separately to gain better control over the venous return and facilitate operating on structures in the right ventricle or atrium ('bicaval' cannulation). Venous drainage from the femoral vein can offer an alternative, particularly during thoracic aortic or minimally invasive procedures.

Cardiopulmonary bypass circuit

Once the circuit is connected (***Figure 59.1***) the CPB machine ('pump') gradually takes over circulation and ventilation. Once full flow is established (the required cardiac output depends on many factors, including the patient's body surface area and temperature), the ventilator is stopped and the heart can be isolated from the rest of the circulation and stopped. Blood is drained from the heart to the venous reservoir using a siphon effect (gravity) as it is usually placed 50–70 cm below the level of the heart and oxygenated using an oxygenator that allows gas exchange across its membrane. Oxygenated blood is then pumped back to the patient by the bypass machine via the aortic cannula.

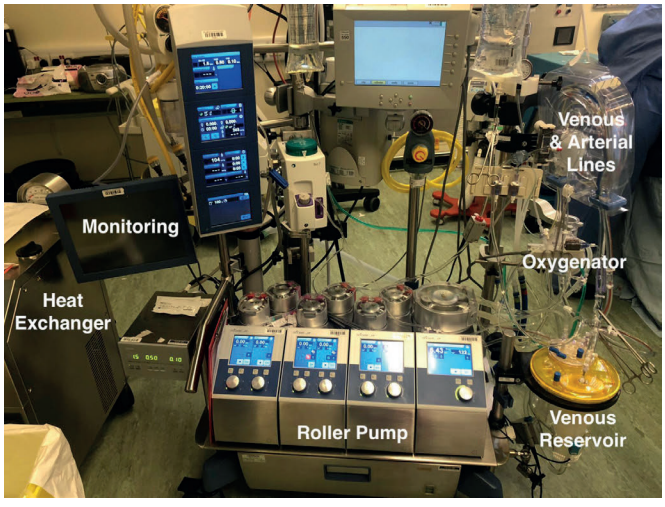

Figure 59.1 The cardiopulmonary bypass circuit shown here in use during 'on-pump' cardiac surgery.

The patient's core temperature can be lowered if needed by passing the returning blood through a heat exchanger, reducing the metabolic demands of the tissues. The degree of cooling is managed according to the severity and complexity of the surgical procedure as well as the surgeon's preference. Suction pumps can be used to keep the operative field clear. Vents, which are small cannulae that are inserted during surgery and connected to the CPB circuit, are used to keep the heart empty by draining any blood that accumulates inside the heart during surgery.

Myocardial protection

Once CPB has been established, the ascending aorta is usually cross-clamped to obtain a bloodless operative field. The heart ceases ejecting and becomes anoxic owing to inhibition of coronary blood flow. Permanent myocardial damage can develop within 15–20 minutes, therefore most cardiac operations require some form of myocardial protection. Techniques of myocardial protection and the operative management of the myocardium have had a significant impact on the complexity of cardiac surgery. Methods of myocardial protection include intracoronary infusion of a cardioplegic solution (antegrade), infusion via the coronary sinus (retrograde), intermittent cross-clamp fibrillation and total circulatory arrest.

Cardioplegia solutions vary in temperature, pH, osmolality and the presence of red cells. Potassium is the most commonly used arresting agent, stopping the heart in diastole by

depolarisation of the cardiac myocyte cellular membrane. Cold (4–10°C) isotonic crystalloid or blood solutions aid myocardial protection by reducing metabolic requirements through local hypothermia. Warm cardioplegic solutions, on the other hand, may facilitate better myocardial recovery postoperatively by aiding activation of intramyocardial enzymes. Cardioplegia solutions will need to be given repeatedly every 15–20 minutes during surgery. Other cardioplegia solutions that can be given as a single dose are usually reserved for more complex and longer operations.

Intermittent cross-clamp fibrillation is a technique in which intermittent ventricular fibrillation (VF) is induced by a small electrical charge. The heart does not eject and is relatively still but not bloodless. The aorta is cross-clamped to render the heart ischaemic. The heart can tolerate short periods (10–20 minutes) of ischaemia, providing it is reperfused when the cross-clamp is released and allowed to beat following cardioversion for short periods.

Total circulatory arrest is necessary when visibility and clarity of the operative field is crucial, as in paediatric surgery or in surgery of the ascending arch of the aorta. CPB is established and the core body temperature reduced to 15–18°C (profound hypothermia). The metabolic rate of all body organs is reduced by 50% with every 7°C drop in temperature. Using this technique, circulatory arrest (in which the CPB machine is switched off) can be tolerated for up to 20–30 minutes. Additional cerebral protection can be provided with ice packs placed around the head, pharmacological agents such as thiopental or steroids and cerebral perfusion techniques that allow for longer arrest times.

Discontinuing cardiopulmonary bypass

At the end of the procedure, air must be meticulously excluded from the cardiac chambers (de-airing). Once perfusion is restored to the coronary arteries (by removing the cross-clamp) the heart may beat spontaneously. If VF is present, cardioversion may be required. Epicardial pacing wires are usually placed to treat postoperative bradycardia or heart block. The patient is rewarmed, acidosis and hypokalaemia are corrected and ventilation is restarted. The heart gradually takes over the circulation while the arterial flow from the CPB machine is reduced ('weaning from bypass'). When the blood pressure is acceptable and the surgeon is confident that the heart function is adequate, CPB is discontinued and anticoagulation is reversed by administering protamine and the cannulae are removed.

Complications of CPB

CPB is a complex technique requiring careful interaction and communication between surgeon, anaesthetist and perfusionist to ensure patient safety. Difficulties can occur during cannulation (aortic dissection or atrial injury), at the start of CPB (oxygenator failure) and at the end of CPB (coagulopathy). Other complications can occur following blood exposure to the non-physiological surface of the CPB circuit. This leads to the activation of inflammatory and coagulation cascades, giving rise to a post-CPB systemic inflammatory response syndrome (SIRS) that can lead to multiorgan failure.

Recent improved understanding of the impact of CPB on coagulation and the inflammatory response (SIRS) has resulted in the development of smaller 'mini' CPB circuits, which have demonstrated some advantages in terms of reduced post-CPB inflammatory responses and blood transfusion requirements. Alternative methods include surgery 'off-pump' on a beating heart without the use of CPB; this has some advantages but its use remains restricted to coronary artery bypass grafting (CABG).

CORONARY ARTERY BYPASS SURGERY

Introduction

Before the 1950s, surgical attempts to treat CAD through grafting of non-coronary flow to the myocardium was via pericardial or omental adhesions, with limited success. From the 1960s onwards, the importance of aortocoronary saphenous vein grafts and the value of the internal mammary (internal thoracic) artery were increasingly recognised. Outcomes of CABG surgery were carefully scrutinised and, by the 1970s, multiple large, prospectively randomised, multicentre trials were conducted. All trials showed that a subset of patients had improved survival after surgery, compared with other treatments. With the advent of percutaneous coronary intervention (PCI) in the 1980s, the patient population undergoing CABG has changed, becoming progressively sicker but often with the most to gain. Over the last decade, there have been major advances in PCI, including the use of several generations of drug-eluting stents, as well as biodegradable stents, in an attempt to reduce restenosis. Although the role of CABG in the treatment of IHD has been questioned, several multicentre randomised trials carried out comparing CABG with PCI with drug-eluting stents have clearly shown that CABG remains the gold standard operation in certain groups of patients, such as those with left main stem disease, three-vessel coronary disease, diabetes or those at high risk.

Summary box 59.2

Potential complications of CPB

- Coagulopathy
- Infection
- Air embolism
- Gastrointestinal complications (bowel and liver ischaemia/pancreatitis)
- Microembolisation (eyes, brain)
- Myocardial depression
- Neurological dysfunction
- Postcardiotomy syndrome (similar to Dressler's)
- Pulmonary injury
- Systemic organ dysfunction
- Vascular injury

William Dressler, 1890–1969, cardiologist and Director of Cardiology at Maimonides Medical Center, Brooklyn, NY, USA.

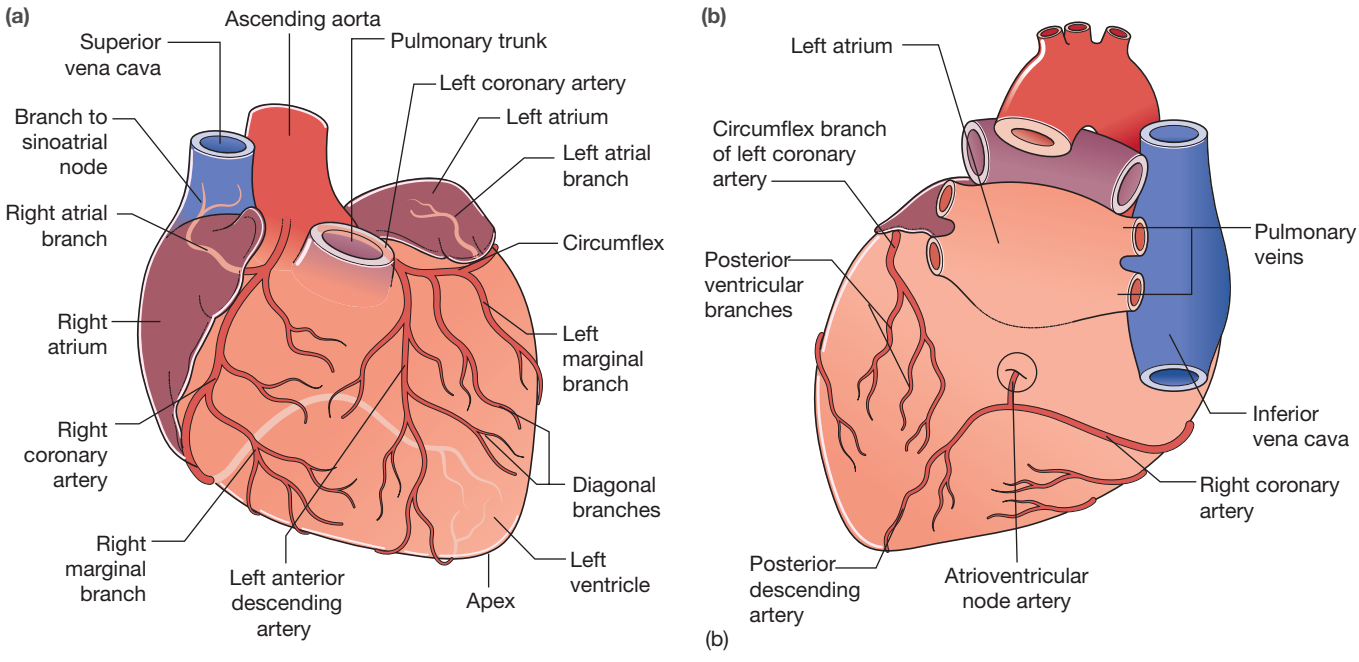

Figure 59.2 The heart, showing the distribution of the left and right coronary arteries. **(a)** Anterior surface of the heart; **(b)** base and diaphragmatic surface of the heart.

Coronary artery anatomy

The coronary arteries are branches of the ascending aorta, arising from ostia in the aortic sinuses above the aortic valve, the right from the anterior sinus and the left from the left posterior sinus (*Figure 59.2*).

Summary box 59.3

Coronary artery bypass surgery

- Randomised controlled trials have confirmed improvement in survival following CABG for certain groups of patients
- Randomised controlled trials have confirmed symptomatic benefits (relief of angina) following CABG

Left coronary artery

The left main coronary artery, which arises from the aortic root, can be the site of significant stenosis ('left main stem disease') and carries the worst prognosis in terms of survival without surgery. The artery is inaccessible at its origin and therefore grafts are anastomosed to its branches, the left anterior descending (LAD) artery or anterior interventricular artery and obtuse/marginal (OM) branches of the circumflex artery. The LAD artery is the most frequently diseased coronary artery and most often bypassed during CABG surgery.

Right coronary artery

The right coronary artery (RCA) passes from its origin anteriorly between the right atrial appendage and the pulmonary trunk and courses in the atrioventricular groove around the margin of the right ventricle. It usually forms an anastomosis with the circumflex artery at the junction of the right and left atria and the interventricular septum (the crux) on the back of the heart. It continues as the posterior descending artery or interventricular artery. Common sites of stenosis of the RCA are in its proximal portion or at the bifurcation or crux. In the presence of disease at the bifurcation, a graft can be anastomosed distally to the posterior descending artery.

Anatomical dominance is determined by the artery that supplies the posterior descending artery. In approximately 90% of cases the posterior descending artery arises from the RCA, a pattern referred to as right dominance. The posterior descending artery can also arise from the circumflex artery, a pattern referred to as left dominance, which occurs in approximately 10% of cases. Co-dominance describes the situation in which there are two posterior descending arteries, one each arising from the right coronary and circumflex arteries; the incidence is around 5%.

Ischaemic heart disease

IHD is a major cause of morbidity and mortality in resource-rich countries. The underlying pathology is usually atherosclerosis of the coronary arteries.

Pathophysiology

Atherosclerosis is the process underlying the formation of focal obstructions or plaques in large- and medium-sized arteries. It is a chronic inflammatory process resulting from interactions between plasma lipoproteins, leukocytes (monocyte/macrophages, T lymphocytes), vascular endothelial cells and smooth muscle cells. Different progressive stages of atherosclerosis exist; namely

- **The fatty streak**. The first evidence of atherosclerosis can be found in children aged 10–14 years. This appears

as a yellow streak running along the major arteries. The streak consists of smooth muscle cells, which are filled with cholesterol, and foam cells (lipid-laden macrophages).

- **Fibrous plaque**. A fibrous plaque consists of large numbers of smooth muscle cells, foam cells and leukocytes. As the fibrous plaque grows, it projects into the vessel lumen, causing narrowing that, in turn, can lead to ischaemia or infarction.
- **Complicated lesion**. This occurs when the fibrous plaque ruptures, provoking activation of the coagulation cascade and the formation of thrombus. The end result is often a calcified ulcerated plaque with areas of haemorrhage and thrombus.

Clinical manifestations

The principal symptoms of IHD are chest pain or angina, breathlessness, fatigue, peripheral oedema, palpitations and syncope. The severity of symptoms and the extent to which the symptoms interfere with everyday activities and quality of life are important aspects of the clinical history. An assessment of risk factors should be included. Clinical examination follows and, although often normal, any evidence of myocardial ischaemia such as new murmurs or heart sounds associated with heart failure or stigmata of associated disease, such as diabetes or peripheral vascular disease, should be noted.

Summary box 59.4

Risk factors for IHD

- Smoking
- Diabetes mellitus
- Advancing age
- Male gender
- Hyperlipidaemia
- Hypertension
- Family history of IHD
- Obesity
- Reduced physical activity

Investigations

Non-invasive methods of diagnosis

Resting electrocardiography

As a baseline test, a 12-lead resting electrocardiogram (ECG) often provides the first indication of ischaemic cardiac disease and is essential in the acute clinical setting. However, it may be normal even in the presence of severe multivessel coronary disease. Evidence of previous myocardial infarction (MI) is indicated by Q waves and/or non-specific ST- and T-wave changes and angina by ST depression.

Troponin and cardiac isoenzymes

These are useful in assessing patients with an acute coronary syndrome (ACS), which is the umbrella term for STEMI (ST elevated myocardial infarction), non-STEMI and unstable angina, especially when the diagnosis is in doubt. Standard enzyme measurement such as troponin, creatine kinase myocardial band and lactate dehydrogenase can also aid both diagnosis and prognosis.

Exercise tolerance testing

Exercise tolerance testing (ETT) is a valuable technique for assessing myocardial ischaemia, both for diagnostic purposes and as a prognostic tool. However, an abnormal exercise test must be interpreted in the light of the probability of CAD and the physiological response to exercise as measured by the percentage of the maximum predicted heart rate achieved. A positive test with evidence of ischaemia on the ECG (ST depression of ≤2 mm) does not always indicate IHD, and a negative test does not always exclude its presence. ETT should be avoided in patients with cardiac disorders such as aortic stenosis.

Echocardiography

Performed through either a transthoracic or transoesophageal approach, echocardiography is valuable for the evaluation of ventricular function and regional wall motion, as well as valvular lesions. Transoesophageal echocardiography provides essential real-time information intraoperatively.

Stress echocardiography can detect regional wall motion abnormalities brought on by exercise or the use of dobutamine or dipyridamole. It is reliable in identifying viable myocardium. Impaired but recoverable myocardium possesses a functional reserve that allows it to be temporarily recruited into action, whereas scar tissue does not. The development of real-time three-dimensional echocardiography (RT3DE) with the ability to carry out valve reconstruction from different aspects has recently revolutionised preoperative surgical planning in patients with complex valvular lesions.

Radionuclide studies and cardiac magnetic resonance imaging

The main type of radionuclide study used is myocardial perfusion scanning using specific radioisotopes (such as thallium-201) to assess the significance of coronary disease and viability of the myocardium.

Cardiac magnetic resonance imaging (MRI) can be performed to evaluate the ischaemic burden of coronary disease (using pharmacological agents to stress the heart) and to provide details of tissue viability when using gadolinium as a contrast agent. Close gap MRI is also very useful in assessing cardiac tumours, pericarditis and other structural heart diseases.

Positron emission tomography

Positron emission tomography (PET) provides information on myocardial perfusion, metabolism and cell membrane function. Positron-emitting isotopes are used to label physiological substances, which can measure the regional distribution of these substances. PET is valuable in the diagnosis of CAD, particularly when the more widely available imaging modalities are inconclusive. It can identify injured but viable myocardium that is potentially salvageable by revascularisation.

Computed tomography

With the development of ECG-gated computed tomography (CT) scanners, multislice high-resolution CT imaging may become an alternative to coronary angiography. It allows assessment of coronary disease, particularly proximal CAD, and gives some information about the degree of coronary

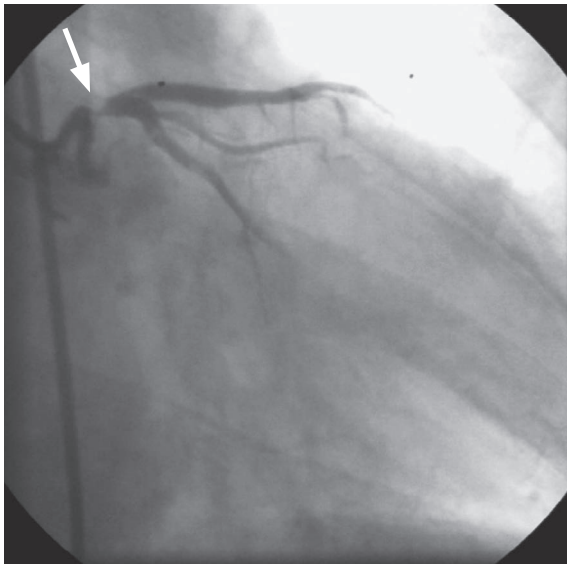

Figure 59.3 Coronary angiogram demonstrating severe stenosis in the left main stem prior to bifurcation of the left anterior descending and circumflex arteries. The arrow indicates the area of severe stenosis.

artery calcification (calcium score) that is very helpful when stratifying patients to determine which ones will benefit from more invasive coronary angiography. It is also useful in patients in whom angiography is challenging (e.g. difficult anatomy).

Invasive methods of diagnosis

Coronary angiography

Selective coronary angiography remains the gold standard diagnostic technique for accurate diagnosis of the presence and extent of CAD (*Figure 59.3*). In spite of the availability of newer imaging techniques such as cardiac MRI, selective coronary angiography provides high image quality, demonstrating the extent, severity and location of coronary artery stenoses and the quality and size of the distal coronary arteries. Different categories of coronary disease are shown in *Table 59.1*. In addition, angiography can assess ventricular function and provide the cardiac surgeon with information to determine operability, operative risk and probability of success.

Coronary angiography only outlines the coronary anatomy; it does not demonstrate ischaemia and it carries an overall complication rate of less than 1%. However, flow measurement across a stenotic area, using techniques such as fractional flow reserve, has been effective in predicting those patients who are likely to benefit from revascularisation. Moreover, intravascular ultrasound can provide more detailed information regarding the degree of stenosis, especially in left main stem disease. A reduction in the luminal diameter of ≥70% usually means an inability to increase coronary flow above resting values.

Summary box 59.5

Coronary angiography

- Gold standard for imaging coronary anatomy
- Demonstrates extent, severity and location of stenosis
- Demonstrates quality and size of distal arterial tree
- Aids diagnosis of ischaemia
- Evaluates suitability for surgery
- Aids in prognostic assessment

Indications for surgery

The decision to offer CABG is based on the balance between expected benefit and potential risks to the patient. Two issues need to be addressed when determining surgical suitability: the appropriateness of revascularisation and the relative merits of CABG versus the alternative PCI. Current best evidence shows that revascularisation can be readily justified on symptomatic grounds in patients with persistent limiting symptoms (angina or angina equivalent) despite optimal medical therapy and/or on prognostic grounds in certain anatomical patterns of disease.

The myocardial revascularisation guidelines of the European Society of Cardiology and the European Association for Cardio-Thoracic Surgery (EACTS) can be useful for identifying patients with certain angiographic features who can benefit from surgery, such as patients with complex coronary anatomy or left main stem disease.

Summary box 59.6

Indications for surgery

- >50% stenosis of the left main stem ('critical left main stem disease')
- >50% stenosis of the proximal left anterior interventricular artery
- Three main coronary arteries diseased ('triple-vessel disease')
- Two-vessel disease including the proximal LAD

Acute coronary syndromes

Substantial benefit is gained with an early invasive revascularisation strategy with PCI or surgery or both. After defining the anatomy with angiography, a decision about the type and extent of intervention can be made. Angiography in combination with ECG changes often identifies the culprit lesion and PCI may be used to treat it. In patients who become stable after an episode of ACS, the indications for CABG are similar to those for patients with stable chronic disease (see *Summary box 59.6*).

TABLE 59.1 Luminal stenosis of coronary arteries and angiographic findings.

	Minimal	Mild	Moderate/significant	Severe	Occluded
Angiographic degree of stenosis	0%	20–49%	50–69%	>70% reduction	Complete occlusion
Luminal cross-sectional stenosis	0%	40–60%	75%	>90%	100%

Optimal timing of revascularisation differs between PCI and CABG. The benefits of PCI in patients with non-ST segment elevation occur with early intervention whereas the benefits of CABG are greatest when patients undergo surgery after several days of medical stabilisation. However, emergency CABG may be indicated for unstable patients with left main stem, multivessel disease and failed PCI.

Surgery for the complications of myocardial infarction

MI leads to myocyte necrosis that usually heals by formation of scar tissue but may lead to rupture of the ventricular wall. Free rupture of the ventricle is usually fatal.

Ventricular septal rupture typically presents 3–7 days after infarction with pulmonary oedema, a pansystolic murmur and haemodynamic instability. Advances in reperfusion therapy such as early access to angiography/PCI services have reduced the incidence to <1%. Diagnosis is usually confirmed with echocardiography, and repair can be performed with a pericardial or artificial Dacron patch in addition to CABG for diseased vessels supplying viable myocardium. Such surgery is usually associated with significant mortality owing to the associated impairment of the ventricular function. Mitral valve papillary muscle necrosis causes acute mitral regurgitation. Diagnosis is made by echocardiography, and right heart catheterisation may be required in the presence of poor right ventricular function and high pulmonary pressure. Mitral valve intervention in addition to CABG is usually necessary, but the mortality rate is higher than in valve intervention for non-ischaemic disease. Ventricular aneurysm may occur following partial-thickness necrosis of the ventricular wall if the free wall is replaced with non-contractile fibrous tissue. Left ventricular function is affected because the fibrous wall balloons out during systole and reduces stroke volume. Repair is undertaken using CPB, and CABG and mitral valve replacement may also be necessary.

Acute failure of percutaneous coronary angioplasty

Since the advent of intracoronary stents, the need for emergency CABG following complications of PCI is low at <1%. The mortality rate of CABG in this group is significantly higher than in the elective setting.

Preparation for surgery

Clinical assessment

Before CABG, the severity and stability of the patient's IHD, the presence of significant valvular disease and the status of left ventricular function should be properly evaluated. Any comorbid risk factors for IHD should be documented and, in particular, the state of coexisting diseases assessed. Attention is paid to the presence of carotid artery disease, peripheral vascular disease, respiratory status, preoperative diabetic control and presence of associated diabetic complications, significant renal dysfunction or coagulopathy. All medications taken by the patient are noted, and some routinely stopped before surgery (e.g. antiplatelet agents, including aspirin; anticoagulants; and oral hypoglycaemics). Others, including diuretics and angiotensin-converting enzyme inhibitors, are stopped at the discretion of the surgeon. Cardiac and antihypertensive medications should be taken preoperatively.

Risk assessment

Myocardial revascularisation by CABG is appropriate when the expected benefits (i.e. survival or health outcomes) exceed the expected negative consequences of the procedure. Therefore, objective methods for risk assessment are essential to determine the patient's suitability for surgery and to provide patients with adequate information for informed consent. Various scoring systems have been developed for risk stratification in cardiac surgery, including the EuroSCORE II and the Society of Thoracic Surgeons (STS) score. EuroSCORE II is the system most commonly used in the UK and takes into account different factors such as age and gender, coexisting conditions such as diabetes and peripheral vascular disease and the proposed operation.

Selection of conduit

Venous grafts

The long saphenous vein is the most commonly used venous conduit as it is straightforward to harvest, provides good length and is easy to handle. Historical studies showed a limited long-term patency rate for long saphenous vein grafts (50–60% at 10 years). However, recent studies suggest that early postoperative use of lipid-lowering agents and antiplatelet agents such as low-dose aspirin can improve vein graft long-term patency. In assessing the patient preoperatively, the legs should be checked for varicose veins. Alternative vein conduits include the short saphenous vein or upper limb veins such as the cephalic vein; however, these grafts are associated with poorer long-term patency rates.

Arterial grafts

The left internal mammary artery (LIMA), or internal thoracic artery, has become the conduit of choice for LAD grafting. Evidence from the mid-1980s to the present day suggests a 10-year patency rate of >95%, with a lower reoperation rate. As this arterial conduit avoids the late complication of vein graft atherosclerosis, interest has focused on the use of bilateral internal mammary artery grafts although there is currently no supporting evidence for this.

The use of the radial artery as an alternative arterial bypass graft has undergone a recent revival. This has been driven by the belief that total arterial revascularisation (avoiding venous conduits) might improve long-term results of coronary surgery. Different studies have demonstrated excellent patency rates at 1 and 5 years with this strategy. When assessing a patient in whom a radial artery harvest is planned, an Allen's test should be performed. The alternative would be vascular assessment of the radial and ulnar arteries with ultrasound.

Edgar Van Nuys Allen, 1900–1961, Professor of Medicine, Mayo Clinic, Rochester, MN, USA.

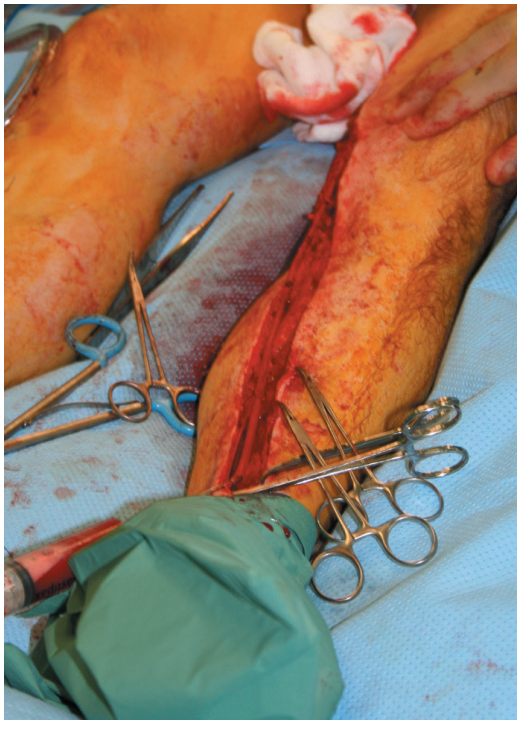

Figure 59.4 Open long saphenous vein harvesting is performed through an incision starting anteriorly to the medial malleolus of the ankle, extending to the groin if necessary.

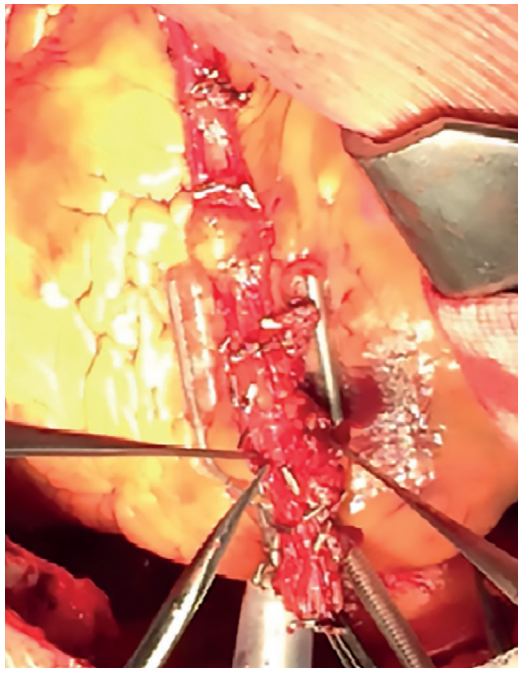

Figure 59.5 A pedicled left internal mammary artery is dissected off the chest wall and divided distally after systemic heparinisation. It is left attached to the subclavian artery proximally.

Summary box 59.7

Allen's test

- The patient repeatedly clenches and unclenches the fist while the surgeon compresses both radial and ulnar arteries digitally at the wrist; this empties blood from the hand
- The hand is then relaxed and compression of the ulnar artery is released; the speed of returning colour to the hand is assessed
- If colour returns in 5–7 seconds, patency and collateral flow from the ulnar artery are confirmed and it is safe to harvest the radial artery

The operation

Intraoperative monitoring includes continuous central venous pressure and blood pressure recording (via a central line in the internal jugular or subclavian vein and radial artery line, respectively), urine output via a urinary catheter, temperature using a nasopharyngeal probe and continuous ECG monitoring.

The operation commences with harvesting of the conduits (long saphenous vein from the leg [*Figure 59.4*] and/or radial artery) while the chest is opened via a median sternotomy and the LIMA is dissected from the chest wall (*Figure 59.5*). The patient is placed on CPB after heparinisation, the aorta is cross-clamped and the heart arrested with cardioplegia. The grafts are anastomosed to coronary arteries distal to the stenoses (*Figure 59.6*).

The aortic cross-clamp is removed and the heart is reperfused with oxygenated blood. A side-biting clamp is applied to the ascending aorta and the proximal anastomoses are completed. Occasionally, the surgeon may opt to carry out the whole operation while the cross-clamp is applied to reduce

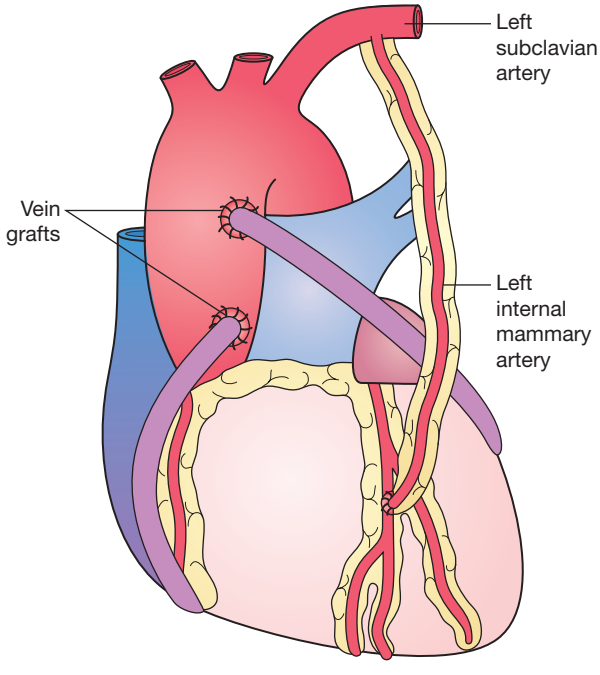

Figure 59.6 Completed coronary artery bypass grafts.

the risks associated with aortic manipulation. The patient is warmed and weaned from CPB. The heparin is reversed and the patient is transferred to the intensive care unit (ICU).

Postoperative recovery

The majority of patients are extubated a few hours postoperatively and remain in the ICU for 24 hours. In some centres, 'fast tracking' appropriate patients allows earlier transfer to a recovery area or high-dependency unit. Discharge is routinely 4–8 days after surgery.

Postoperative complications

Bleeding

Significant bleeding occurs in approximately 2–3% of patients. Rarely, acute cardiac tamponade or profound hypotension may occur in the early postoperative period and requires emergency resternotomy.

Arrhythmias

The most common postoperative arrhythmia is sinus tachycardia, closely followed by atrial fibrillation (AF). AF occurs in around 30–60% of patients undergoing CABG and often spontaneously reverts to sinus rhythm. Treatment includes correction of potassium (>4.5 mmol/L), the use of β-blockers, amiodarone or digoxin and, if necessary, cardioversion.

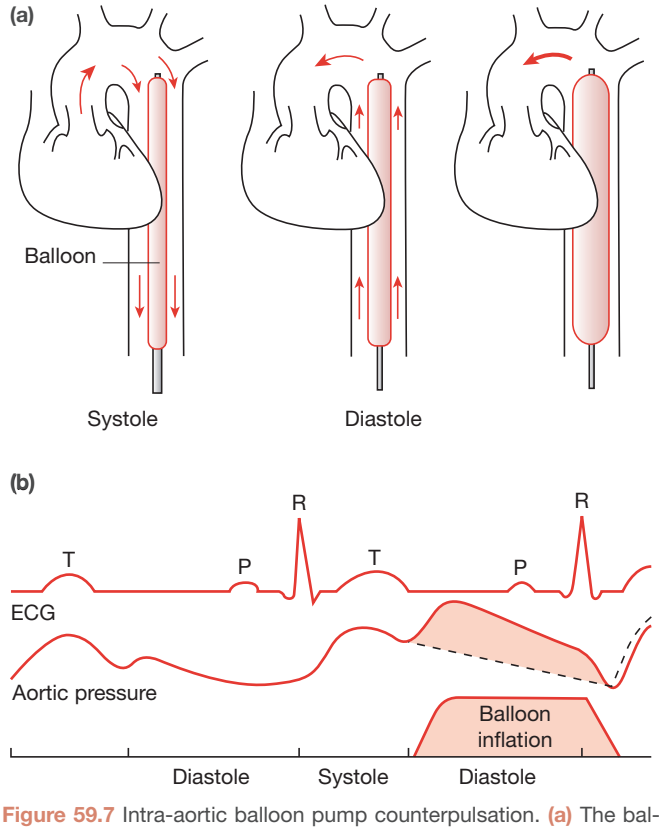

Figure 59.7 Intra-aortic balloon pump counterpulsation. **(a)** The balloon deflates during systole and thereby lowers systemic resistance. It inflates during diastole and increases coronary perfusion in addition to augmenting the systemic blood pressure. **(b)** The pressure changes and phases of the electrocardiogram (ECG) are shown.

Bradycardia is rare, but temporary pacing via epicardial pacing wires inserted intraoperatively may be required in the postoperative period.

Poor cardiac output state

Myocardial function typically declines in the first few hours following cardiac surgery, presumably in response to ischaemia/reperfusion-type injury. Inotropic agents are often required at this time to support heart function and maintain the circulation. Occasionally, the patient develops a persistent low cardiac output state. The clinical manifestations include poor peripheral perfusion, low urine output, a developing metabolic acidosis and low blood pressure.

There are several mechanisms that may cause this complication in the early postoperative period, including depressed myocardial contractility, reduced preload, increased afterload and a disturbance in heart rate or rhythm.

Treatment is aimed at the underlying cause but generally includes oxygenation, optimising preload, reducing afterload, managing any rhythm disturbances and improving contractility. If the low cardiac output state persists, the heart may require pharmacological or mechanical support.

Pharmacological support

Different agents can be used to support patients after surgery by altering the systemic vascular resistance, increasing the heart rate and increasing the force of myocardial contractility. Commonly used pharmacological agents include dopamine, dobutamine, adrenaline (epinephrine) and noradrenaline (norepinephrine).

Mechanical support

If low cardiac output persists despite inotropic support, the heart may require mechanical support while it recovers its function. Mechanical support can be achieved using an intra-aortic balloon pump (IABP), ventricular assist device (VAD) or extracorporeal membrane oxygenation (ECMO).

An IABP is a device that is inserted, either percutaneously or under direct vision, into the common femoral artery. It is advanced into the aorta until its tip lies just distal to the aortic arch vessels (***Figure 59.7***). Balloon filling and emptying is triggered by the ECG, deflating during ventricular systole (reducing afterload) and inflating in diastole (displacing blood into the coronary arteries retrogradely).

A VAD is a mechanical circulatory supporting device used to replace the function of a failing heart. It can be used as a short-term measure typically for patients recovering from heart attacks or heart surgery (bridge) or as a long-term support for patients with congestive heart failure (destination). Current VAD devices are all continuous flow and have been shown to be superior to pulsatile flow devices. Blood is exposed in these devices to a non-biological surface that can activate proinflammatory and coagulation cascades, leading to strokes and bleeding. Another important complication associated with VAD is infection.

ECMO is another circulatory support device that is similar to CPB; it can be established using venous access only (VV-ECMO) or venous and arterial access (VA-ECMO). Indications for ECMO include neonates and adults with

potentially reversible respiratory failure, postcardiac surgery support or as a temporary stabilisation method for patients who may need a VAD (bridge therapy).

Neurological dysfunction

Stroke leading to a focal neurological deficit occurs in approximately 2% of patients following CABG. Embolisation, probably originating from the aortic arch or heart chambers, is the most common mechanism for territorial infarcts, with hypoperfusion leading to watershed infarcts. Diffuse neurological injury may also occur, leading to subtle cognitive abnormalities in memory, concentration and attention.

Wound infection

Significant deep wound infection resulting in sternal dehiscence and mediastinitis occurs in around 0.5–2% of patients. This is associated with significant morbidity, with a prolonged hospital stay and further surgical interventions for debridement and/or rewiring of the sternum. It has a significant mortality rate of up to 40%. Wound infections are more common in those with diabetes, dialysis patients, smokers, patients with high transfusion requirements and the obese.

Mortality

In the UK, the mortality rate for patients undergoing CABG is 1–3%. Multiple factors have been demonstrated to affect mortality after CABG, including age, gender, existing morbidities, left ventricular function and the use of LIMA.

Surgical outcome

Relief of symptoms

If revascularisation is complete, CABG alleviates or improves anginal symptoms in more than 90% of patients at 1 year; this falls to 80% at 5 years and 60% at 10 years. This symptomatic deterioration usually reflects progression of atherosclerotic disease in vein grafts and native coronary arteries.

Survival

Studies have reported survival rates to be >95% at 1 year, 90% at 5 years, 75% at 10 years and 60% at 15 years. These results may improve in the future because of increased use of arterial conduits and widespread use of dual antiplatelet therapy, β-blockers and lipid-lowering agents.

Summary box 59.8

Coronary artery bypass surgery outcome

Mortality
- 1–3%

Perioperative infarct
- 2–3%

Angina
- Improved in >90% at 1 year
- 80% at 5 years
- 60% at 10 years

Survival
- >95% at 1 year
- 90% at 5 years
- 75% at 10 years
- 60% at 15 years

Off-pump coronary artery surgery

CABG without the use of CPB is gaining popularity and may be combined with a minimally invasive approach or carried out through a conventional sternotomy. It avoids the potential physiological stress associated with CPB and, to some extent, the aortic manipulation that can lead to neurological injury through atherosclerotic embolisation. Since the introduction of cardiac stabilising devices such as the Octopus® (***Figure 59.8***), off-pump coronary artery bypass (OPCAB) grafting has become widespread in the UK and around the world.

The advantages of off-pump surgery over on-pump have recently been questioned, especially with the development of mini-bypass pumps, which offer a closed circuit and minimal non-physiological surface area. This reduces proinflammatory activation but at the same time allows the surgeon to operate on a still, bloodless heart. The disadvantages of OPCAB are mainly related to the quality and number of anastomoses. There is still no evidence to support the superiority of any of the above-mentioned techniques and the final decision is usually based on the surgeon's skills and the required operation.

Minimal access surgery

Minimally invasive direct coronary artery bypass (MIDCAB) grafting is performed through a small incision and avoids the invasive aspects of conventional CABG. Through an anterior submammary incision the LIMA can be dissected using a thoracoscope and grafted to the LAD. More lateral incisions allow access to other coronary vessels, including branches of the circumflex artery. Although not yet evidence based, one approach is to combine MIDCAB (typically LIMA to LAD) with PCI to other less accessible coronary arteries ('hybrid' coronary revascularisation).

VALVULAR HEART DISEASE

Introduction

Early surgical management of valvular heart disease concentrated on valve repair. The heroic early procedures for valve stenosis were closed and therefore 'blind' commissurotomies

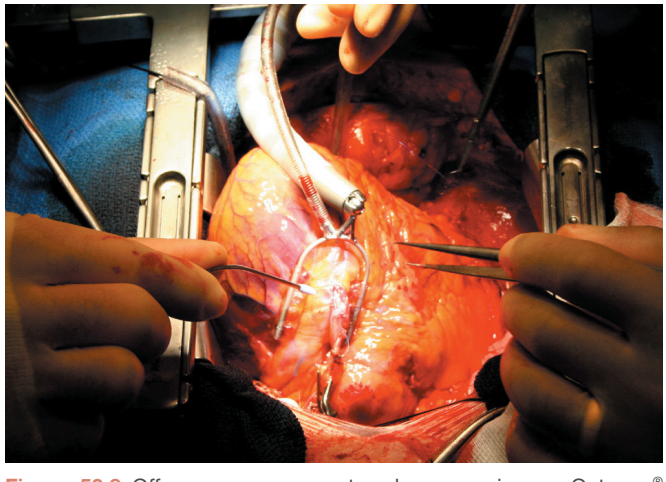

Figure 59.8 Off-pump coronary artery bypass using an Octopus® stabiliser to perform the distal anastomosis.

on a beating heart without CPB. They were replaced by open procedures with full visualisation, allowing precise repair and replacement. The first prosthetic valve replacement was performed by Dwight Harken, who replaced an aortic valve, followed by a mitral valve replacement by Starr a year later. Continued improvements in perioperative care, myocardial protection and, in particular, the development of prosthetic heart valves have improved long-term haemodynamic results, provided symptom relief and prolonged survival. The majority of valvular operations involve surgery on the aortic or mitral valve; tricuspid and pulmonary valve surgery is rarely undertaken in isolation unless it is part of staged congenital surgery.

Surgical anatomy

Heart valves serve to maintain pressure gradients between cardiac chambers, thus ensuring a unidirectional flow of blood through the heart. The aortic valve is tricuspid, with semilunar leaflets attached to the aortic wall at the annulus, the aortic sinuses being above the base of each leaflet, two of which form the origin or ostium of the coronary arteries. The intrinsic shape of the aortic semilunar valve allows blood to leave the ventricle during systole and prevents regurgitation during diastole. If disease leads to disruption of the leaflets or the annulus, valve function will be affected.

The mitral valve is bicuspid; the anterior cusp is larger in area and lies between the orifices of the mitral and aortic valves. The leaflets, like those of the aortic valve, are attached to an annulus. The leaflets join at two commissures and are supported by a subvalvular apparatus, consisting of chordae tendinae and papillary muscles. The papillary muscles contract in ventricular systole, pulling the cusps towards the atrioventricular orifice and holding blood within the ventricle. The proper functioning of the mitral valve depends on the integrity of the annulus, leaflets, chordae and papillary muscles. If surgical repair is required, these structures should be preserved whenever possible (*Figure 59.9*).

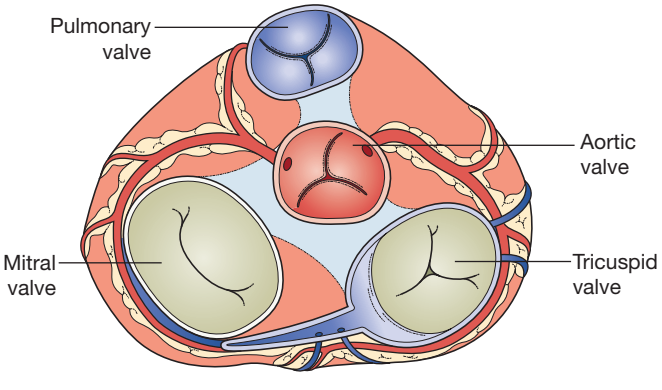

Figure 59.9 Four valves of the heart.

Surgical options for heart valve disease

The decision to either repair or replace a valve depends on the underlying pathology, severity of disease and quality and/or involvement of the supporting structures. Generally, repair is favoured when possible in mitral valve disease, particularly in degenerative mitral regurgitation, where it has been shown to have good long-term outcomes. Repair is the operation of choice in tricuspid valve disease, but aortic valve surgery generally involves replacing the diseased valve (*Table 59.2*).

Important factors in selecting the procedure and prosthesis include patient choice, age, existing comorbidities and the need for anticoagulation. Because of uncertainties about its longevity, most surgeons use a bioprosthetic (biological) valve in patients over 60 years. The need for anticoagulation with warfarin may have an impact on choice of valve, particularly in women of childbearing age, the elderly, the presence of congenital or acquired bleeding diathesis and when there is the need for further major surgery.

Types of prosthetic valves

Mechanical valves

Mechanical valves can be used in any age group to replace any valve (*Figure 59.10*). They are extremely durable but thrombogenic and patients require systemic anticoagulation, usually with warfarin. The patient should be warned about the risk of haemorrhagic (intracerebral, epistaxis, gastrointestinal bleed) or thrombotic (cerebral infarction) complications.

Bioprosthetic (biological) valves

Bioprosthetic valves include cadaveric **homograft** (or **allograft**) valves; **autografts**, a patient's own valve; and, most commonly, **heterografts** (or **xenografts**) prepared from animal tissues. All have three semilunar leaflets with central flow, so decreasing pressure gradients and minimising turbulence (*Figure 59.11*). Heterograft 'tissue' valves are the

Figure 59.10 Bileaflet mechanical valve.

Dwight Harken, 1910–1993, American surgeon. In June 1948, in Boston, MA, USA, Harken successfully introduced a cardiovalvulotome through the left atrial appendage and into the heart of a 27-year-old with severe mitral stenosis. In 1950, he developed and implanted the first stainless steel cage prosthesis in the aortic position.

Albert Starr, b. 1926, formerly Professor of Surgery, The University of Oregon, OR, USA. Inventor of the world's first durable artificial mitral valve; winner of Lasker award in 2007 – an award given by the Lasker Foundation in the USA to a person (or persons) who has made major contributions to medical science or who has performed public service on behalf of medicine.

TABLE 59.2 Comparing options for heart valve surgery.

Valve repair	Mechanical replacement	Biological valves		
		Stented	Stentless	Homograft
Advantages				
No need for long-term anticoagulation Mimics 'natural' haemodynamics	Can be used in younger patients Good history of evidence	No need for long-term anticoagulation Good evidence base		Does not require anticoagulation Long-term results unknown
Disadvantages				
Technically challenging	Nidus of infection (endocarditis), can be disastrous Requires anticoagulation		Technically more challenging to insert	Requires specialist expertise Increased complexity of surgery
Lifespan				
Variable among techniques and valve involved	Excellent long-term durability (patient lifetime)	Lifespan limited (traditionally 10–15 years, although constantly improving) More suited to older patient		Little evidence, although may be limited
Comments				
Mostly performed for mitral valve disease Evidence for other valves is limited	Many different types and sizes for a range of scenarios	Mostly made of bovine or porcine pericardium Growing evidence for the use of antiplatelet agents postoperatively		Usually taken from deceased donors

most commonly used valves and can be stented with a limited durability of 10–15 years, whereas stentless (or frameless) valves are expected to have less late calcific degeneration but are more technically difficult to insert.

Sutureless and rapid deployment valves

In recent years, there has been an increase in the number of available valves using rapid deployment and sutureless technology. These valves are quicker to implant as they do not require extensive numbers of sutures (usually three in the case of rapid deployment and none in the case of sutureless). These valves are anchored in position with a balloon inflatable stent. This is advantageous in elderly or high-risk patients and in minimally invasive aortic surgery.

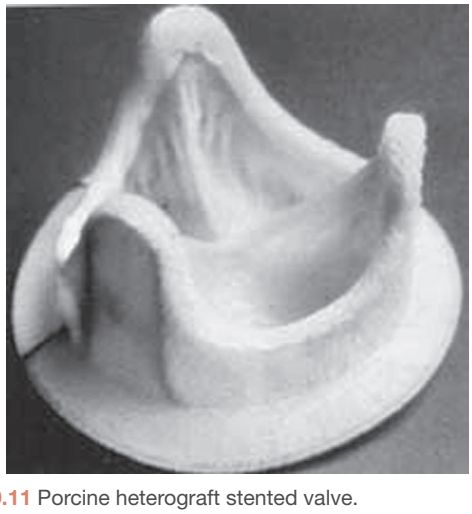

Figure 59.11 Porcine heterograft stented valve.

Prosthetic valve dysfunction and complications

Structural valve failure

Structural failure rates for the currently used bioprosthetic valves, although rare in those over 70 years of age, can reach 60% after 15 years. Structural failure of a mechanical valve is generally uncommon. Recently, a new generation of bioprosthetic valves has been introduced with a novel leaflet preparation method. These valves are associated in theory with more durability and can be used for the younger cohort of patients requiring prosthetic valve replacement.

The increased utilisation of transcatheter aortic valve insertion (TAVI) means that many patients with degenerative prosthetic valve disease can have a new valve inserted inside the old valve without the need for reoperation. This has encouraged many young patients to select a bioprosthetic valve as the preferred choice for replacement.

Paravalvular leak

Early-onset paravalvular leaks usually result from technical difficulties at insertion. Late-onset leaks can occur and may be precipitated by an episode of endocarditis or by leaflet degeneration. The leak can cause haemolytic anaemia or haemodynamic compromise and the valve may need replacement. Recent improvements in catheter techniques have resulted in the ability to close small areas of paravalvular leak with special occlusion devices, thus reducing the need for reoperation.

Thrombosis and thromboembolism

Thrombus formation is the most common complication of a mechanical valve (*Figure 59.12*). The risk of thromboembolism is greater with a mitral valve (mechanical or biological)

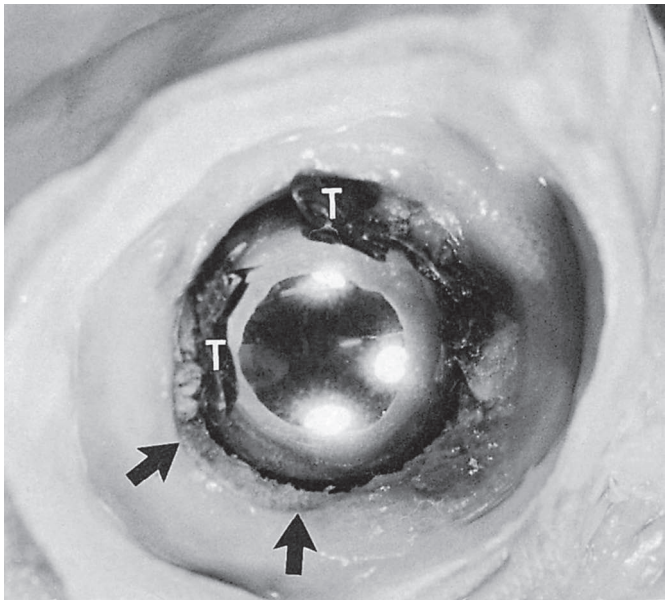

Figure 59.12 Thrombus (marked T and indicated with arrows) on the moving components of a ball-and-cage valve.

than with one in the aortic position. The incidence of thromboembolism in current mechanical valves is 0.5–3% per patient-year. Management depends on the extent of the thrombosis and valve dysfunction and can include either thrombolysis or surgery.

Prosthetic valve endocarditis

The incidence of prosthetic valve endocarditis (PVE) is 2–4%. The risk is lifelong and is at its greatest in the first 3 months after surgery. The incidence of PVE is higher with mechanical and bioprosthetic valves and lowest with homograft and autograft valves. The diagnosis is suspected following symptoms of septicaemia, development of a new murmur or a septic embolus. It is confirmed with echocardiography, which may show vegetations and even abscess formation. A high index of suspicion is required and early multiple blood cultures are needed to confirm the diagnosis, identify the infective organism and choose appropriate antibiotic therapy. The most common organisms in prosthetic and native valve endocarditis are shown in *Table 59.3*.

The treatment of choice is early aggressive intravenous antibiotic therapy. Serial echocardiography to assess extent of infection and involvement of surrounding myocardial tissue, as well as functional assessment of the infected valve, may help in optimising decisions on timing of surgical intervention. Multidisciplinary team discussion is essential. The principle of surgical treatment is radical debridement of all infective tissue followed by reconstruction of any defects in the annulus and replacement. The prognosis of PVE remains poor, with an overall mortality rate of over 20%.

Postoperative management

Antibiotic prophylaxis

Currently the National Institute for Health and Care Excellence recommends that prophylactic antibiotics are not required for patients with prosthetic valves undergoing dental procedures. Other leading European bodies have recently supported the above recommendation.

Antithrombotic therapy

All patients with mechanical valves require anticoagulation, usually started on the first or second postoperative day. Use of anticoagulants with biological valves is based largely on the manufacturer's guidance.

Direct oral anticoagulants such as apixaban and rivaroxaban are not currently licensed for use with mechanical prosthetic valves. Warfarin is currently the drug of choice and the target international normalised ratio (INR) should be adapted to patient risk factors and thrombogenicity of the prosthesis with evidence supporting a lower INR target for aortic valves; however, the range of INR can vary between 2.5 and 4.

Mitral valve disease

Mitral regurgitation

Any pathological process affecting the mitral valve apparatus may lead to mitral regurgitation. As such, there are many causes of regurgitation and they can be broadly classified into four headings. They are shown in *Table 59.4*.

Pathophysiology

There is an important distinction between acute and chronic mitral regurgitation. The former is usually the result of

TABLE 59.3 Common organisms in infective endocarditis.

Classification of organism	Native valve	Prosthetic valve
Gram-negative bacteria	*Streptococcus viridans/milleri* HACEK (*Haemophilus* spp., *Aggregatibacter* spp., *Cardiobacterium*, *Eikenella*, *Kingella* spp.)	*Streptococcus* spp.
Gram-positive bacteria	*Staphylococcus aureus/epidermidis* *Streptococcus faecalis*	Coagulase-negative *Staphylococcus* spp. *Staphylococcus aureus* Enterococci
Other	*Candida* *Histoplasma* *Aspergillus*	*Candida* Non-tuberculous mycobacteria

TABLE 59.4 Causes of mitral regurgitation.

Degenerative causes	Ventricular causes	Autoimmune and infective causes	Other causes
Barlow's disease (myxomatous degeneration)	Transient ischaemia and dynamic regurgitation	Infective endocarditis	Trauma (rarely)
Calcification of the leaflets or annulus	Myocardial infarction resulting in papillary muscle rupture	Rheumatic fever (post-streptococcal throat infection)	Congenital defects such as isolated mitral cleft
Marfan/Ehlers–Danlos syndromes and other connective tissue disorders	Cardiomyopathy and annular dilatation		Associated with certain medications (those containing ergotamine)
			Radiotherapy

ischaemic papillary muscle rupture or following infective endocarditis, whereas the latter is the result of longstanding myxomatous degeneration or fibroelastic changes in the leaflets.

In acute mitral regurgitation, the left ventricle ejects blood back into a small, poorly compliant left atrium, imposing a sudden volume load on the left atrium during ventricular systole. This leads to an abrupt rise in left atrial pressure followed by a rise in pulmonary venous pressure and pulmonary oedema.

Chronic mitral regurgitation progresses slowly, allowing compensatory left ventricular dilatation and hypertrophy, and atrial dilatation without significant increase in pressure, protecting the pulmonary circulation. As the disease advances left atrial pressure begins to rise, leading to a rise in pulmonary venous pressure and progressive pulmonary congestion, with eventual congestive cardiac failure.

Clinical features

In acute mitral regurgitation, the patient is usually unwell, presenting with clinical and radiological evidence of acute pulmonary oedema and a loud apical pansystolic murmur. Patients with mild chronic mitral regurgitation are usually asymptomatic. With progressive pulmonary congestion and left ventricular failure, the patient develops fatigue, exertional dyspnoea and orthopnoea. The development of AF with left atrial dilatation is common. The enlarged left ventricle leads to a heaving apical impulse and a pansystolic murmur.

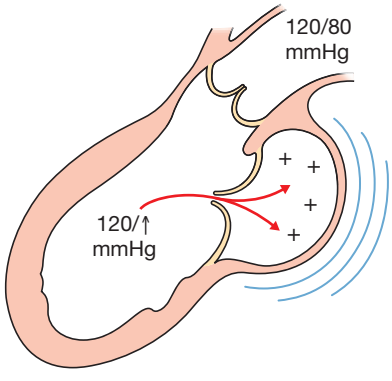

Figure 59.13 Features and pathophysiology of mitral regurgitation. There is a loud parasystolic murmur and the left atrium enlarges. The left ventricle enlarges as a consequence of volume overload.

Investigations

- **ECG**: may show left atrial hypertrophy (bifid P waves, known as 'P mitrale'), left ventricular hypertrophy and AF.
- **Chest radiography**: there may be cardiomegaly with prominent pulmonary vasculature.
- **Echocardiography**: this is often combined with colour flow Doppler imaging, which shows the severity of the regurgitant jet of mitral regurgitation.
- **Coronary angiography**: in patients >40 years of age to investigate the coronary arteries.
- **Cardiac MRI**: increasingly popular as it can give detailed information on structure and function.

Indications for surgery

Indications for surgery in patients with primary mitral regurgitation include severe symptoms or associated changes in left ventricular function or dimension (e.g. left ventricular end-systolic diameter). Evidence suggests that changes in this setting are usually associated with significant mortality if not corrected (*Figure 59.13*). It is also recommended to treat severe mitral disease if a patient is undergoing cardiac surgery for a different reason.

Surgical treatment of primary mitral regurgitation usually involves valve repair. When repair is not feasible, valve replacement with attempts to preserve the subvalvular apparatus should be considered.

The treatment of ischaemic mitral regurgitation remains controversial and current evidence suggests that patients with

John Brereton Barlow, 1924–2008, South African cardiologist.
Bernard Jean Antonin Marfan, 1858–1942, physician, L'Hôpital des Enfants-Malades, Paris, France, described this syndrome in 1896.
Edward Ehlers, 1863–1937, Professor of Clinical Dermatology, Copenhagen, Denmark.
Henri Alexandre Danlos, 1844–1912, dermatologist, Hôpital St Louis, Paris, France.
Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the 'Doppler principle' in 1842.

severe ischaemic regurgitation may benefit from mitral valve replacement, while patients with moderate regurgitation should usually undergo repair along with CABG if indicated.

Mitral stenosis

The most common cause of mitral stenosis worldwide remains rheumatic fever, despite the fact that the incidence of overt rheumatic fever in resource-rich countries has decreased. During the healing phase of acute rheumatic fever, the valve leaflets become adherent to each other at their free border so that the commissures become obliterated, narrowing the valve orifice. Symptoms of mitral stenosis usually develop more than 10 years after the acute attack.

Pathophysiology

Mitral stenosis slows diastolic ventricular filling and left atrial pressure rises to maintain cardiac output. This leads to atrial hypertrophy and dilatation. Pulmonary congestion results from the rise in left atrial pressure with time. Although the lungs are protected against pulmonary oedema by constriction of the pulmonary vessels, this adaptive response, along with the passive 'back pressure' generated by the rise in left atrial pressure, leads to pulmonary hypertension (>25 mmHg). This leads to an increased demand on the right ventricle with eventual right heart failure and tricuspid regurgitation. The development of AF is common and can lead to a significant reduction in cardiac output. AF predisposes to thrombi forming in the left atrium, which may embolise to the systemic circulation.

Summary box 59.9

Causes of mitral valve disease

Stenosis

- Rheumatic heart disease (common)
- Calcification of valve or chordae tendinae
- Congenital (rare)

Regurgitation

- Rheumatic heart disease
- Valve prolapse
- Left ventricular dilatation or hypertrophy
- Ischaemia
- Bacterial endocarditis

Clinical features

Some patients may remain asymptomatic for years and then present with symptoms when the heart is stressed by events such as pregnancy, fever, chest infection or with the onset of AF. The common symptoms are fatigue and dyspnoea on exertion, which result from the combination of reduced forward flow and increased back pressure. The resulting pulmonary congestion adds to breathlessness and may produce a cough or haemoptysis.

In severe mitral stenosis, there may also be a right ventricular heave due to right ventricular hypertrophy in response to pulmonary hypertension. Auscultation may reveal an opening snap soon after the second heart sound, as the diseased valve is opened forcibly by the high pressure in the left atrium. The reverse happens when the valve closes and there is a loud 'tapping' first heart sound. In addition, a rumbling mid-diastolic murmur can be heard. The duration of the murmur is related to the severity of the mitral stenosis, increasing in length as the stenosis becomes more severe.

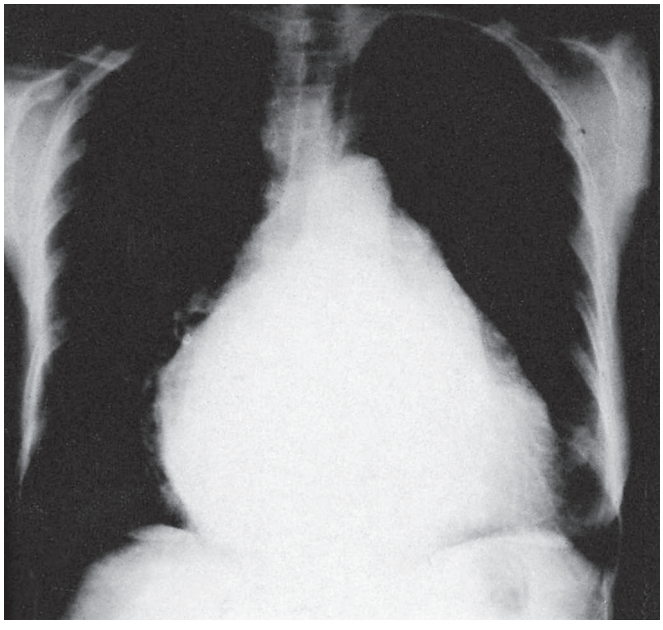

Figure 59.14 Chest radiograph of longstanding mitral stenosis, showing a massive left atrium.

Investigations

- **ECG** may show left atrial enlargement or AF, right axis deviation or other signs of right ventricular hypertrophy (tall QRS complexes in the right ventricular leads V1–3).
- **Chest radiography**: there is a small aortic outline and a prominent pulmonary artery. The left atrium is enlarged (sometimes to an enormous degree) along with upper lobe diversion as a result of the raised pulmonary venous pressure. The right ventricle also appears enlarged (*Figure 59.14*).
- **Echocardiography**, in combination with colour flow Doppler imaging, allows assessment of the flow across the valve and, therefore, the degree of stenosis. Transoesophageal echocardiography (TOE) may be better at assessing valve morphology and excluding the presence of an atrial thrombus.
- **Coronary angiography**: to investigate the coronary arteries.
- **Cardiac MRI**.
- **Right heart catheterisation**.

Indications for surgery

Medical management includes anticoagulation in patients with AF or left atrial enlargement. Tachyarrhythmias should

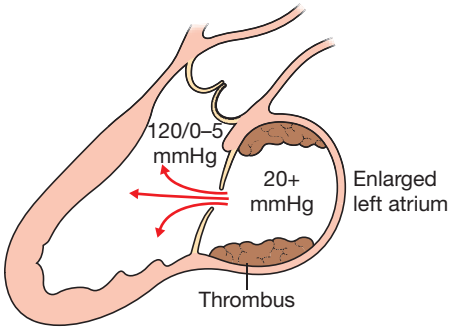

Figure 59.15 Pathophysiology of mitral stenosis. The aorta and left ventricle are relatively small because of chronically reduced cardiac output. The atrium is enlarged and may fibrillate, become stagnant and contain a thrombus. The ventricle fills with a turbulent jet that may be detected as a diastolic murmur or a thrill at the apex.

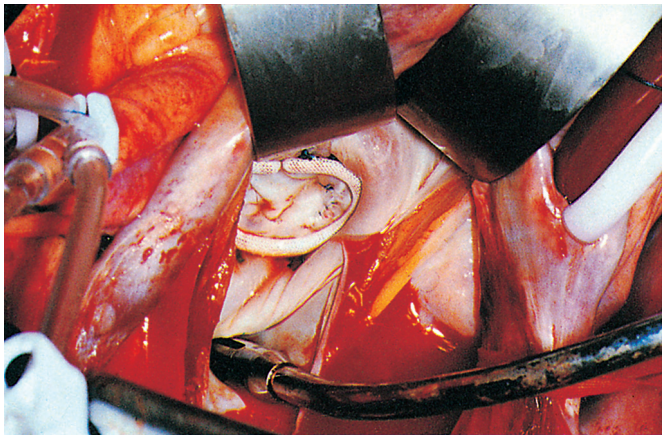

Figure 59.16 Operative view of the mitral valve repair using a Carpentier–Edwards annuloplasty ring (courtesy of A Murday, FRCS).

be treated using pharmacological agents such as digoxin to avoid decompensation and cardiac failure. Diuretics may also provide some benefit. The first-line invasive intervention is balloon valvuloplasty (PMBV); surgery is indicated for severely symptomatic patients who are unsuitable for PMBV or in whom PMBV failed. The prognosis is determined by the severity of the stenosis, the size of the atrium, the presence of AF and rising pulmonary artery pressure (***Figure 59.15***). Surgical options include mitral valve repair or mitral valve replacement. Formerly common surgical procedures such as closed or open commissurotomy are now rarely performed.

Mitral valve operations

Approaches to the mitral valve vary; commonly a median sternotomy or, occasionally, right thoracotomy is performed ('mini'-mitral surgery). The valve can be approached directly through the left atrium in the interatrial groove, through the right atrium and then the interatrial septum or through the left atrial appendage.

Mitral valve repair

Restoration of normal valve function and preservation of the mitral apparatus is preferable to replacement in specific groups of patients, as it can be associated with improved long-term ventricular remodelling and function. This approach reduces the bleeding complications associated with anticoagulants. The functional classification system developed by Carpentier serves as a guideline in valve reconstruction. It classifies mitral insufficiency into one of three groups according to the amplitude of the leaflet motion and provides a useful framework for the mechanisms of failure of the mitral valve. As a rule, several valvular lesions or abnormalities are involved in a functional abnormality, with specific techniques developed to correct each lesion.

At surgery, the anatomy of the valvular apparatus and subvalvular structures is carefully inspected. The extent of annular dilatation, leaflet prolapse and chordal dysfunction is assessed. Repair should respect rather than resect tissues, restoring a good coaptation surface between the two leaflets. The mitral valve repair can employ various techniques, including insertion of a prosthetic ring annuloplasty (***Figure 59.16***); triangular or quadrangular resection of the leaflet; use of a sliding plasty; chordal shortening; chordal transposition; and neochordea implantation.

Many techniques exist, indicating that no one technique addresses all possible findings in mitral regurgitation. Valve repair offers better preservation of ventricular function and avoids prolonged anticoagulation, and valve-related complications such as PVE or structural dysfunction. Recent advances in surgical techniques and the development of different types of rings has led to increased use of mitral valve repair with excellent results, making it the standard operation. The operative mortality is 1–3%. One of the major issues related to mitral repair is the incidence of regurgitation recurrence, which varies between series but can be up to 30% at 5 years. This is related to which leaflet is repaired and the amount of foreign material used in the repair (patch).

Mitral valve replacement

When valve repair is not feasible, mitral valve replacement is necessary. This usually involves a median sternotomy and access to the left atrium on CPB. The diseased valve is excised and a suitably sized mechanical or bioprosthetic valve is implanted. The atriotomy is closed following de-airing of the left heart. Intraoperative TOE can be used to assess adequate valve function.

The mortality rate for elective mitral valve replacement may be up to 5%, depending largely on the state of the myocardium and the general condition of the patient. Common serious in-hospital complications include stroke (<3%) and renal failure (3%). The longer term prognosis for patients following mitral valve replacement is generally good in comparison with the natural history of mitral valve disease. Indeed, more recent evidence suggests that patients with ischaemic severe mitral regurgitation can benefit more from valve replacement than from repair.

Alain Carpentier, b. 1933, cardiothoracic surgeon, Hôpital European Georges Pompidou, Paris, France.

Transcatheter mitral valve repair

The MitraClip® is a device used to reduce mitral valve regurgitation. The method involves suturing of the leaflets of the mitral valve together so that regurgitation into the left atrium is prevented. The valve continues to open through the sides of the suture and therefore blood continues to flow into the left ventricle. Access is usually from the groin where a catheter is inserted in the femoral vein to the right atrium. The left atrium is accessed by making a septal puncture. Although this method is less invasive and associated with rapid recovery and reduced in-hospital stay, it is however technically demanding and long-term durability of the results of the device is unknown.

Data suggest that the MitraClip® may be suitable for a small subset of high-risk patients (e.g. chronic heart failure), but the vast majority are better served by surgery that leaves them with substantially less mitral regurgitation.

Aortic valve disease

Approximately two-thirds of all valve surgery performed in the UK is for aortic valve disease, which remains common despite a reduction in the incidence of rheumatic fever in resource-rich countries.

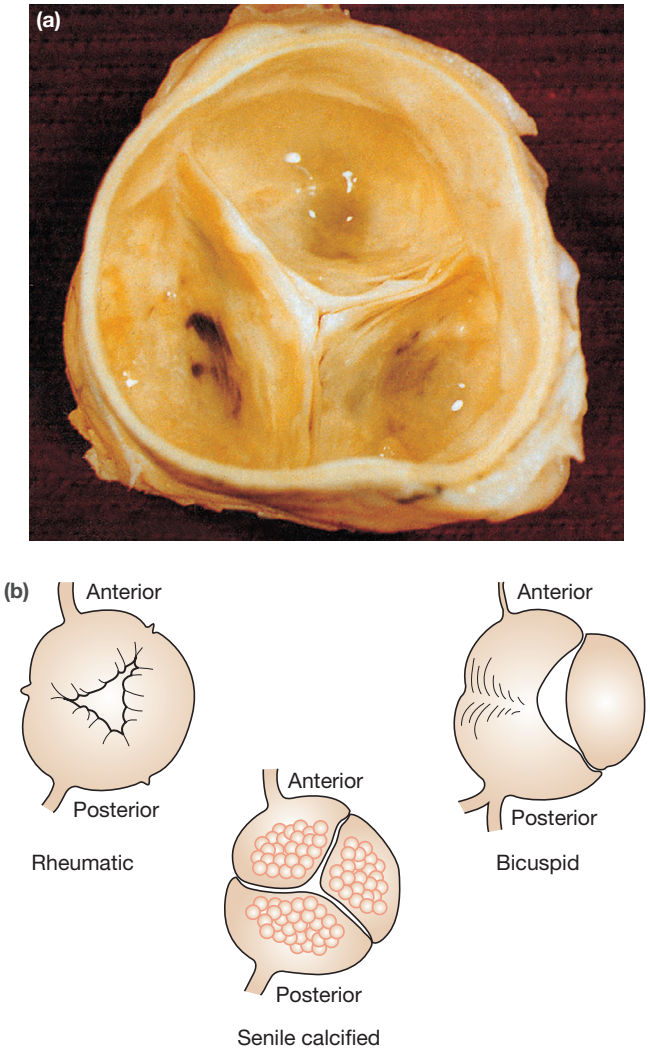

Figure 59.17 (a) Formaldehyde-treated aortic valve (normal tricuspid configuration). **(b)** Aortic stenosis, different pathologies.

Aortic stenosis

The commonest cause of aortic stenosis in adults is an acquired, degenerative, calcific process that results in immobile aortic valve cusps. Progressive fibrosis and calcification of a congenitally abnormal valve can mimic this degenerative process. The usual congenital abnormality is commissural fusion, leading to a bicuspid aortic valve, which occurs in approximately 1% of the population (*Figure 59.17*).

Pathophysiology

A pressure gradient develops between the left ventricle and the aorta, with the ventricle adapting to this systolic pressure overload by an increase in wall thickness or hypertrophy. This adaptive response is an attempt to normalise left ventricular wall stress in the face of increased left ventricular systolic pressure and may maintain a normal cardiac output, prevent left ventricular dilatation and avoid significant symptoms for a number of years. Eventually, myocardial function is affected and, together with insufficient left ventricular hypertrophy to normalise wall stress (load mismatch), ventricular contractility is reduced.

As aortic stenosis worsens, cardiac output cannot increase with exertion and eventually becomes insufficient at rest. The reduction in ventricular contractility leads to an irreversible decline in left ventricular function, with dilatation and a rise in left ventricular end-diastolic pressure, to the point of overt left heart failure. The severity of aortic stenosis is shown in *Table 59.5*.

TABLE 59.5 Classification of the severity of aortic stenosis.

	Mild	Moderate	Severe
Valve area (cm^2)	>1.5	1.0–1.5	<1.0
Mean gradient (mmHg)	<20	20–40	>40
Velocity (m/s)	2.6–2.9 (<2.5 found in aortic sclerosis)	3.0–4.0	>4.0
Velocity ratio	>0.50	0.25–0.50	<0.25

Clinical features

Patients are often asymptomatic until decompensation occurs, typically presenting with dyspnoea and angina due to the increased oxygen needs of the hypertrophied left ventricle, reduced coronary filling and inadequate exertional cardiac output. Patients often describe feeling light-headed or 'near' syncope on effort. Arrhythmias can also occur. Auscultation demonstrates an ejection systolic murmur that is typically harsh and best heard over the aortic area with radiation to the carotids. The murmur may become quieter with reduced cardiac output in critical stenosis. The apex beat may be displaced in late disease along with signs of cardiac congestion (*Figure 59.18*).

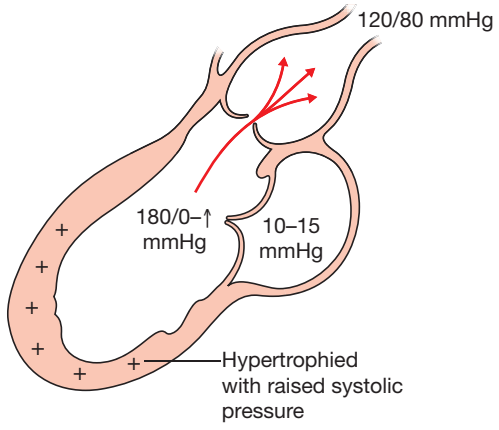

Figure 59.18 Features and pathophysiology of aortic stenosis. Haemodynamic changes in aortic stenosis. Aorta with poststenotic dilatation.

Investigations

- **ECG**: there is left ventricular hypertrophy with tall R waves in the lateral leads and ST depression with inverted T waves – ('strain pattern').
- **Chest radiography** may be normal. Cardiomegaly and pulmonary congestion may be seen with left ventricular failure. Poststenotic dilatation of the aorta is occasionally seen (***Figure 59.19***).
- **Echocardiography** confirms the diagnosis and colour flow Doppler imaging allows assessment of the aortic valve gradient, valve area and evaluation of left ventricular dimensions.
- **Coronary angiography**: to investigate the coronary arteries in patients >40 years of age.

Indications for surgery

Medical management focuses on the avoidance of systemic hypotension and arterial vasodilatation, which may reduce myocardial perfusion pressure and provoke ischaemia.

The natural history of symptomatic patients with aortic stenosis is dismal, with 10-year mortality around 80–90%. The risk of sudden death is related to the severity of stenosis.

Surgery is indicated in asymptomatic patients with severe stenosis and impaired left ventricular function or when the patient is undergoing concomitant procedures such as CABG. An abnormal blood pressure response to exercise (low blood pressure) is also a sign that there is limited reserve in asymptomatic patients.

Aortic regurgitation

The causes of aortic regurgitation can be classified according to the speed of development of the regurgitant jet (acute or chronic) or according to the anatomical location of pathology (valve leaflet or aortic wall). The causes of acute aortic regurgitation include infective endocarditis, aortic dissection and trauma. The common causes of chronic aortic regurgitation include degeneration leading to aortic root and/or annular dilatation, congenital bicuspid valve and previous rheumatic fever or endocarditis. Causes are shown in ***Table 59.6***.

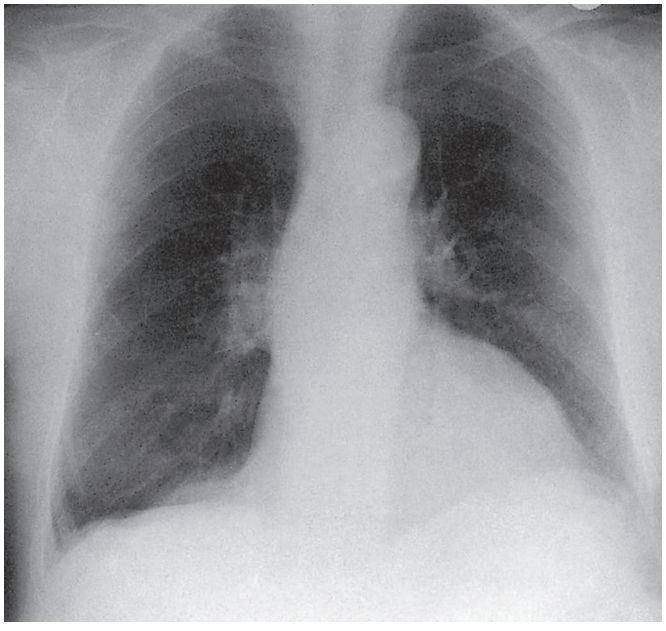

Figure 59.19 Chest radiograph in aortic stenosis.

Pathophysiology

In acute aortic regurgitation, backflow of blood increases ventricular load. It causes a sharp rise in left ventricular end-diastolic pressure, premature closure of the mitral valve and inadequate forward left ventricular filling. The result is sudden haemodynamic deterioration and acute respiratory compromise.

In chronic aortic regurgitation, the left ventricle dilates as a result of volume load, and eccentric hypertrophy is a compensatory mechanism to maintain cardiac output. Systolic and diastolic function is abnormal, and sudden deterioration can occur.

Clinical features

Longstanding aortic regurgitation is usually asymptomatic until left ventricular failure develops, when exertional dyspnoea (predominantly) or angina may develop. A wide pulse pressure due to a reduction in diastolic pressure and a collapsing pulse (water hammer pulse) are commonly seen.

TABLE 59.6 Causes of aortic regurgitation.

Acute aortic regurgitation	Chronic aortic regurgitation
Leaflet abnormalities	
Infective endocarditis Prosthetic valve dysfunction Traumatic leaflet rupture	Bicuspid aortic valve Calcific degeneration Fenfluramine usage (appetite suppressant)
Aortic wall abnormalities	
Aortic wall dissection Aortic trauma	Calcific degeneration Marfan syndrome, Ehlers–Danlos Aortic root dilatation Rheumatoid arthritis, systemic lupus erythematosus, ankylosing spondylitis

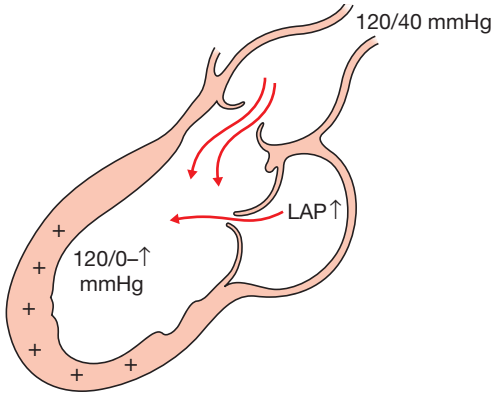

Figure 59.20 Haemodynamic consequences of aortic regurgitation. The left ventricle dilates and hypertrophies and there is a diastolic murmur. LAP, left atrial pressure.

Other manifestations of the wide pulse pressure include visible capillary pulsation of the nail bed (Quincke's sign), pulsatile head bobbing (de Musset's sign), visible arterial pulsation in the neck (Corrigan's sign), a 'pistol shot' sound on auscultating over the femoral artery (Traube's sign) and uvular pulsation (Müller's sign). The apex is displaced laterally and is often visible and hyperdynamic or 'thrusting' in nature because of the left ventricular hypertrophy. Auscultation reveals a high-pitched early diastolic murmur best heard at the left sternal edge (*Figure 59.20*).

Investigations

- **ECG**: there is left ventricular hypertrophy and sometimes a 'strain pattern'.
- **Chest radiography**: cardiomegaly can be seen if the left ventricle is dilating; sometimes, the aortic shadow may also indicate dilatation.
- **Echocardiography**: this allows assessment of the underlying cause and severity of aortic regurgitation and enables the diameter of the aortic root as well as left ventricular dimensions to be determined. Colour flow Doppler imaging quantifies the size of the regurgitant jet.
- **Coronary angiography**: to investigate the coronary arteries in patients >40 years of age.

Indications for surgery

Medical therapy with vasodilator drugs for relief of dyspnoea or angina improves forward stroke volume and reduces regurgitant volume. It is important to note that symptomatic relief does not alter the need for valve surgery.

The indications for surgery include severe regurgitation in symptomatic patients. Asymptomatic patients with severe aortic regurgitation and left ventricular dysfunction should also be offered surgery. Valve replacement should also be considered in asymptomatic patients with severe regurgitation if they are undergoing cardiac surgery for any other reason, or when there is evidence of progressive left ventricular dilatation (left ventricular end-systolic diameter >50 mm). Aortic valve replacement is recommended if there is a decrease in systolic function.

Summary box 59.10

Causes of aortic valve disease

Stenosis
- Congenital
- Rheumatic heart disease
- Acquired calcification and fibrosis of valve

Regurgitation
- Rheumatic heart disease
- Infective endocarditis
- Congenital
- Inflammatory:
  - Systemic lupus erythematosus
  - Rheumatic ankylosing spondylitis
- Dilatation of aortic root:
  - Marfan syndrome
  - Dissection
- Systemic disease:
  - Syphilis
  - Ulcerative colitis

Aortic valve surgery

Unlike mitral valve surgery, there are few occasions when the aortic valve can be repaired and usually the valve requires replacement. However, in neonates and children, aortic valve repair or valvotomy is well established. Percutaneous aortic balloon valvotomy also has a role in children, but appears to only result in temporary benefit in adult aortic valve disease.

Aortic valve replacement

Aortic valve replacement is performed through a median sternotomy or mini-sternotomy on CPB. The aorta is cross-clamped and opened proximally to reveal the diseased valve. Cardioplegic solution is infused into the coronary arteries to arrest the heart in diastole. The valve is excised, leaving the annulus *in situ* but removing as much calcific debris as possible. The annulus is sized and the mechanical or biological valve is then placed into position at the level of the native annulus and the aortotomy is closed.

The operative mortality rate for elective aortic valve surgery is 2–3%. It is higher in emergency surgery, surgery for endocarditis and in older patients.

Heinrich Irenaeus Quincke, 1842–1922, Professor of Medicine, Kiel, Germany.
Louis Charles Alfred de Musset, 1810–1857, French poet and playwright in whom the sign, traditionally, was first noticed.
Sir Dominic John Corrigan, 1802–1880, physician, Jervis Street Hospital, Dublin, Ireland.
Ludwig Traube, 1818–1876, physician, The Charité, Berlin, Germany.
Friedrich von Müller, 1858–1941, physician, Munich, Germany.

Major complications include stroke (2%), perioperative MI (2%) and heart block requiring a permanent pacemaker (<1%). The major determinant of late survival after aortic valve surgery is preoperative left ventricular function. The 5-year survival rate is approximately 75–85%, with the majority of late deaths related to myocardial factors.

Transcatheter aortic valve implantation

Although aortic valve replacement is still the gold standard treatment, a significant number of patients affected by severe aortic stenosis do not undergo surgery because they are high risk (owing to age, frailty or heart failure) or because they are affected by concomitant comorbidities that noticeably increase the operative risk. In such patients TAVI is an attractive alternative to standard aortic valve replacement. Other indications include heavily calcified ('porcelain') ascending aorta and the presence of severe congenital thoracic wall distortion. The advances in TAVI techniques and the currently available evidence suggests that TAVI can be an option in intermediate-risk patients.

There are different approaches for valve implantation; the most commonly used are transapical (retrograde) and transluminal (antegrade).

- **Transapical approach**. In transapical TAVI, the cardiac apex is prepared through a small left anterolateral mini-thoracotomy using a purse-string or a crossing suture reinforced by pledgets. The device is advanced in the left ventricle between the purse-string sutures. This approach reduces the risk of calcium dislodgement due to the passage of a stiff transluminal device into a diseased aortic arch.
- **Transluminal approach**. This can be carried out via direct access to the aorta, or femoral or subclavian arteries. This is a useful technique for patients with previous cardiac surgery; however, the presence of poor access because of peripheral vascular disease, small vessel diameters, tortuous vessels, aortic disease or previous aortic surgery contraindicates this approach.

Whichever approach is used, a balloon catheter is advanced into the left ventricle over a guidewire and positioned at the aortic valve orifice. The existing aortic valve is dilated in order to make room for the prosthetic valve. Rapid right ventricular pacing is used to interrupt cardiac output through the existing aortic valve and to reduce movement during implantation. The new valve, mounted on a metal stent, is manipulated into position and is either self-expanding or deployed using balloon inflation. Deployment leads to obliteration of the existing aortic valve.

Complications associated with TAVI include mortality (5–18% at 30 days), mild-to-moderate aortic regurgitation (30–50%), stroke (3–9%), perioperative open conversion (9–12%), vascular complications (10–15%), atrioventricular block (4–8%) and access artery problems such as bleeding or thrombosis. A recent MI (<3 months), severe pulmonary dysfunction and the presence of an apical thrombus are contraindications for transapical TAVI. Interestingly, recent multicentre trials have demonstrated that the role of TAVI may be offered to intermediate-risk patients, with satisfactory mid-term outcomes.

CONGENITAL HEART DISEASE

Introduction

Congenital heart diseases are abnormalities of cardiac structure that are present from birth. Such developmental abnormalities of the heart typically arise in the third to eighth week of gestation. The first operation for congenital heart disease was patent ductus arteriosus (PDA) ligation by Gross in 1938. With the development of neonatal CPB, improved myocardial protection and microsurgical techniques, an increasing number of corrective and palliative operations are possible.

Development of the heart and fetal circulation and circulatory changes at birth

By 12 weeks of fetal life the primitive vascular tube is fully developed. Fetal circulation differs from that of the adult in that the right and left ventricles pump blood in parallel rather than in series. This arrangement allows the heart and head to receive more highly oxygenated blood. This is possible because of the presence of three structural shunts: the ductus venosus, foramen ovale and ductus arteriosus (***Figure 59.21***).

Soon after birth, pulmonary vascular resistance falls because of the action of breathing and resulting pulmonary vasodilatation. Within 30 minutes of delivery, the ductus arteriosus constricts in response to increasing blood oxygen levels. The result is a reversal of the pulmonary–systemic pressure gradient and termination of blood flow from the pulmonary artery into the aorta.

After birth, cutting and tying of the umbilical cord stops venous blood flow from the placenta. This lowers inferior vena cava pressure and, with falling pulmonary vascular resistance, right atrial pressure falls. The result is closure of the foramen ovale. The abolition of venous return from the placenta also causes the ductus venosus to close.

Closure of the fetal circulatory shunts in the few hours following birth is functional, with complete structural closure typically taking several months. In 20% of adults the structural closure of the foramen ovale remains incomplete, but is of no cardiovascular significance.

Abnormalities of cardiac structure may arise from the persistence of normal fetal channels (PDA, patent foramen ovale), failure of septation (atrial septal defect [ASD], VSD, tetralogy of Fallot), stenosis (intracardiac, supravalvular, valvular, infravalvular or extracardiac coarctation of the aorta), atresia or abnormal connections (transposition of the great vessels

Robert E Gross, 1905–1988, Surgeon-in-Chief, Cardiovascular Surgery, Children's Hospital, Boston, MA, USA.
Etienne Arthur Louis Fallot, 1850–1911, Professor of Medicine, Marseilles, France.

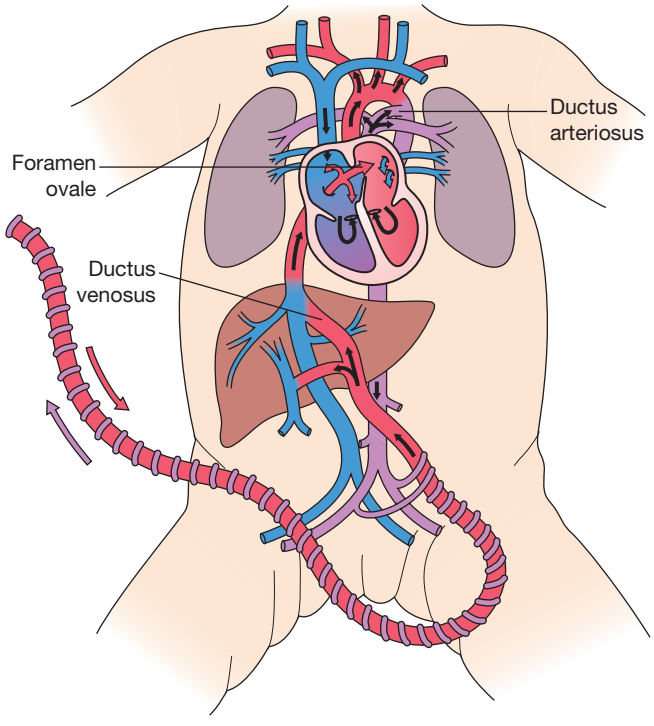

Figure 59.21 Fetal circulation.

(TGV), total anomalous venous drainage). Fetal echocardiography is now sufficiently sensitive to detect intracardiac lesions in the second trimester.

Incidence

Cardiac defects are the most common congenital abnormalities in the UK; the incidence of significant cardiac abnormalities is 8 per 1000 live births. Many spontaneous abortions or stillbirths have cardiac malformations or chromosomal abnormalities associated with structural heart defects. In neonates and children with congenital heart disease, 15% will have more than one cardiac abnormality and 15% will have another extracardiac abnormality.

Aetiology

There is often no obvious aetiology; most abnormalities appear to be multifactorial with both genetic and environmental influences. There are well-recognised associations.

Summary box 59.11

Recognised associations with congenital heart disease

Maternal (environmental) factors

- Infection: rubella
- Disease: systemic lupus erythematosus, diabetes mellitus, maternal phenylketonuria
- Drugs/medications: alcohol abuse, warfarin, phenytoin, lithium, thalidomide

Genetic factors

- Single gene defects: Marfan, Noonan and Holt–Oram syndromes; numerous single-gene disorders
- Chromosomal defects: trisomy 21 (Down syndrome), trisomy 18 (Edwards syndrome), trisomy 13 (Patau syndrome), Turner syndrome, Klinefelter syndrome
- Deletions: DiGeorge and Williams syndromes

Diagnosis

Antenatal diagnosis is occasionally possible, with severe defects detected *in utero* at 16–18 weeks. If an infant has suspected congenital heart disease, a diagnostic evaluation begins with an accurate history from the parents and specific questions about maternal health and drug use. A detailed family history is important because some defects are familial. Clinical examination may reveal a murmur, evidence of heart failure, failure to thrive and cyanosis. In addition, congenital heart disease can present with hypertension, an arrhythmia, evidence of polycythaemia or a thromboembolic event. Investigation is much the same as for the adult patient and, with fetal echocardiography available, cardiac catheterisation is now avoided whenever possible.

Classification

Congenital heart disease can be broadly classified according to the presence or absence of cyanosis, although the distinction is not always clear-cut. Central cyanosis – blueness of the trunk and mucous membranes – results from levels of deoxygenated haemoglobin of >3–5 g/dL in the arterial circulation.

Cyanotic congenital heart diseases make up 25% of cases (8 or 9/1000 live births) and are usually more complex, although they do include simple defects. Cyanotic congenital cardiac lesions can involve:

Jacqueline Anne Noonan, 1928–2020, pediatric cardiologist, the University of Kentucky College of Medicine, Lexington, KY, USA, described this condition in 1963.
Mary Clayton Holt, 1924–1993, cardiologist, The London Hospital for Women and Children, London, UK.
Samuel Oram, 1913–1991, cardiologist, King's College Hospital, London, UK. Holt and Oram described this syndrome in a joint paper in 1960.
John Langdon Haydon Down, 1828–1896, physician, The London Hospital, London, UK.
John Hilton Edwards, 1928–2007, Professor of Genetics, University of Oxford, Oxford, UK.
Klaus Patau, 1908–1975, German-born American geneticist, University of Wisconsin–Madison, Madison, WI, USA.
Henry Hubert Turner, 1892–1970, Professor of Medicine, The University of Oklahoma, Oklahoma City, OK, USA.
Harry Klinefelter, 1912–1990, American rheumatologist and endocrinologist, first described the syndrome in 1942.
Angelo M DiGeorge, 1921–2009, Professor of Pediatrics, Temple University, Philadelphia, PA, USA.
John CP Williams, b. 1922, New Zealand born cardiologist, described the condition in 1961.

- Right–left shunting of blood resulting in decreased pulmonary blood flow. Many lesions consist of septal defects in conjunction with a right-sided obstructive lesion, producing obligatory right-to-left shunts. The most common cause of this is the tetralogy of Fallot.
- Parallel systemic and pulmonary blood flow. If there is no mixing this is incompatible with life; neonates have a patent foramen ovale or VSD that allows some mixing of the two circulations at this level. The most common example of this is TGV.
- Defects in the connections of the heart in which there is mixing of the systemic and pulmonary flows. An example of such a complex lesion is total anomalous pulmonary venous drainage (TAPVD).

Acyanotic congenital heart diseases represent 75% of cases and are usually less complex. They result in an increase in the work imposed on the heart because of either:

- A left-to-right shunt with increased pulmonary blood flow, causing an increase in volume work of the heart. Examples include PDA, ASD and VSD.
- Obstruction of blood flow across a left-sided heart valve, such as aortic stenosis, or in the aorta itself, as occurs with coarctation of the aorta, leading to an increase in pressure and work of the heart.

Typically, acyanotic congenital heart disease presents as heart failure in infancy because of pulmonary congestion caused by increased pulmonary blood flow or increased pulmonary venous blood pressure resulting from an obstructive lesion. The common acyanotic cardiac defects can also present as a murmur in infancy or later.

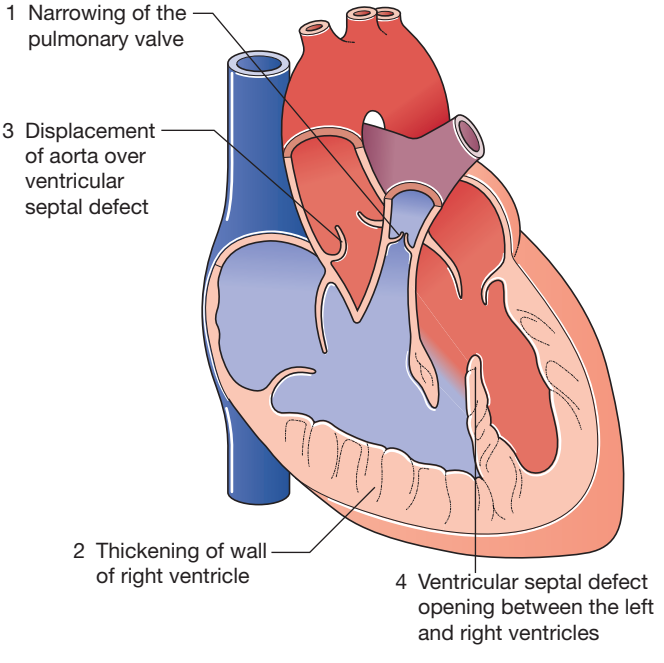

Figure 59.22 Fallot's tetralogy. Four abnormalities that result in insufficiently oxygenated blood being pumped to the body.

Cyanotic congenital heart disease

Tetralogy of Fallot

This is the most common cyanotic congenital heart disease in children surviving to 1 year and accounts for about 4–6% of all congenital heart diseases. The four intracardiac lesions originally described (***Figure 59.22***) were:

- VSD;
- overriding aorta;
- pulmonary (infundibular or subpulmonary) stenosis;
- right ventricular hypertrophy.

There may be no initial clinical signs, but, as pulmonary stenosis progresses, cyanosis typically develops within the first year of life. Squatting is an adaptation by the child to hypoxic spells, increasing systemic vascular resistance and the venous return to the heart. Consequently blood is diverted into the pulmonary circulation, increasing oxygenation. Lethargy and tiredness are also common. Plain radiography classically demonstrates a 'boot-shaped' heart with poorly developed lung vasculature. The diagnosis is confirmed with echocardiography. Surgical correction is the mainstay of treatment and is usually carried out at 4–6 months of age, when possible. Repair is achieved using a patch to close the VSD and resection of the obstructing infundibular septum. Surgical results are good, with a late survival rate of 95% at 5–10 years following correction of tetralogy, an operative mortality rate for a repair of between 5% and 10% and an incidence of reoperation following tetralogy repair of 5–10%.

Transposition of the great vessels

This is the second most common cyanotic congenital heart disease and most common cause of cyanosis from a congenital cardiac defect discovered in the newborn period. TGV results from abnormal development, with the aorta arising from the right ventricle and the pulmonary artery from the left ventricle (***Figure 59.23***). The resulting transposition causes pulmonary and systemic circulations to run in parallel rather than in series; oxygenated pulmonary venous blood returns to the lungs and desaturated systemic venous blood is pumped around the body. The situation is incompatible with life and mixing of the

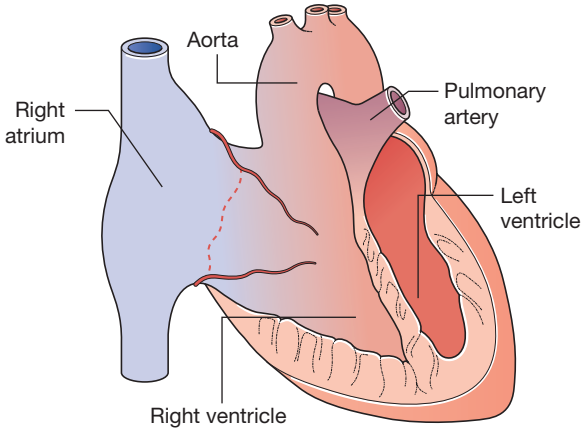

Figure 59.23 Transposition of the great vessels.

blood must occur through associated shunts, such as a patent foramen ovale or VSD.

Patients often present with severe central cyanosis occurring within 48 hours of birth. However, if there is a large ASD or VSD there may be minimal cyanosis initially. Typically, progress is poor and, as pulmonary vascular resistance declines in the neonatal period, high pulmonary flow develops, with cardiac enlargement and left ventricular failure.

The chest radiograph shows pulmonary plethora, with the heart having an 'egg on its side' appearance, with a small pedicle (aorta in front of pulmonary artery). Cardiac echocardiography is sufficient to confirm the diagnosis and delineate the anatomy.

Many infants will die without treatment within 1 month of birth. Initial stabilisation can be achieved by performing percutaneous balloon septostomy to increase the systemic arterial oxygen saturation. Alternatively, intravenous prostaglandins can be administered to keep the PDA open and increase systemic–pulmonary shunting. Arterial switch repair is currently the standard operation and is typically carried out within the first few weeks of life. Long-term outcomes of the operation are excellent and many patients achieve good exercise tolerance; however, some patients will require reoperation for neopulmonary stenosis.

Total anomalous pulmonary venous drainage

TAPVD accounts for 1–2% of congenital heart disease. In TAPVD, the pulmonary venous drainage has disconnected from the left atrium and drains into the systemic venous circulation at some other point (inferior vena cava, superior vena cava, coronary sinus or right atrium). TAPVD presents after the first week of life with cyanosis that is mild to moderate depending on pulmonary flow. Infants with high pulmonary flow develop cardiac failure, recurrent chest infections, failure to thrive and feeding difficulties. If high pulmonary flow is associated with a large ASD, cyanosis is often minimal and the lesion is tolerated well. If there is additional venous obstruction, cyanosis presents at birth with dyspnoea and pulmonary oedema. Echocardiography and cardiac (pulmonary) angiography are necessary to confirm the diagnosis and delineate the anomalous drainage.

The surgical principle is to re-establish the pulmonary venous drainage into the left atrium. The exact operative technique depends on the anatomy and type of TAPVD. The long-term results for survivors of the operation are generally good. Late death following repair is uncommon but, when it occurs, it is often caused by intimal fibroplasia of the pulmonary veins away from the anastomosis.

Eisenmenger syndrome

Eisenmenger syndrome is becoming less common due to development of corrective techniques for congenital heart disease with fewer patients developing a fixed increase in their pulmonary vascular resistance. It follows reversal of a left-to-right shunt, that occurs with, for example, a ASD or VSD, such that de-oxygenated blood now flows from right to left causing cyanosis. These congenital anomalies (ASD, VSD) cause an increase in flow and higher right-sided pressures, which lead to compensatory right ventricular hypertrophy and a subsequent rise in pulmonary artery pressure. Increasing pulmonary hypertension leads to equalisation of pressures either side of the shunt but, at some point, the right-sided pressures will exceed those on the left side, resulting in shunt reversal and desaturated blood entering the left side of the circulation. Cyanosis and dyspnoea are the most common clinical features. Closure of the shunt is contraindicated if pulmonary hypertension is irreversible because the right-to-left shunt now serves to decompress the pulmonary circulation.

Acyanotic congenital heart disease

Patent ductus arteriosus

The ductus arteriosus, a normal fetal communication, facilitates the shunting of oxygenated blood from the pulmonary artery to the aorta, away from the lungs. Normally, functional closure of the ductus occurs within a few hours of birth; it is abnormal if it persists beyond the neonatal period. The ductus closes in response to an increase in peripheral oxygen saturation and a drop in the resistance of the pulmonary circulation as the lungs expand; this causes the ductal tissue to contract through a prostaglandin inhibition mechanism. A cyclo-oxygenase inhibitor (e.g. indomethacin) may be used therapeutically to close the ductus in the first few weeks of life. In premature babies the ductus is more likely to remain patent for longer or permanently. In the isolated case of PDA, there is a left-to-right shunt of blood, resulting in a high pulmonary blood flow. Small shunts usually cause few symptoms and signs apart from the continuous machinery murmur in the left second intercostal space. Larger ducts cause cardiac failure and can uncommonly lead to shunt reversal with cyanosis and clubbing. The diagnosis is best confirmed by echocardiography with colour flow Doppler imaging.

After 6 months of age, PDA closure is rare. Most should be closed by preschool age, regardless of symptoms, if the risks of infective endocarditis, left ventricular failure or, rarely, Eisenmenger syndrome are to be avoided. In the adult, surgical treatment is indicated if there is a persistent left-to-right shunt, even in the presence of reversible pulmonary hypertension. In the premature infant, if medical treatment to close the ductus is unsuccessful, the PDA may be treated by percutaneous interventional cardiology techniques using an umbrella or coil duct occlusion device. If the PDA is very large or the patient very small, surgical closure via a left thoracotomy is preferred. This can be accomplished by either ligation or division of the PDA. The operative mortality rate is low and outcome generally very good.

Coarctation of the aorta

This accounts for 6–7% of congenital heart disease and is defined as a haemodynamically significant narrowing of the

Victor Eisenmenger, 1864–1932, Austrian physician who described this condition in 1897, but the term 'Eisenmenger syndrome' was introduced in 1958 by an Australian cardiologist, **Paul Hamilton Wood** (1907–1962).

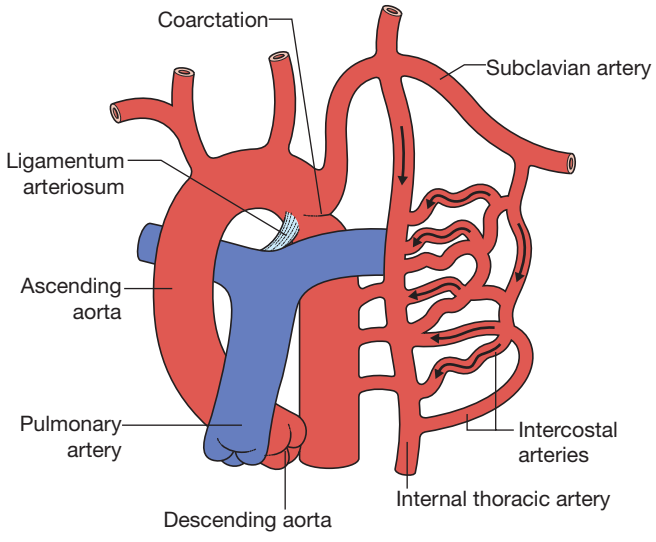

Figure 59.24 Coarctation of the aorta. Coarctation causes severe obstruction of blood flow in the descending thoracic aorta. The descending aorta and its branches are perfused by collateral channels from the axillary and internal thoracic arteries through the intercostal arteries (arrows).

aorta, usually in the descending aorta just distal to the left subclavian artery, around the area of the ductus arteriosus (***Figure 59.24***). The coarctation typically puts a pressure load on the left ventricle, which can ultimately fail. The upper body is well perfused but the lower body, including the kidneys, is poorly perfused, leading to fluid overload, excess renin secretion and acidosis. Coarctation usually affects boys and, if it occurs in girls, is suggestive of Turner syndrome.

In the neonatal period, coarctation ('infantile' or preductal coarctation) presents with symptoms of heart failure. The child may appear well in the first few days of life because the coarctation is bypassed by the ductus arteriosus and oxygenated blood reaches the systemic circulation. As the ductus closes, the child becomes progressively more unwell. In adult-type coarctation (juxtaductal or slightly postductal) obstruction is gradual with complications developing in adolescence or early adulthood. Hypertension is a common presenting problem in older children – often upper body hypertension only with development of enormous collateral vessels that may cause rib-notching and flow murmurs over the scapula. Other symptoms include prominent pulsation in the neck, tired legs or intermittent claudication on exercise. Clinical examination of the pulses may demonstrate a radio-femoral delay and a murmur that is continuous and heard best over the thoracic spine or below the left clavicle.

The chest radiograph classically demonstrates rib-notching because of dilated posterior intercostal vessels. The heart is usually of normal size in the older child and shows a classical 'three sign' replacing the typical aortic knuckle. The upper part of the three sign is the dilated left subclavian, the middle part is the narrowing at the coarctation site and the lower part is the poststenotic dilatation of the descending aorta. Echocardiography is diagnostic. Infant coarctation typically presents with cardiac failure, often requiring vigorous medical treatment, including the administration of prostaglandin to reopen the ductus and general resuscitation before corrective surgery. Definitive treatment is usually surgical repair via a left thoracotomy. Coarctation presenting in the child or later typically requires surgical repair, as most patients die before the age of 40 years because of the associated complications. Percutaneous stenting is currently the standard treatment for adults with isolated coarctation. Without correction, the majority of deaths are caused by heart failure, infective endocarditis, rupture of the aorta or haemorrhagic stroke. The preoperative hypertension may not resolve despite surgical repair.

Atrial septal defects

An ASD is a defect in the septum between the left and right atria leading to a left-to-right shunt, the significance of which is determined by the size of the defect and the relative compliance of the ventricles. The development of the atrial septum is complex and abnormalities of development lead to three commonly recognised ASDs (***Figure 59.25***).

The most common type is an ostium secundum ASD. The anomaly is caused by failure of the septum primum to develop, leading to incomplete coverage of the ostium secundum. These defects are usually asymptomatic in childhood, with symptoms developing insidiously, typically presenting in middle age with congestive cardiac failure secondary to pulmonary hypertension or with atrial arrhythmias.

In ostium primum ASD, the anomaly is a form of partial atrioventricular canal defect or endocardial cushion defect. The abnormalities are confined to the atrial septum and are caused by the endocardial cushions failing to develop and so close the ostium primum part of the interatrial septum. The defect is associated with abnormalities of the mitral valve, leading to mitral regurgitation. There is a relatively high incidence of this abnormality in trisomy 21 (Down syndrome). Typically,

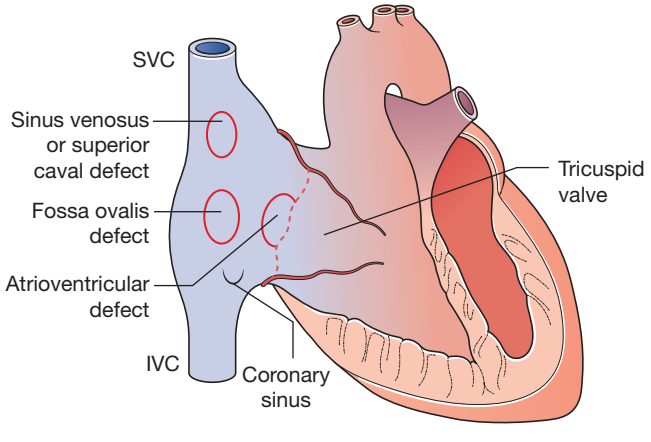

Figure 59.25 Atrial septum viewed from the right. The fossa ovalis is a useful reference point; the most common defect is in this area and is called a fossa ovalis (or ostium secundum) defect. A defect near the atrioventricular junction may be part of the spectrum of atrioventricular septal defects; defects near the entry of the superior vena cava (SVC) are commonly associated with anomalies of venous drainage into the atria. IVC, inferior vena cava.

primum defects present earlier than ostium secundum in childhood, with dyspnoea, recurrent chest infections and, if pulmonary hypertension develops, cyanosis.

A sinus venosus ASD is a rare defect and is the result of failure of partition of the pulmonary and systemic venous circulations. These defects are most commonly located high in the atrial septum at the junction of the superior vena cava and the right atrium. They are frequently associated with anomalous pulmonary venous drainage, with right superior pulmonary veins draining into the superior vena cava or right atrium directly.

Summary box 59.12

Atrial septal defects (ASDs)

Common defects

- Ostium secundum: fossa ovalis defect (approximately 70% of ASDs)
- Ostium primum: atrioventricular septal defect (approximately 20% of ASDs)
- Sinus venosus defect: often associated with anomalous pulmonary venous drainage (approximately 10% of ASDs)
- Patent foramen ovale: common in isolation, usually no left-to-right shunt (not strictly an ASD)

Rarer defects

- Inferior vena cava defects: a low sinus venosus defect and may allow shunting of blood into the left atrium
- Coronary sinus septal defect: also known as unroofed coronary sinus, with the left superior vena cava draining to the left atrium as part of a more complex lesion

Closure is performed during the first decade of life, even in the absence of symptoms, to avoid late-onset right ventricular failure, endocarditis and paradoxical emboli. In adults, closure is still appropriate for symptomatic improvement and avoidance of complications. The traditional method of closure involves open-heart surgery with CPB and closure of the defect, either directly with sutures, as with most secundum defects, or, if the defect is large, using a pericardial or synthetic patch. Closure of small to moderate ASDs using percutaneous catheter-delivered devices in the cardiology catheter laboratory is increasingly common. Primum atrioventricular defect repairs may require additional mitral valve repair. The operative mortality rate for isolated atrioventricular defect repairs is <1%, with an excellent prognosis. Surgical correction of complete atrioventricular canal defects, with closure of the ASD and ventricular septal components and mitral valve repair, is possible, but with a higher surgical mortality rate.

Ventricular septal defects

A VSD is a defect in the interventricular septum that allows left-to-right shunting of blood. VSDs account for 20–30% of congenital heart disease and affect approximately 2 in 1000 live births. They may occur in isolation or as part of a more complex set of cardiac abnormalities (e.g. tetralogy of Fallot, complete atrioventricular canal defect). Four major anatomical types of VSD are described, based on the anatomical subsections of the interventricular septum (*Figure 59.26*).

Summary box 59.13

Types of ventricular septal defects (VSD)

Perimembranous (conoventricular) defect

- The most common defect (70–80%), usually located within the membranous septum and may extend to the tricuspid valve annulus or the base of the aortic valve

Muscular (trabecular) defect

- Occurs in 10% of cases and is located within the membranous septum and can be multiple

Atrioventricular (inlet) defect

- Also called an atrioventricular canal-type defect; occurs in 5% of cases and is located in the atrioventricular canal beneath the tricuspid valve

Subarterial (outlet) defect

- Occurs in 5–10% of cases and lies within the conal septum immediately beneath the pulmonary valve annulus

The VSD permits a ventricular left-to-right shunt, with subsequent right ventricular volume overload and increased pulmonary blood flow. This may lead to progressive pulmonary oedema and congestive cardiac failure. Persistently elevated pulmonary blood flow and pulmonary vascular resistance also lead to irreversible pulmonary hypertension. They may eventually result in reversal of flow across the defect and Eisenmenger syndrome. The clinical presentation reflects the magnitude of the left-to-right shunt, which, in turn, depends on the size of the VSD and the pulmonary and systemic vascular resistances. Small defects may close or cause little systemic disturbance (maladie de Roger); infants are asymptomatic with normal development. In the first 5 years, up to 50% of VSDs close spontaneously. Clinically, a loud pansystolic murmur can

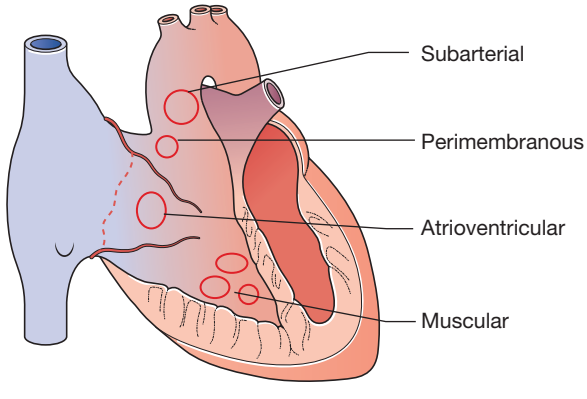

Figure 59.26 Ventricular septum viewed from the right, showing the characteristic sites of ventricular septal defects.

Henri Louis Roger, 1809–1891, physician, Hôpital Sainte-Eugene, Paris, France.

be detected at the left sternal border because of high-pressure flow between the ventricles. Large defects typically present with congestive cardiac failure in the first 2 months of life. Because of the size of the VSD, ventricular pressures are equalised and often only a soft systolic murmur is detected. If left untreated, pulmonary hypertensive changes start from about 1 year of age. Eisenmenger syndrome, secondary to shunt reversal in such cases, may become evident in the second decade of life.

Echocardiography confirms the diagnosis and can estimate the degree of shunting across the defect. Cardiac catheterisation can quantify right and left cardiac pressures and the degree of pulmonary hypertension, as well as demonstrate a step-up in oxygen saturation between left and right ventricles. Generally, surgical closure is indicated for large defects; when there is failure to respond to medical therapy; for left-to-right shunts of >2:1; when there are signs of increasing pulmonary vascular resistance; and in the presence of complications of VSD. These include: (i) aortic regurgitation, which occurs in about 5% of defects; (ii) infundibular stenosis, which tends to be progressive and leads to shunt reversal; and (iii) infective endocarditis, often presenting with pneumonia or pleurisy as the infected 'emboli' in a VSD with a typical left-to-right shunt flows into the pulmonary circulation.

THE THORACIC AORTA

The most common pathologies affecting the thoracic aorta are aneurysm formation and aortic dissection.

Thoracic aortic aneurysms

A true aneurysm is a localised dilatation of a blood vessel involving all three layers of the vessel wall, whereas a false aneurysm has compressed supporting tissue as its wall and is usually the result of a defect in the vessel intima (from trauma, dissection or previous surgery). Aneurysms are described as fusiform when the whole circumference is affected or saccular when only part of the circumference is involved. When the whole length of a vessel is affected, the clinical and anatomical situation is referred to as ectasia.

Aortic aneurysms can develop anywhere along its length, but thoracic aortic aneurysms, including those that extend into the upper abdomen (thoracoabdominal aneurysms), account for 25%, typically occurring in men in the fifth to seventh decade or younger in those with connective tissue disorders. Although a national UK screening programme exists for abdominal aortic aneurysm, this is not true for thoracic disease.

Aetiology

The most common aetiology is atherosclerosis, but connective tissue disorders account for many aneurysms in the aortic root and ascending aorta now that tertiary syphilis is rare. Marfan syndrome is associated with cystic medial degeneration involving the vessel wall and causes widening of the proximal aorta and aortic root, leading to aortic valve insufficiency. It is caused by a mutation in the fibrillin gene. Other disorders associated with aneurysm formation and dissection include Ehlers–Danlos syndrome, which is associated with a range of complications including aortic dissection, joint dislocations, scoliosis and osteogenesis imperfecta.

Many aneurysms are asymptomatic and are discovered incidentally on routine chest radiographs. Others present as a space-occupying lesion in the thorax with pain caused by pressure on adjacent structures (vertebra), hoarseness (left recurrent laryngeal nerve), dysphagia (oesophagus) and respiratory symptoms (left main bronchus). Aortic root aneurysms may lead to dilatation of the aortic root annulus and aortic regurgitation.

Rupture can lead to cardiac tamponade or haemorrhage into the left pleural space, leading to dyspnoea and, if the tracheobronchial airway or oesophagus is involved, haemoptysis or haematemesis.

Investigations

The diagnosis is confirmed by CT or MRI. Arteriography is not necessary for diagnosis but is often required to demonstrate the relation of the arch vessels to the aneurysm.

Indications for surgery

Without treatment the aneurysm is likely to expand and ultimately rupture. Important factors to consider when planning treatment are age, comorbidity and coexisting coronary disease.

In ascending aneurysms, the presence of progressive aortic valve insufficiency is an important indication for surgery. Other indications in this group, including Marfan-related aneurysms, are a diameter of 4.5–5 cm and the presence of symptoms. In descending aneurysms, indications for surgery include symptoms, acute enlargement and a diameter of approximately 6 cm.

Surgical options

The approach adopted for surgical treatment depends on the location of the aneurysm, but typically involves a median sternotomy, CPB and occasionally cooling the patient to 18°C before cross-clamping the aorta above the aneurysm at the distal ascending aorta just before the innominate artery (***Figure 59.27***). If the aortic root is involved, the aorta, together with its annulus and valve, is resected and a composite graft is sutured to the aortic root. The circulation is arrested and, after removal of the aortic cross-clamp, the distal anastomosis is completed. The coronary ostia require reimplantation into the graft (Bentall's operation). More recently there has been increased interest in valve-sparing root surgery or valve repair and root replacement, which is based on two original techniques, namely the remodelling technique described by Magdi Yacoub and the reimplantation technique described by Tirone David. These techniques are associated with reduced thromboembolic complications, but are usually demanding with a small increased risk of requiring reoperation at a later stage.

Hugh Henry Bentall, 1920–2012, Professor of Cardiac Surgery, The Royal Postgraduate Hospital, Hammersmith, London, UK.
Sir Magdi Yacoub, b. 1935, Professor of cardiac surgery, Imperial College, UK.
Tirone David, b. 1944, Professor of Surgery, Toronto, Canada.

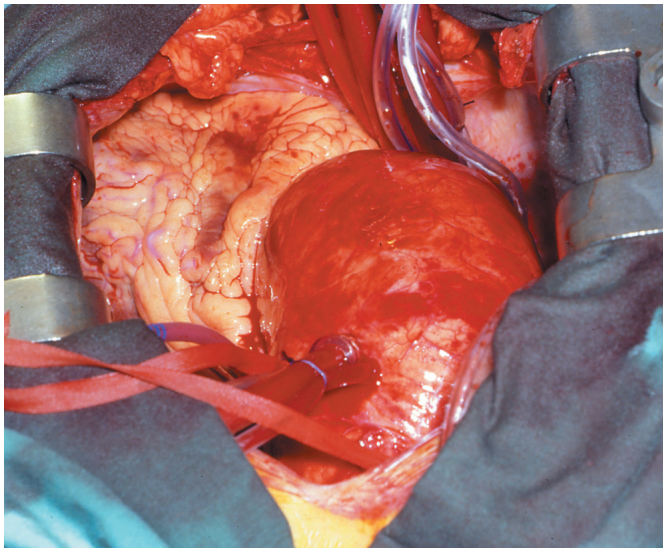

Figure 59.27 A large thoracic aortic aneurysm.

If the ascending aorta is involved, it is resected and replaced with a tube graft. For aortic arch aneurysms, surgery on this section of the aorta is a formidable undertaking because the cerebral and subclavian vessels have to be anastomosed to the graft, either separately or en bloc. Typically, it involves a period of circulatory arrest and some form of cerebral protection. Excision of a descending aortic aneurysm is with graft replacement under CPB, with exposure via a left thoracotomy or with a heparin-bonded shunt. Increasingly, thoracic aneurysms at the aortic arch or more distal are repaired using a percutaneous approach via the femoral artery, with insertion of an endovascular stent graft under radiological guidance.

Surgical outcome

The operative mortality rate is variable depending on the location and type of repair required, but electively is between 5% and 15% and is considerably higher in emergency repairs. Long-term survival depends on underlying pathology but, for ascending aneurysm repairs, the 5-year survival rate is approximately 65%. The major complications of descending aneurysm repairs include paraplegia, renal failure and ventricular dysfunction.

Aortic dissection

This occurs when a defect or flap occurs in the intima of the aorta, resulting in blood tracking into the aortic tissues, splitting the medial layer and creating a false lumen. It most commonly occurs in the ascending aorta or, less often, just distal to the left subclavian artery. It is also more common in men, typically those aged 50–70 years, and in Afro-Caribbean patients.

Aetiology

It usually occurs as a spontaneous or sporadic event, often in a patient with a history of hypertension. Other important associations include Marfan syndrome and pregnancy.

Summary box 59.14

Predisposing factors for aortic dissection

- Age
- Hypertension
- Marfan syndrome
- Pregnancy
- Other connective tissue disorders, e.g. Ehlers–Danlos syndrome, giant cell arteritis, systemic lupus erythematosus
- Coarctation of the aorta
- Turner or Noonan syndromes
- Aortic cannulation site following previous cardiac surgery (iatrogenic)

Clinical features

The presentation is often with tearing interscapular pain not unlike the pain of myocardial ischaemia, and it may be difficult to distinguish between the two. The extent of arterial dissection may produce widespread symptoms and signs.

The dissection can extend distally down the aorta and spiral to involve:

- the renal arteries (renal pain and renal failure);
- the mesenteric arteries (abdominal pain and bowel ischaemia);
- the spinal arteries (paraplegia);
- the iliac arteries (leg pain, pallor, loss of or reduced pulses and acute limb ischaemia).

The dissection may track proximally to involve:

- the head and neck vessels (symptoms and signs of a stroke or transient ischaemic attack);
- the coronary vessels (MI);
- the aortic root (aortic regurgitation).

The dissection may also result in aortic wall rupture into the pericardium (cardiac tamponade) or mediastinum (left haemothorax).

Classification

There are two classifications, both of which are limited in their application but widely used. The DeBakey classification is based on the pattern of dissection, whereas the Stanford classification is based on whether the ascending aorta is involved (*Figure 59.28*).

Investigations

The diagnosis is suspected based on the clinical presentation and careful history taking. Diagnosis is confirmed by CT, which is the standard method for diagnosis. Other imaging modalities such as TOE or MRI can be utilised in cases where the CT is equivocal (*Figure 59.29*).

Management

Initial management of all types of aortic dissection includes blood pressure control (which is usually high at presentation)

Michael Ellis DeBakey, 1908–2008, American cardiac surgeon, Baylor College of Medicine, Houston, TX, USA.

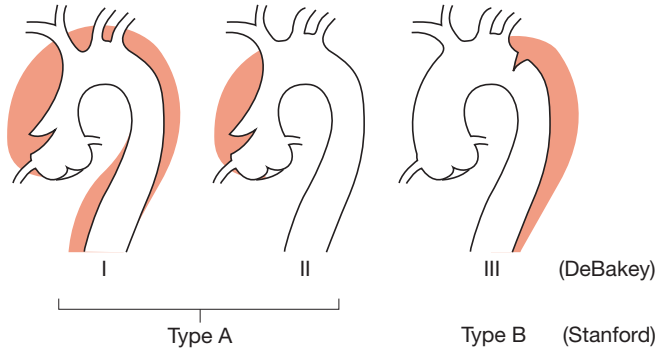

Figure 59.28 Stanford classification of aortic dissections according to whether the ascending aorta is involved (type A) or not (type B). This is simpler than the DeBakey classification (types I, II and III).

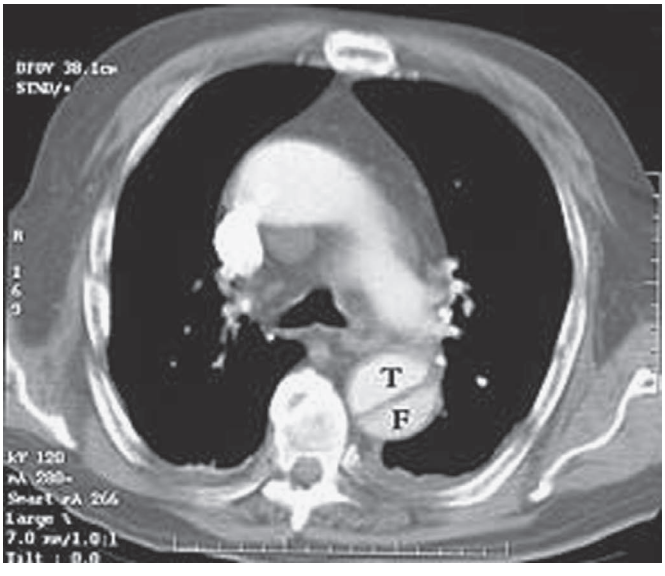

Figure 59.29 Computed tomography scan showing acute dissection of the descending thoracic aorta. F, false lumen; T, true lumen.

and strict pain management, followed by prompt referral for specialist management. The advent of specialist regional centres and regional referral pathways has been shown to improve outcomes in these patients.

Surgical options

Type A (or type I and II) dissections

Those involving the ascending aorta usually require surgical intervention. The chest is opened through a median sternotomy and CPB is commenced, often with core cooling down to 18°C based on the technique used. The aorta is cross-clamped as high up the ascending aorta as possible and opened. Cardioplegic solution is infused into the coronary ostia to arrest the heart in diastole. If the intimal tear is present and localised, the ascending aorta is excised with the tear and replaced with a synthetic graft. The distal anastomosis is performed with circulatory arrest. Recently there have been attempts to carry out endovascular stenting of type A dissections with variable degrees of success. The extent of replacement of the aorta in the setting of acute type I dissection is debatable and is based on the clinical picture and surgical experience.

Type B (or type III) dissections

Initially, these are best managed medically with antihypertensive drugs and monitoring on an acute care unit. Intervention is indicated in complicated cases if the pain increases (signalling impending rupture) or fails to resolve; or when the dissection is associated with evidence of malperfusion (organ, limb or neurological symptoms). The use of percutaneously placed endovascular stents is currently the standard intervention of choice in patients with complicated type B dissection, and surgery is reserved for the rare case that is not suitable for stenting.

Outcomes

If type A dissection is untreated, the mortality rate is 50% within 48 hours and 75% within 1–2 weeks, whereas patients with type B dissections have a better prognosis. Surgical mortality is variable but is around 20–25% for proximal aortic dissection. The overall survival rate for patients leaving hospital, regardless of the type of dissection, is around 80% at 5 years and 40% at 10 years.

PERICARDIAL DISEASES

There is a fibrous envelope covering the heart and separating it from the mediastinal structures. This includes a parietal layer and allows the heart to move with each beat. It can be left wide open after cardiac surgery without any ill effects; however, there are a number of conditions affecting the pericardium that may present to the surgeon.

Pericardial effusion

There is continuous production and resorption of pericardial fluid; if this balance is disturbed, a pericardial effusion may develop. If the pressure exceeds the pressure in the atria, compression will result in reduced venous return and compromised circulation. This state of affairs is called tamponade. A gradual build-up of fluid (e.g. malignant infiltration) may be well tolerated for a long period before tamponade occurs, and the pericardial cavity may contain up to 2 litres of fluid. Acute tamponade (from penetrating trauma, coronary angiography or postoperatively) may occur in minutes with small volumes of blood. The clinical features are low blood pressure with a raised jugular venous pressure and paradoxical pulse. Kussmaul's sign is a characteristic pattern that is seen when the jugular venous pressure rises with inspiration as a result of the impaired venous return to the heart.

Emergency treatment of pericardial tamponade is aspiration of the pericardial space. A wide-bore needle is inserted under local anaesthesia to the left of the xiphisternum, between the angle of the xiphisternum and the ribcage (***Figure 59.30***). The needle is advanced towards the tip of the scapula into the pericardial space. An ECG electrode attached to the needle

Adolf Kussmaul, 1822–1902, Professor of Medicine at, successively, Heidelberg, Erlangen, Freiburg and Strasbourg, Germany.

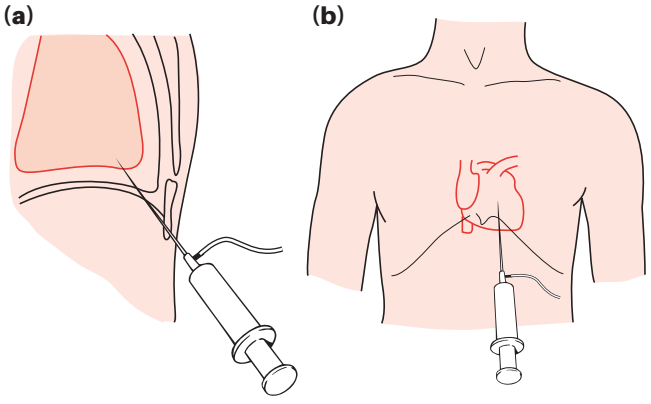

Figure 59.30 (a) Pericardial aspiration through the subxiphoid region. (b) Site of needle insertion for pericardial aspiration.

will indicate when the heart has been touched. This will relieve the situation temporarily until the cause of the tamponade is established. Penetrating wounds of the heart usually require exploration through a median sternotomy. Emergency room thoracotomy is rarely required. Chronic tamponade is usually a result of malignant infiltration of the pericardium (usually secondary carcinoma from breast or bronchus) or, very occasionally, uraemia or connective tissue disease. Treatment sometimes requires a pericardial window between the pericardial space and the pleural or peritoneal space.

Pericarditis

Infection and inflammation may also affect the pericardium. Acute pericarditis usually occurs following a viral illness. Treatment is with non-steroidal anti-inflammatory drugs and bed rest (in case there is an underlying myocarditis). Acute purulent pericarditis is uncommon but requires urgent drainage and intravenous antibiotics, with attention to the underlying cause.

Chronic pericarditis is an uncommon condition in which the pericardium becomes thickened and non-compliant. The heart cannot move freely and the stroke volume is reduced by the constrictive process. The central venous pressure is raised and the liver becomes congested. Peripheral oedema and ascites are also a feature. Treatment is surgical and is aimed at relieving the constriction.

CARDIAC MASSES

Cardiac masses can be either thrombus (blood clots) or tumours. Thrombus can be found in patients with poor left ventricular function or longstanding AF, as well as in patients with proximal pulmonary embolus, in either the ventricles or the left atrium.

Cardiac tumours can be either benign or malignant, which in turn can be secondary (from lung, oesophagus, breast, etc.) or primary.

Atrial myxoma

This is the most common benign cardiac mass in adults. Myxomas are neoplasms of endocardial origin, often appearing as pedunculated masses most commonly seen in the left (75%) or the right (20%) atria. They are rarely found in the ventricles (*Figure 59.31*). Myxomas are associated with a congenital disorder (Carney complex) in 5% of cases. They usually present with symptoms related to blood flow obstruction through heart valves or systemic embolisation. Treatment is by surgical excision and recurrence rates are usually <5%.

Rhabdomyoma

Cardiac tumours in children are incredibly rare (<0.2% of the population), although this is the most common benign cardiac tumour. It usually presents with symptoms related to valve dysfunction or arrhythmias. There are usually multicentric pedunculated masses in either or both ventricles. Rhabdomyoma is associated with tuberous sclerosis in >50% of the cases. Treatment is usually by surgical excision.

Primary malignant cardiac tumours

These are extremely rare and less common than secondary malignancies. They include angiosarcoma, rhabdomyosarcoma and leiomyosarcoma. Patients usually have advanced disease when they are discovered, and they are associated with poor outcomes even with multimodality treatment (surgery and chemoradiation).

Figure 59.31 Transthoracic echocardiography view of a left atrial (LA) myoma (arrow). RA, right atrium.

J Aidan Carney, b. 1934, County Roscommon, Ireland, pathologist at the Mayo Clinic, described a syndrome of myxomas, spotty pigmentation and endocrine overactivity in 1985.

MANAGEMENT OF CARDIAC ARREST AFTER CARDIAC SURGERY

Introduction

The incidence of cardiac arrest after cardiac surgery is around 0.7–8.0%, with 17–79% survival rates. VF accounts for up to 50% of arrests; tamponade and major bleeding account for most others. Multiple variables may dictate differences in the management of cardiac arrest after cardiac surgery when compared with other situations. Therefore, EACTS published guidelines for resuscitation of cardiac arrest after cardiac surgery, which are summarised below.

Cardiac arrest with 'non-shockable' rhythm

Cardiac surgical patients with a non-VF/ventricular tachycardia (VT) arrest commonly have tamponade, tension pneumothorax or severe hypovolaemia. Prompt treatment is associated with an excellent outcome. Resternotomy should be performed promptly if connecting the pacemaker and atropine fail to resolve the arrest, especially if a prolonged period of CPR is needed, which will be better performed by internal massage.

Emergency resternotomy for ventricular fibrillation or pulseless ventricular tachycardia

A precordial thump may be successful if performed within 10 seconds of the onset of VF or pulseless VT; however, this should not delay cardioversion by defibrillation. In VF or pulseless VT, emergency resternotomy should be performed after three failed attempts at defibrillation.

Emergency resternotomy

After the identification of cardiac arrest, basic life support according to the Advanced Life Support guidelines should be initiated while preparing for emergency resternotomy. Emergency resternotomy may be required in 0.8–2.7% of all patients undergoing cardiac surgery. Emergency resternotomy is a multipractitioner procedure, which should be rapidly performed with a full aseptic technique.

Preparation for emergency resternotomy

- A gown and gloves should be donned in a sterile fashion, but opening should not be delayed in the arrest situation.
- The drape is applied, ensuring that the whole bed is covered (if an all-in-one sterile drape is used then there is no need to prepare the skin with antiseptic).
- The scalpel is used to cut the sternotomy incision, including all sutures, deeply down to the sternal wires.
- All sternal wires are cut with the wire cutters. The sternal edges will separate a little, which may relieve tamponade.
- Suction is used to clear excessive blood or clot.
- The retractor is placed between the sternal edges and the sternum opened.
- If cardiac output is restored expert assistance should then be summoned. If there is no cardiac output, the position of any grafts should be carefully identified and internal cardiac massage and internal defibrillation performed, if required.

Internal cardiac massage

This is a potentially dangerous procedure. Risks include avulsion of a bypass graft, with the LIMA being at particular risk, and right ventricular rupture, especially if it is thin or distended. Therefore, it is important to carefully remove any clot and identify structures at risk such as grafts before placing hands around the heart. There are several methods of internal massage; however, the two-hand technique is the safest.

Two-hand technique

The heart should be inspected to locate the internal mammary and other grafts if present, followed by removal of any blood clots. The right hand is passed over the apex of the heart and then advanced round the apex to the back of the heart, palm up and hand flat. The left hand is then placed flat onto the anterior surface of the heart and the two hands squeezed together at a rate of 100 per minute. Flat palms and straight fingers are important to avoid an unequal distribution of pressure onto the heart, thereby minimising the chance of trauma. If there is a mitral valve replacement or repair, care should be taken not to lift the apex by the right hand, as this can cause a posterior ventricular rupture.

ACKNOWLEDGEMENTS

The author and editors wish to acknowledge the help of Mr Nathan Tyson in the preparation of this chapter.

PART 9 | Cardiothoracic

CHAPTER 60

The thorax

Learning objectives

To understand:

- The anatomy and physiology of the thorax
- Investigation of chest pathology
- The role of surgery in pleural disease
- The assessment of patients requiring lung surgery
- Surgical oncology as applied to chest surgery
- Chest wall disorders

INTRODUCTION

Anatomical development of the lungs

The lungs are derived from an outpouching of the primitive foregut during the fourth week of intrauterine life. This bud becomes a two-lobed structure, the ends of which ultimately become the lungs. The lobar arrangement is defined early and is fairly constant but anomalies of fissures and segments leading to anatomical variation in the adult are common.

The primitive lungs drain into the cardinal veins, which ultimately become the pulmonary veins draining into the left atrium. Variability in venous drainage is very common and is usually of little functional significance. At the most severe end of the spectrum is total anomalous drainage, which presents in early infant life because oxygenated blood is all directed back to the right heart.

Anatomy of the lungs

The left lung is divided by the oblique fissure, which lies nearer to the vertical than horizontal, so the upper and lower lobes could also be called anterior and posterior. On the right, the equivalent of the left upper lobe is further divided to give the middle lobe. Each lobe is composed of segments, with anatomically defined and named bronchial, pulmonary arterial and venous connections (*Figure 60.1*).

The right main bronchus (RMB) is shorter, wider and nearly vertical compared with the left main bronchus (LMB). As a consequence, inhaled foreign bodies are more likely to enter the RMB than the left (*Figure 60.2*). The trachea and bronchi have a systemic arterial blood supply delivered by the bronchial arteries, which arise directly from the nearby thoracic aorta.

Lymphatic drainage tends to follow the bronchi. Lymph nodes are both named and identified by numbered 'stations' and more recently into zones, which are of importance in staging of lung cancer (*Figure 60.3*).

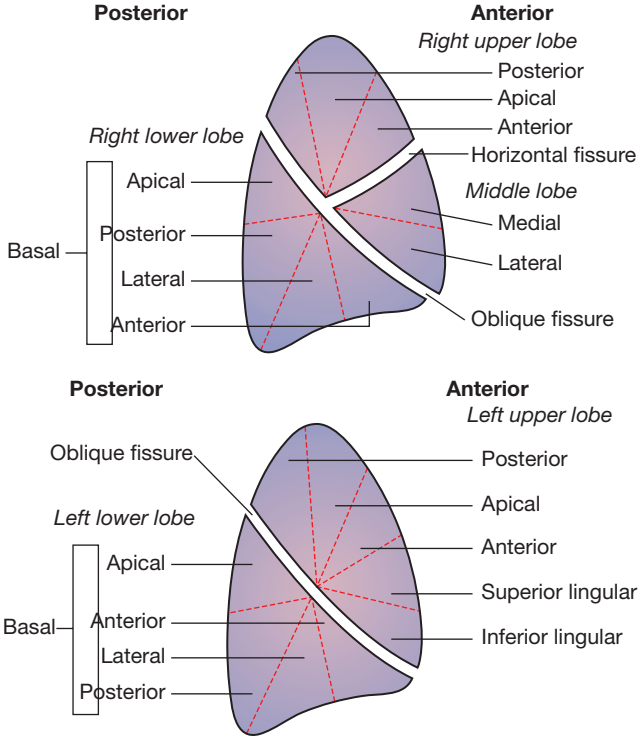

Figure 60.1 The lobar and segmental divisions of the lungs, right lung above and left lung below as if viewed from the side.

Mechanics of breathing

The intercostal muscles contract, causing the ribs to move upwards and outwards, thereby increasing the transverse and anteroposterior dimensions of the chest wall. Along with the diaphragm, which contracts simultaneously and flattens, increasing the vertical dimension of the chest cavity, these muscles are the muscles of respiration. In addition, the accessory muscles of respiration – the neck and spinal muscles such as sternocleidomastoid – may be used particularly during heavy breathing, such as when exercising or during periods of illness

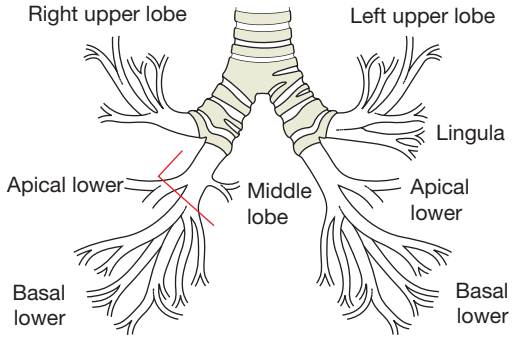

Figure 60.2 Surgical anatomy of the bronchial tree. To surgically remove the right lower lobe and conserve the middle lobe, the surgeon must be prepared to dissect and separately divide the apical bronchial segment (red line).

such as a pneumonia (lung infection). As the volume increases, the intrathoracic pressure falls and air flows in until the alveolar pressure is the same as the atmospheric pressure. The only force used in normal expiration is the elastic recoil of the lung.

Ability to cough comfortably to clear retained secretions is an essential part of recovery from surgery. In a vigorous cough, probably the only muscle in the body that is relaxed is the diaphragm; as the abdomen and chest wall and accessory muscles contract, the limbs are braced and the sphincters are tightened. When the intrathoracic and abdominal pressure is built up, the glottis is opened and the diaphragm is forced up as a piston, or like the plunger of a syringe, to expel air at high velocity.

ASSESSMENT OF FITNESS FOR MAJOR THORACIC SURGERY

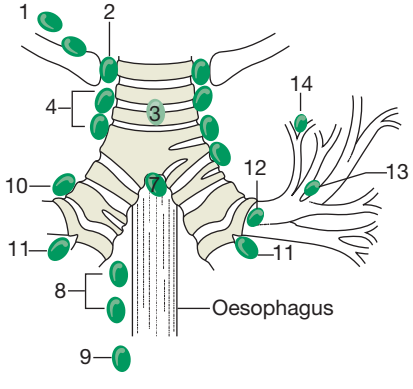
The British Thoracic Society (BTS) recommends a tripartite risk assessment model for patients undergoing lung resection, considering the risk of operative mortality, risk of perioperative myocardial events and risk of postoperative dyspnoea (***Figure 60.4***).

Risk of operative mortality

The Thoracic Surgery Scoring System (Thoracoscore) is the most widely used model to assess the risk of operative mortality in thoracic patients. Risk is calculated based on nine variables – age, sex, American Society of Anesthesiologists score, performance status, dyspnoea score, priority of surgery, extent of surgery, malignant diagnosis and composite comorbidity score. It is currently the most robust model available to estimate the risk of death when considering patients for thoracic surgery.

Risk of perioperative myocardial event

History, physical examination and resting electrocardiogram (ECG) form the basics of assessing perioperative cardiovascular risk. Patients who are found to have an active cardiac condition should be evaluated by a cardiologist and optimised (medical, revascularisation or cardiac surgery) before thoracic surgery. Surgery should be avoided within 30 days of myocardial infarction.



Supraclavicular zone
Station 1: low cervical, supraclavicular sternal notch

Upper zone

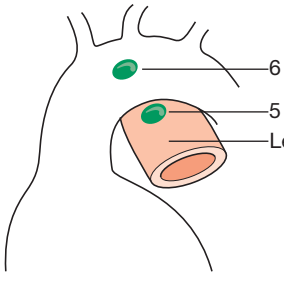
Station 3: prevascular/retrotracheal
Station 4: lower paratracheal



Subcarinal zone
Station 7: subcarinal

Hilar/interlobular zone
Station 10: hilar
Station 11: interlobar

Lower zone
Station 8: paraoesophageal
Station 9: pulmonary ligament

Peripheral zone
Station 12: lobar
Station 13: segmental
Station 14: subsegmental

AP zone
Station 5: subaortic
Station 6: para-aortic

Figure 60.3 Lymph node stations related to the bronchial tree are particularly important in the staging of lung cancer, with N1 nodes (10–14) and N2 nodes (2–9) shown. AP, anteroposterior.

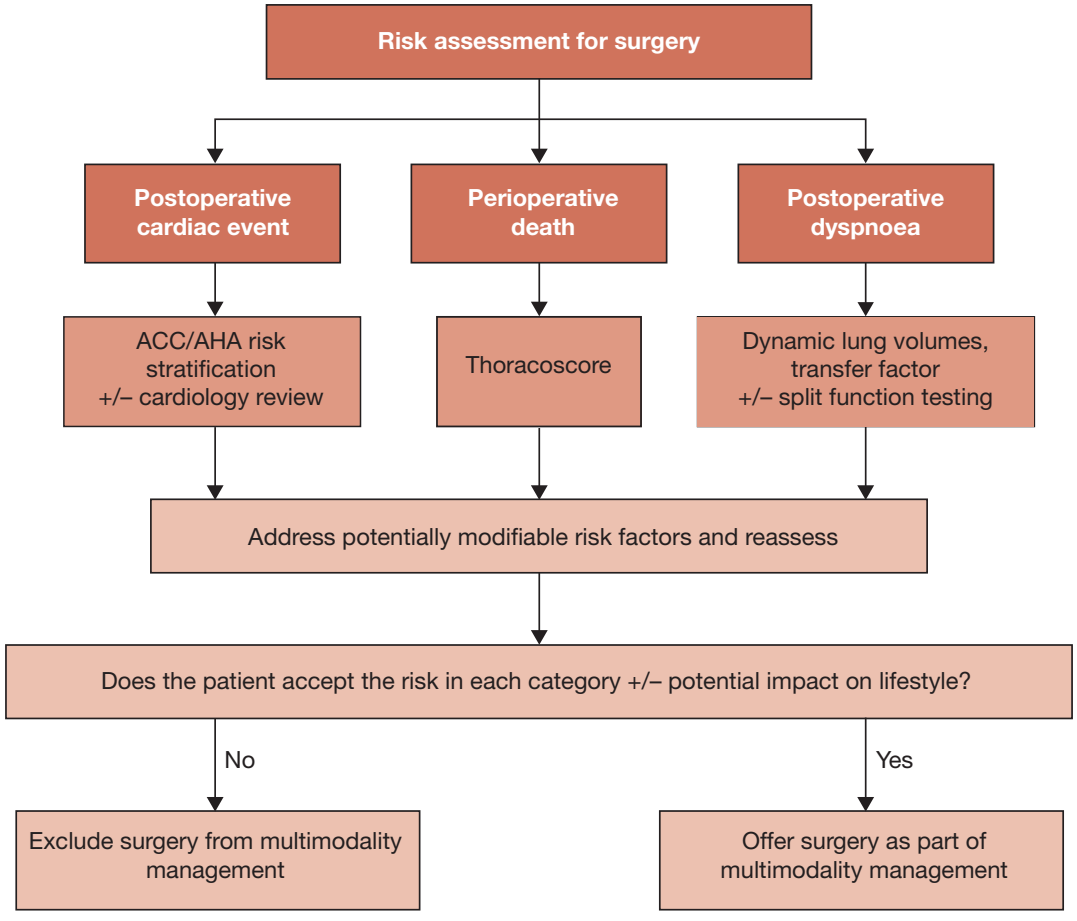


Figure 60.4 Tripartite risk assessment. ACC, American College of Cardiology; AHA, American Heart Association.

Risk of postoperative dyspnoea

Any patient undergoing general anaesthesia requires some assessment of respiratory function. This may be a clinical appraisal of fitness, but more detail is necessary for patients who are undergoing lung resection.

Investigation of the respiratory system

Pulmonary function tests (PFTs) are useful in determining the functional capacity of the patient and the severity of pulmonary disease, and in predicting the response to various treatments. The tests range from simple clinic or bedside measurements to those only available in specialist centres. Spirometry is the most commonly performed PFT and measures specifically the amount (volume) and/or speed (flow rate) of air that can be inhaled or exhaled. It is reported in both absolute values and as a predicted percentage of normal. Normal values vary, depending on gender, race, age and height. The most common parameters measured in spirometry are defined below and illustrated in *Figure 60.5*.

Peak expiratory flow rate

Peak expiratory flow rate (PEFR) is measured by a Wright peak flow meter or a peak flow gauge. This is the maximum airflow velocity achieved during an expiration delivered with maximal force from the total lung capacity. It is a reliable and reproducible test but has the disadvantage of being effort dependent, and it may therefore be affected by abdominal or thoracic wound pain. PEFR measurements are often used in managing asthma, but there are many other causes of low PEFR such as a problem with large airway patency.

Forced expiratory volume in 1 second

The forced expiratory volume in 1 second (FEV_1) is the amount of air forcibly expired in 1 second. It is low in obstructive lung disease and may be normal in patients with poor gas exchange.

Forced vital capacity

The forced vital capacity (FVC) is the volume of air forcibly displaced following maximal inspiration to maximal expiration. The FEV_1 and the FVC can be measured using a Vitalograph,

Basil Martin Wright, 1912–2001, member of the scientific staff of the Medical Research Council Research Centre, Northwick Park Hospital, Harrow, UK.

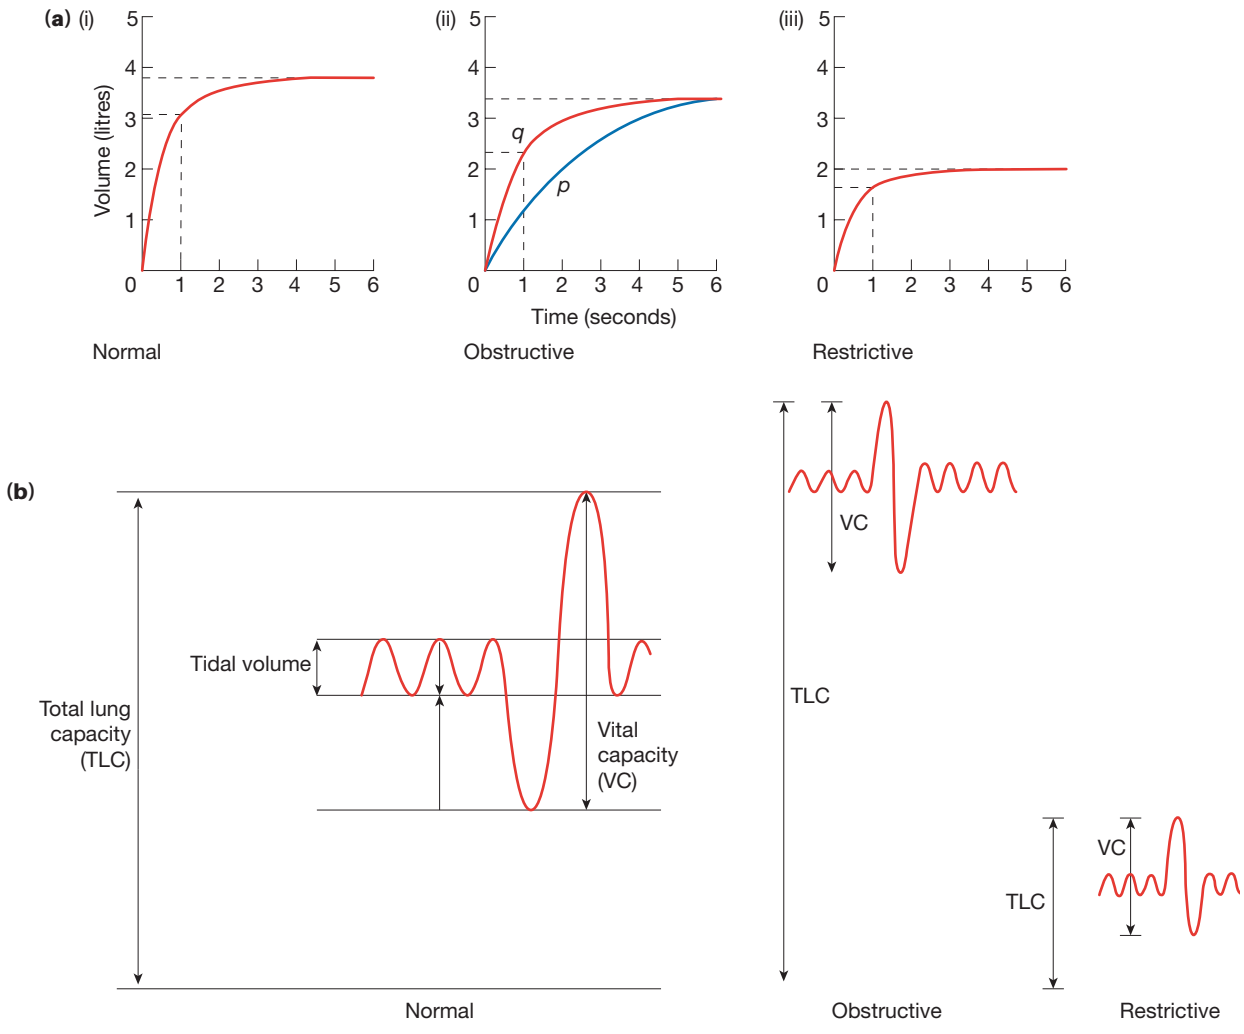

Figure 60.5 Spirometry. **(a)** Spirogram tracings obtained from a Vitalograph: **(i)** normal forced expiratory volume in 1 s (FEV_1) 3.1 litres, forced vital capacity (FVC) 3.8 litres, FEV_1/FVC 82%; **(ii)** obstructive defect, reversible asthma, *p* before a bronchodilator, FEV_1 1.4 litres, FVC 3.5 litres, FEV_1/FVC 40%; q after a bronchodilator, FEV_1 2.5 litres, FVC 3.5 litres, FEV_1/FVC 71%; **(iii)** restrictive defect, fibrosing alveolitis, FEV_1 1.8 litres, FVC 2.0 litres, FEV_1/FVC 90%. No change with bronchodilators. **(b)** Changes in lung volume in obstructive and restrictive lung disease. (Reproduced from Gray HH. Pulmonary embolism. *Medicine International* 1993; **21**: 477, by kind permission of the Medicine Group (Journals) Ltd.)

and a ratio (FEV_1/FVC) can be calculated (***Figure 60.5***). A low ratio indicates obstruction and the test should be repeated after bronchodilators. A normal ratio (FVC and FEV_1 reduced to the same extent) indicates a restrictive pathology.

There are two physiological categories of lung disease: obstructive and restrictive (***Table 60.1***). In obstructive conditions such as asthma or emphysema, the flow of air in and out of the lungs is impaired. In restrictive disease, such as lung fibrosis, the lungs have lost size or elasticity, becoming 'stiff' so that they do not fill or expand properly.

TABLE 60.1 Spirometry values in obstructive and restrictive lung diseases.

	Obstructive pattern	Restrictive pattern
PEFR	↓↓	Normal or ↓
FEV_1	↓↓	Normal or ↓
FVC	Normal or ↓	↓↓
FEV_1/FVC	<70	>80

FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity; PEFR, peak expiratory flow rate.

Diffusion capacity

The diffusion capacity (DLCO) is a measurement of the lung's ability to transfer gases and is often referred to as the 'transfer factor'. It cannot be performed at the bedside, requires the patient's current haemoglobin level and is a test of the integrity of the lung's alveolar–capillary surface area for gas exchange. In lung diseases that damage the alveolar walls, such as emphysema, or that thicken the alveolar membrane, such as lung fibrosis, it may be reduced. In patients who require surgery to remove part of their lung, for example for lung cancer, measurement of DLCO is an important determinant of 'fitness' for surgery and it should be measured formally as part of a lung function test.

Oxygen saturation

Oxygen saturation (S_pO_2) refers to the degree of oxygen molecules (O_2) carried in the blood attached to haemoglobin molecules (Hb). It is a measure of how much oxygen the blood is carrying as a percentage of the maximum it could carry. The common method of monitoring the oxygenation of a patient's haemoglobin is through a pulse oximeter.

Blood gases

The S_pO_2 measured non-invasively with a pulse oximeter measures only oxygenation, not ventilation, and provides no information regarding a patient's carbon dioxide or bicarbonate levels, blood pH or base deficit. This requires arterial blood sampling or 'blood gases' (*Table 60.2*).

TABLE 60.2 Arterial blood gases: 'normal values'.

pH 7.35–7.45
$PaCO_2$ 4.5–6 kPa (35–50 mmHg)
PaO_2 11–14 kPa (83–105 mmHg)
Standard bicarbonate 22–28 mmol/L
Anion gap 10–16 mmol/L
Chloride 98–107 mmol/L

The FEV_1 and DLCO are often used to predict the risk of postoperative dyspnoea after lung resection. The predicted postoperative values can be calculated by considering the volume of lung, more specifically the number of bronchopulmonary segments, expected to be removed at surgery. For example if five segments of the left upper lobe are to be removed, the postoperative predicted FEV_1 in a patient with a preoperative FEV_1 of 2.5 litres (85% predicted) is $((19 - 5)/19) \times 2.5 = 1.84$ litres and $((19 - 5)/19) \times 85\% = 62.6\%$ predicted. This assumes that all bronchopulmonary segments are functioning (e.g. not collapsed) and contribute equally to lung function. Although an optimum cut-off of postoperative predicted FEV_1 of 40% is widely cited, there are currently limited data to provide guidance on this figure to help predict an acceptable degree of postoperative dyspnoea and quality of life. Patients should still be offered surgical resection if the predicted risk of postoperative dyspnoea is moderate or high, as long as they are aware of and accept the risks of dyspnoea and associated complications.

Exercise testing

Other functional assessments, including the shuttle walk test, 6-minute walk test, stair climbing coupled with other tests such as oxygen saturations, as well as cardiopulmonary exercise testing (CPET), could be considered for patients at moderate or high risk of postoperative dyspnoea and may help predict surgical outcome after lung resection. In patients with moderate to high risk of postoperative dyspnoea, using a shuttle walk test distance of >400 m and CPET of >15 mL/kg/min are cut-off values for good function.

The pleura

The key to many aspects of practical chest surgery is an understanding of the pleura and of the mechanics of breathing. Management of the essentially healthy pleural space is logical and simple and needs minimal technology. On the other hand, when pleural disease is advanced, for example when there is gross pleural sepsis surrounding a leaking and trapped lung, management is difficult and the patient may require prolonged care with repeated interventions.

The physiology of pleural fluid

The turnover of fluid in the human pleural space is about 1–2 litres in 24 hours, with only 5–10 mL of fluid present at any one time as a film, about 20 μm thick, between the visceral and parietal pleura.

The mechanisms and equations given are simplifications but serve to explain the clinical conditions encountered. The fluid is produced from the capillaries of the parietal pleura as a transudate, according to the Starling capillary loop pressures. However, there is a further negative force in the pleura. The elastic content of the lung causes it to recoil and collapse if not held open by the negative pressure in the pleura. This elastic recoil exerts about 4 mmHg of negative pressure and favours accumulation of fluid. The secreting forces add up to about 11 mmHg in health. Pleural fluid is mainly reabsorbed (about 90%) by the visceral pleura, whose capillaries are part of the pulmonary circulation. The principal force in absorption of pleural fluid is oncotic pressure (approximately 25 mmHg) minus the difference in mean capillary hydrostatic pressure of the pulmonary capillary (8 mmHg). Thus, the overall absorbing pressure is 25 – 8 = 17 mmHg, producing a net drying effect (17 – 11) of about 6 mmHg (*Figure 60.6*).

Gas in the pleural space

There is normally no free gas in the pleural space because the same physiological mechanism that absorbs air from a pneumothorax prevents any gas accumulating.

The partial pressures (water as saturated vapour pressure) of the gases in venous/end-capillary blood are:

- PO_2 40 mmHg 5.3 kPa
- PCO_2 46 mmHg 6.1 kPa
- PN_2 573 mmHg 76.4 kPa
- PH_2O 47 mmHg 6.3 kPa

These partial pressures add up to less than atmospheric pressure (760 mmHg). Free gas is therefore absorbed into the blood and lost to the atmosphere through the lungs, with the gases moving in relation to their solubility (carbon dioxide quickest and nitrogen slowest) and relative concentrations in the pleural space and the blood. This does not favour nitrogen, which constitutes about 80% of atmospheric air. Breathing oxygen accelerates nitrogen removal by reducing the content of nitrogen in the blood and increasing the gradient for its absorption. Nitrous oxide anaesthesia is dangerous in the presence of a pneumothorax; nitrous oxide is very soluble and, although not normally present in the pleural space, it will be

Ernest Henry Starling, 1866–1927, Professor of Physiology, University College, London, UK.

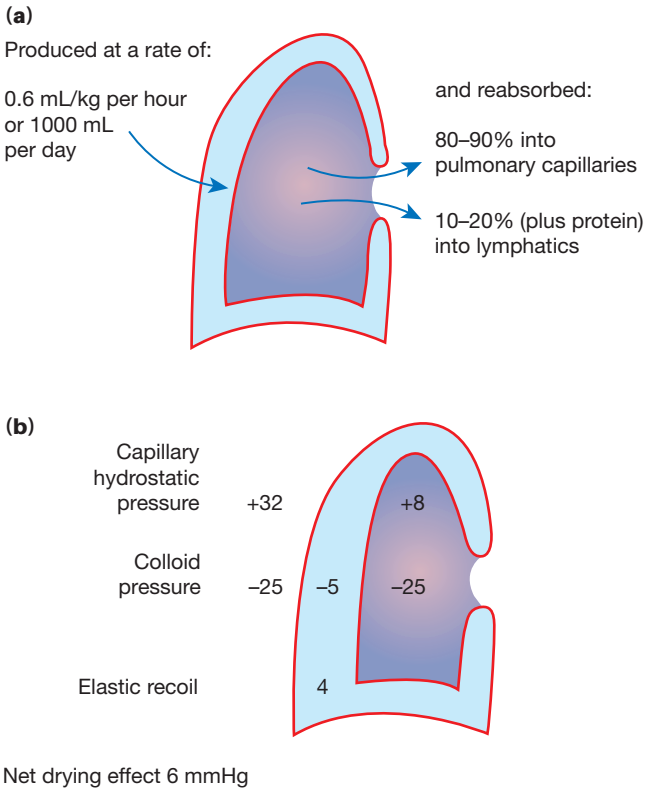

Figure 60.6 (a) Production and absorption of pleural fluid. **(b)** Normal pleural physiology. (See the text for an explanation of this simplistic physiological model.)

rapidly transported into the space if the patient is given nitrous oxide to breathe.

DISORDERS OF THE PLEURA

Pneumothorax

Pneumothorax is the presence of air outside the lung, within the pleural space. It must be distinguished from bullae or air cysts within the lung. Bullae can be the cause of an air leak from the lung and can therefore coexist with pneumothorax.

Spontaneous pneumothorax occurs when the visceral pleura ruptures without an external traumatic or iatrogenic cause. Cases are divided into primary spontaneous pneumothorax (PSP) and secondary spontaneous pneumothorax (SSP). Pneumothorax can also occur following trauma or iatrogenic injury such as insertion of a central line. Tension pneumothorax is when (independent of aetiology) there is a build-up of positive pressure within the hemithorax, to the extent that the lung is completely collapsed, the diaphragm is flattened, the mediastinum is distorted and, eventually, the venous return to the heart is compromised.

Surgical emphysema is the presence of air in the tissues. It requires a breach of an air-containing viscus in communication with soft tissues, and the generation of positive pressure to push the air along tissue planes. The most serious cause is a ruptured oesophagus. Mediastinal surgical emphysema can also occur with asthma or barotrauma from positive-pressure ventilation. A poorly managed chest drain, with intermittent build-up of pressure, allows air to track into the chest wall through the point where the drain breaches the parietal pleura.

Primary spontaneous pneumothorax

This is a common condition characteristically seen in young people from their mid-teens to late twenties. About 75% of cases are in young men, who tend to be tall and have a family history of the condition. It is due to leaks from small blebs, vesicles or bullae, which may become pedunculated, typically at the apex of the upper lobe or on the upper border of the lower or middle lobes.

Secondary spontaneous pneumothorax

This occurs when the visceral pleura leaks as part of an underlying lung disease; any disease that involves the pleura may cause pneumothorax, including tuberculosis, any cavitating lung disease and necrosing tumours. As such it tends to occur in older patients, often with a history of underlying lung disease such as emphysema. The pneumothorax may be less well tolerated.

The risk of recurrent pneumothorax is increased after the first episode. The best estimates of recurrence rates are:

- of patients who experience a first event, only about one-third experience recurrence;
- of those who have a second episode, about one-half go on to experience a third episode;
- those who have had three episodes will probably go on to have repeated recurrences.

Current recommendations from the BTS are that, in cases of persistent air leak following drain insertion or failure of the lung to re-expand, an early (3–5 days) thoracic surgical opinion should be sought.

Summary box 60.1

Indications for surgical intervention for pneumothorax include:

- Second ipsilateral pneumothorax
- First contralateral pneumothorax
- Bilateral spontaneous pneumothorax
- Pneumothorax fails to settle despite chest drainage
- Spontaneous haemothorax: professions at risk (e.g. pilots, divers)
- Pregnancy

Current recommendations (*Figure 60.7*) focus on the use of small bore (10–14 Fr) chest drains, usually of a Seldinger type, inserted ideally under ultrasound guidance. However, knowledge of the role of the 'surgical' chest drain and how to insert it safely is still required.

Sven Ivar Seldinger, 1921–1998, Swedish radiologist, introduced the Seldinger technique to obtain safe access to blood vessels and other hollow organs.

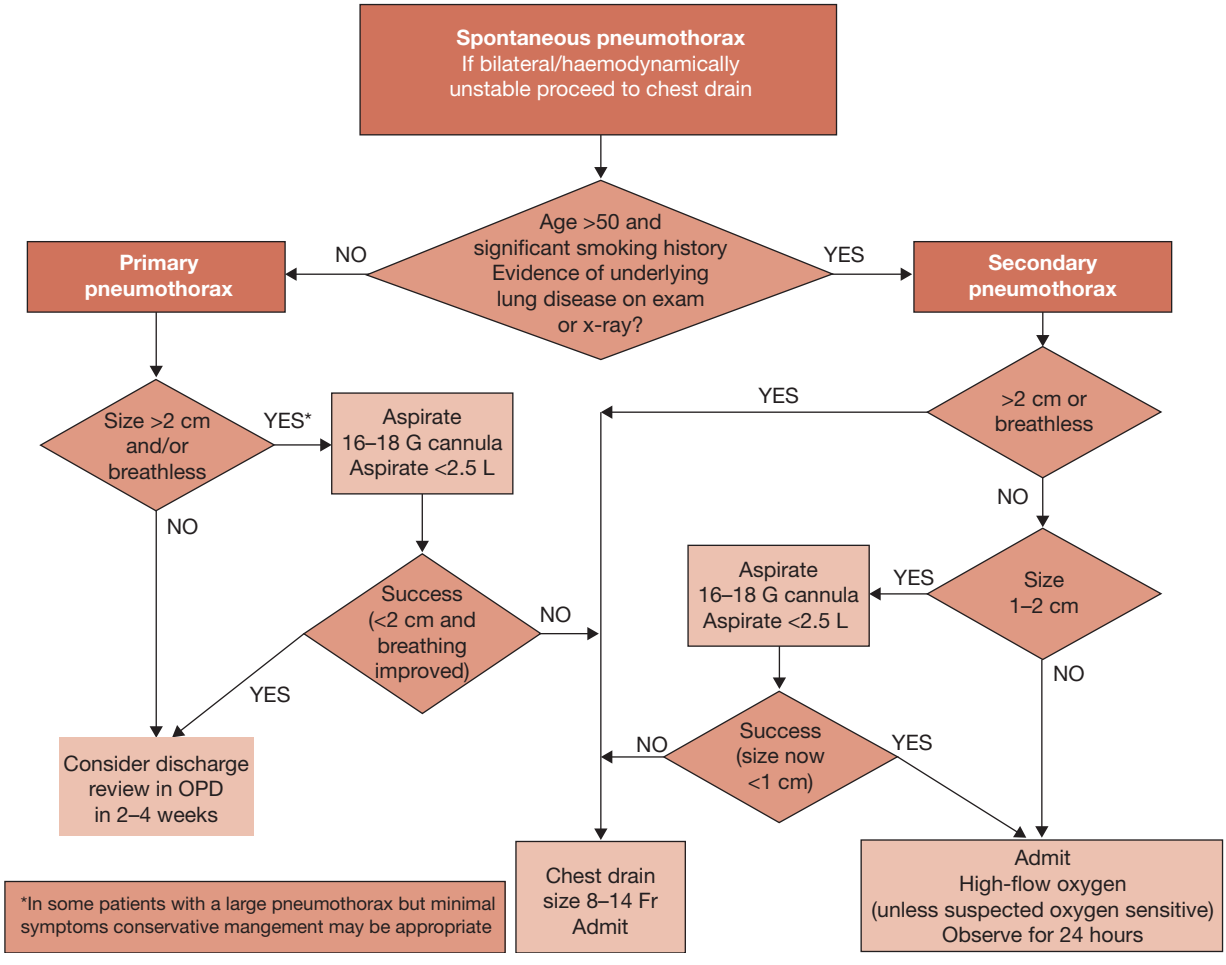

Figure 60.7 British Thoracic Society guidelines on the management of spontaneous pneumothorax (2010) (adapted from www.bts.org.uk). OPD, outpatient department.

Inserting and managing a chest drain

An intercostal tube connected to an underwater seal is central to the management of chest disease; however, the management of the pleura and of chest drains can be troublesome, even in experienced hands.

The safest site for insertion of a drain (***Figure 60.8***) is in the triangle that lies:

- anterior to the mid-axillary line;
- above the level of the nipple;
- below and lateral to the pectoralis major muscle.

This will ideally find the fifth space. The technique includes the following.

- Meticulous attention to sterility throughout.
- Adequate local anaesthesia to include the pleura.
- Sharp dissection to cut only the skin.
- Blunt dissection with artery forceps down through the muscle layers; these should only be the serratus anterior and the intercostals.
- An oblique tract, so that the skin incision and the hole in the parietal pleura do not overlie each other and the drain is in a short tunnel, which reduces the chance of entraining air.
- A drain for pneumothorax and haemothorax should aim towards the apex of the lung. A drain for pleural effusion or empyema should be nearer the base. The drain should pass over the upper edge of the rib to avoid the neurovascular bundle that lies beneath the rib.
- The retaining stitch should be secure but should not obliterate the drain.
- A vertical mattress suture is inserted for later wound closure. This is vital for pneumothorax management but should be omitted if the drain is for empyema (provided there is adherence of the pleura) because that tract should lie open.
- Connect the drain to an underwater seal device which functions as a one-way valve.
- After completion, check that the drain has achieved its objective by taking a chest radiograph.

It is preferable not to apply suction to the drain or clamp it. The danger is that the clamp may be applied for transport and forgotten. Dangers of disconnection and siphoning are small or best averted in other ways apart from clamping.

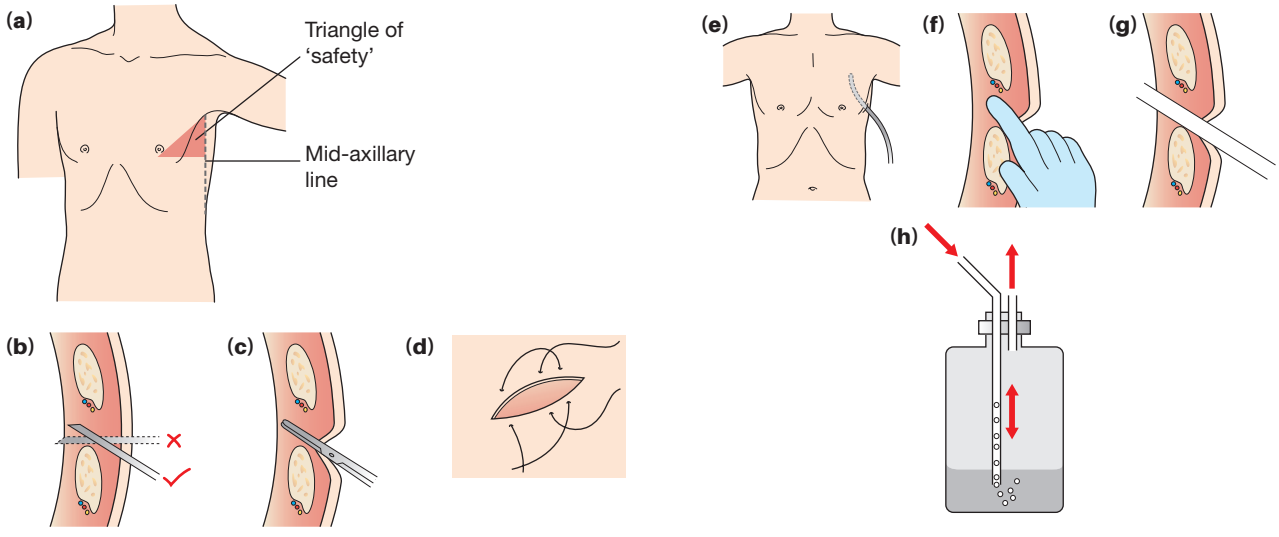

Figure 60.8 Insertion of chest drain: (a) triangle of safety; (b) penetration of the skin, muscle and pleura; (c) blunt dissection of the parietal pleura; (d) suture placement; (e) gauging the distance of insertion; (f) digital examination along the tract into the pleural space; (g) withdrawal of central trochar and positioning of drain; (h) underwater seal chest drain bottle.

A bubbling drain should (almost) never be clamped. Remove the drain when it no longer has a function.

Summary box 60.2

Suction on a pleural tube

- Be aware! Inserting the drain, and not the suction, is the life-saving manoeuvre
- If the lung is reluctant to expand, the suction deviates the mediastinum
- If the lung is fragile, it may worsen an air leak

Surgical management of pneumothorax

Pleurectomy and pleurodesis

Surgery for pneumothorax can be performed by video-assisted thoracoscopic surgery (VATS) or as an open procedure (thoracotomy). The object of the exercise is threefold:

- to deal with any leaks from the lung;
- to search for and obliterate any blebs and bullae;
- to make the visceral pleura adherent to the parietal pleura so that any subsequent leaks are contained and the lung cannot completely collapse.

Pleural adhesion is achieved in one of three ways:

1. **pleurectomy**: systematically stripping the parietal pleura from the chest wall;
2. **pleural abrasion**: a scourer is used to scrape off the slick surface of the parietal pleura;
3. **chemical pleurodesis**: usually talc is used and is insufflated into the chest cavity.

Pleural effusion

Pleural effusion can be readily understood with reference to the physiological mechanisms governing the flux of pleural fluid given above. Pleural effusions are divided into exudates and transudates, depending on protein content (more [exudates] or less [transudates] than 30 g/L), and characterised further according to glucose content, pH and lactate dehydrogenase content. The following are the most common ways in which the pleural fluid balance is disturbed.

Malignant pleural effusion

Pleural effusion is a common complication of cancer. This may be due to:

- lung cancer;
- pleural involvement with primary or secondary malignancy;
- mediastinal lymphatic involvement.

Lung cancer

There may be direct involvement of the parietal and/or visceral pleura, collapse of the lung parenchyma and spread to the mediastinal lymphatics, or a combination of these, causing pleural fluid accumulation. It is usually regarded as a feature that puts lung cancer beyond surgical cure.

Pleural malignancy

The only primary malignancy of the pleura seen with any regularity is malignant mesothelioma. This is a consequence of asbestos exposure, with few exceptions. The peak of asbestos importation into the UK was from 1960 to 1975, with the incidence initially rising but more recently stabilising (2015–2017), with a fall in incidence projected in the future. Mesothelioma commonly presents with breathlessness because of pleural effusions, pain and systemic features of malignancy. Diffuse seeding of the parietal and visceral pleura is a common pattern

of dissemination of cancers, particularly adenocarcinoma of any origin.

Mediastinal lymphatic involvement

In many instances, particularly in breast cancer, there is no evident disease in the pleura. The disease is in the mediastinal lymphatics, which are obstructed, and this upsets the balance of physiological forces that control pleural fluid.

Surgery for patients with malignant pleural effusion

The surgeon has two roles: to make the diagnosis and to achieve effective palliation by draining the fluid and pleurodesis.

Diagnosis

Pleural biopsy can be obtained by a range of techniques, with VATS being the most common. An unequivocally positive biopsy is useful, but a negative biopsy may be a sampling error.

Summary box 60.3

Biopsy of the pleura

- Cytological examination of the pleural fluid (low yield)
- Abrams' needle (low yield in malignancy)
- Computed tomography (CT)-guided needle biopsy of a suspicious area
- VATS biopsy
- Open surgical biopsy

Pleural infection and empyema

Empyema is the end stage of pleural infection from any cause. It most commonly results from infection of the underlying lung, involving pneumonia or a lung abscess, but can occur as a complication of any thoracic operation. It is seen if a traumatic haemothorax becomes infected or in the course of management of pneumothorax or pleural effusions. It may be associated with pus under the diaphragm (***Table 60.3***). The pathological diagnosis requires the presence of thick pus with a thick cortex of fibrin and coagulum over the lung.

When empyema presents *de novo* it usually follows pneumonia, and three phases are described:

1. In the exudative phase, there is a protein-rich (>30 g/L) effusion. If this becomes infected with the organisms from the lung (typically *Streptococcus milleri* and *Haemophilus influenzae* in children), the scene is set for empyema. At this stage antibiotics may be all that is required. Aspiration or drainage to dryness in addition is preferred.
2. Over subsequent days, the fluid thickens to what is known as the fibrinopurulent phase. Drainage at this stage is prudent as antibiotics on their own are unlikely to be curative.
3. The organising phase causes the lung to be trapped by a thick peel or 'cortex' for which surgical management may be required.

TABLE 60.3 Conditions that predispose to empyema formation.

Pulmonary infection	Unresolved pneumonia, bronchiectasis, tuberculosis, fungal infections, lung abscess
Aspiration of pleural effusion	Any aetiology
Trauma	Penetrating injury, surgery, oesophageal perforation
Extrapulmonary sources	Subphrenic abscess
Bone infections	Osteomyelitis of ribs or vertebrae

Surgical management of pleural effusions and infections

Thoracoscopy or video-assisted thoracoscopic surgery (VATS)

The direct-vision thoracoscope has been used for many years, but its use was limited mainly to performing biopsies. Since the advent of video-assisted thoracoscopy (***Figure 60.9***) the surgeon's hands are now free because the camera is attached to the thoracoscope, which can be operated by an assistant with the image displayed on a screen. The surgeon is able to manipulate instruments with both hands to perform a variety of procedures. The number of ports required depends on the type and complexity of the surgery. The patient is usually positioned with the diseased side uppermost, having had a double-lumen endotracheobronchial tube (ETT) placed by the anaesthetist to allow for single-lung ventilation. The principal

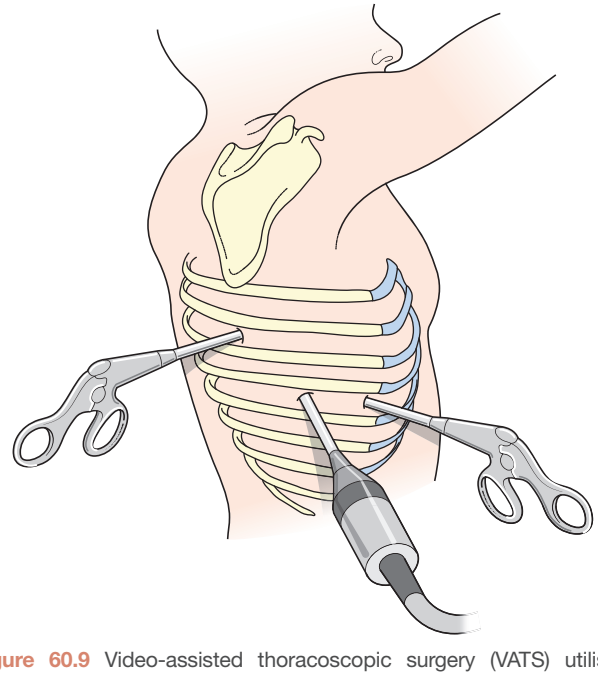

Figure 60.9 Video-assisted thoracoscopic surgery (VATS) utilises modern thoracoscopic instruments and digital technology and avoids large incisions.

Leon David Abrams, 1923–2012, cardiothoracic surgeon, the United Birmingham Hospitals, Birmingham, UK.

advantage is that a large incision is avoided, resulting in less postoperative pain and a more rapid recovery.

VATS drainage, pleural biopsy and talc pleurodesis

VATS drainage, pleural biopsy and talc pleurodesis is increasingly performed for the management of patients with an undiagnosed or malignant pleural effusion. It can be performed using a single port and allows direct visualisation of the pleural cavity for complete drainage, multiple pleural biopsies and excellent talc insufflation to achieve pleurodesis.

VATS debridement of empyema

Pleural infection, particularly early in its evolution, requires drainage, but once the fluid component becomes fibrinopurulent and loculated it requires surgical debridement, which can often be achieved through a VATS approach. The lung is isolated through the use of a double-lumen tube, the patient is positioned disease side up and the pleural cavity is entered. The fluid and debris are vigorously debrided, freeing the lung and allowing for re-expansion. At the end of the case, carefully positioned chest drains are placed to allow for dependent drainage.

Following the procedure, the patient requires good analgesic control, typically using patient-controlled analgesia (PCA), and physiotherapy to help fully re-expand the lung prior to final removal of chest drains.

Decortication

If the lung fails to re-expand after drainage of the empyema, the more radical operation of decortication may be required (*Figure 60.10*). The fibrous cortex or peel from the entrapped underlying lung is removed so that the lung can expand to obliterate the pleural space. This is usually performed through a posterolateral thoracotomy, though in selected cases it can be performed as a VATS procedure. It requires careful dissection to remove the parietal and visceral cortex, taking care not to damage the visceral pleura, so allowing the lung to re-expand fully.

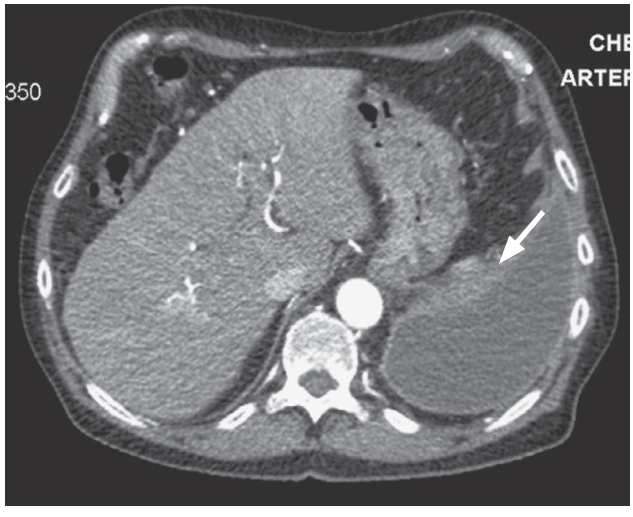

Figure 60.10 Chest computed tomography scan showing an empyema with a grossly thickened pleura (arrow).

DISORDERS OF THE AIRWAY

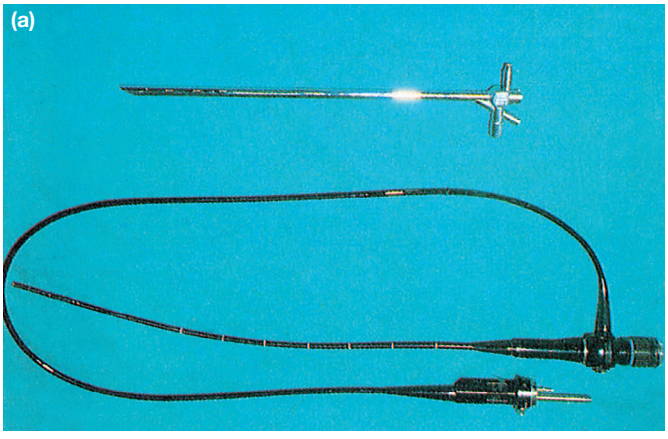
Haemoptysis

Diseases causing repeated haemoptysis include carcinoma, bronchiectasis, carcinoid tumours and some infections. Severe mitral stenosis is now a rare cause. Patients with repeated haemoptysis should be investigated, at the very least by chest radiography and bronchoscopy. Haemoptysis following trauma may be from a lung contusion or injury to a major airway. Treatment depends on the underlying cause.

Common associated chest symptoms include cough with or without sputum, pain, breathlessness, hoarseness and more general symptoms of systemic upset, including fatigue and loss of weight. Occasionally, chest disease may cause palpitations owing to atrial fibrillation. Any of these symptoms in association with haemoptysis requires urgent investigation.

Investigation

Bronchoscopy



Flexible bronchoscopy (*Table 60.4*) may be performed with the patient awake and the oropharynx anaesthetised with topical lignocaine (*Figure 60.11*). The bronchoscope is passed into the nose or mouth and through the vocal folds under direct vision. As the scope is flexible, its tip can be directed into the segmental bronchi with ease. Tissue and sputum samples may be obtained for diagnostic purposes. There is a greater range of movement with this instrument, but the biopsies are relatively small and suction limited.

TABLE 60.4 Uses of bronchoscopy.

Diagnostic	Confirmation of disease: carcinoma of the bronchus; inflammatory or infective processes
Investigative	Tissue biopsy
Preoperative assessment	Before lung resection Before oesophageal resection Persistent haemoptysis
Therapeutic	Removal of secretions Removal of foreign bodies Stent placement, endobronchial resection, etc.

Rigid bronchoscopy requires general anaesthesia in most instances. It is ideal for therapeutic manoeuvres, such as removal of foreign bodies, aspiration of blood and thick secretions, and intraluminal surgery (laser resection or stent placement). The surgeon and the anaesthetist share control of the airway. The bronchoscope is passed under direct vision into the oropharynx, behind the epiglottis, until the vocal folds are seen and introduced into the trachea.

The tracheal rings and the carina should be easily seen. Advancing the bronchoscope into the RMB or LMB reveals the orifices of the more peripheral bronchi. Operability of an endobronchial tumour may be assessed in terms of its location (e.g. the proximity of a lesion to the carina). Complications are rare but include bleeding, pneumothorax, laryngospasm and arrhythmia.

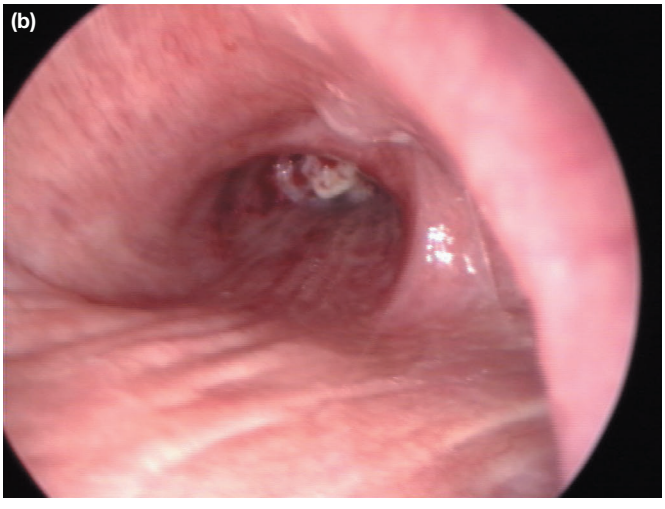


Figure 60.11 (a) Rigid and flexible bronchoscopes. **(b)** View past the carina into the left main bronchus with a tumour seen in the bronchial lumen.

Rigid bronchoscopy can be combined with endobronchial interventions to tackle airway tumours; these techniques include use of laser or cryotherapy, with heat or cold respectively, to excise potentially obstructing endobronchial tumours and improve airway patency and breathing.

Other techniques of biopsy of intrathoracic lesions are often necessary to confirm diagnosis, stage disease and plan treatment. The options range from percutaneous needle biopsy under radiological control (typically CT scan) to open (VATS) lung biopsy.

Endobronchial ultrasound (EBUS) and navigational bronchoscopy are alternative airway techniques used to obtain intrathoracic biopsies.

Summary box 60.4

Biopsy hazards

- Bleeding disorders
- Systemic anticoagulation
- Pulmonary hypertension

Airway obstruction

Tracheal obstruction may present acutely as a life-threatening emergency or insidiously with little in the way of symptoms until critical narrowing and stridor occur. The more common causes of airway narrowing are outlined in *Table 60.5*.

Treatment depends on the underlying cause. Tracheostomy may be required to overcome the obstruction, but there are few indications to do this as an emergency. Tracheal replacement resection of up to 6 cm of trachea is possible. Sleeve resections of the major bronchi are also possible.

TABLE 60.5 Causes of airway narrowing.

Intraluminal	Inhaled foreign body Neoplasm
Intramural	Congenital stenosis Fibrous stricture (post intubation or tuberculosis)
Extramural	Neoplasm (thyroid cancer, secondary deposits) Aortic arch aneurysm

Inhaled foreign bodies

This is a fairly common occurrence in small children and is often marked by a choking incident that then apparently passes. Surprisingly large objects can be inhaled and become lodged in the wider calibre and more vertically placed RMB. There are three possible presentations:

1. asymptomatic;
2. wheezing (from airway narrowing) with a persistent cough and signs of obstructive emphysema;
3. pyrexia with a productive cough from pulmonary suppuration.

Either flexible or more often rigid bronchoscopy is required to remove the foreign body.

NEOPLASMS OF THE LUNG

Primary lung cancer

Lung cancer is one of the most common cancers throughout the world. In the UK, there are approximately 45 000 new cases a year. From the time of diagnosis, 60% of patients are dead within 1 year and only 15% survive 5 years, making lung cancer the most common cause of cancer death. Survival is dependent on the stage that the patient presents with lung cancer.

The number of lung cancer operations performed in the UK has significantly increased over the last 10 years. The proportion of lung cancers in which resection is attempted varies but, in most resource-rich countries, is over 30%. Most patients offered lung cancer surgery are in the early stages. The thoracic surgeon working in a cancer team has a role in diagnosis, staging and palliation, in addition to curative resection in appropriate cases. Cigarette smoking is undoubtedly the major risk factor for developing bronchial carcinoma and accounts for 85–95% of all cases. To a lesser extent, atmospheric pollution and certain occupations (mining of radioactive ore and chromium) contribute.

Pathological types

For practical purposes, lung cancers are divided into small cell lung cancer and non-small cell lung cancer (NSCLC), which are seen in a ratio of about 1:4.

- The pattern of disease, the prognosis and the results of treatment for small cell (also known as oat cell) carcinoma differ from all other types sufficiently for these to be managed differently from the outset on the basis of the histological classification.
- Subdivisions of NSCLC according to histological characteristics are much less important, but pathological staging is critical to treatment and outcome.

Histological classification of lung cancer

Small cell lung cancers were known as oat cell cancers because of the packed nature of small dense cells. They are a type of neuroendocrine tumour (NET) and represent about 20% of all lung cancers. They tend to metastasise early to lymph nodes and by blood-borne spread. The median survival is measured in months. The tumours are very responsive to chemotherapy such that median survival may be doubled (although it is still short) but they are rarely, if ever, cured. Surgery is rarely offered unless in very limited stage disease.

Non-small cell lung cancers: adenocarcinoma is now the most common of the NSCLC types, having overtaken squamous cancer. The increasing incidence is partly due to an increasing incidence in women and may be the result, in part, of a move towards lower tar cigarettes that are inhaled more deeply to get the same effect. Squamous carcinoma typically appears as a cavitating tumour.

Large cell undifferentiated is a discrete histological type of NSCLC and is included within NETs. NETs of the lung are a group of lung cancers that include small cell cancer and large cell undifferentiated lung cancer, but also include other less aggressive tumour types, including typical carcinoid and atypical carcinoid tumours. These occur in the major (central) bronchi and 20% are found peripherally. They are characteristically slow growing and highly vascular. Most behave in a benign way; however, approximately 15% metastasise. The patient often presents with a history of recurrent pneumonia or haemoptysis, but carcinoid syndrome is rare unless there are extensive pulmonary or hepatic metastases. Surgical excision is preferred because the prognosis following complete resection is excellent (>90% 10-year survival).

Accurate diagnosis and staging of the tumour are vital if surgery is to be considered.

Clinical features

Clinical features of lung carcinoma depend on:

- the site of the lesion;
- the invasion of neighbouring structures;
- the extent of metastases.

Common symptoms include a persistent cough, weight loss, dyspnoea and non-specific chest pain.

- Haemoptysis occurs in fewer than 50% of patients presenting for the first time.
- Cough, or a changed cough, is a common presentation but non-specific in this population.
- Severe localised pain suggests chest wall invasion with the infiltration of an intercostal nerve. Invasion of the apical area may involve the brachial plexus, leading to Pancoast's syndrome.
- Dyspnoea or breathlessness may come from loss of functioning lung tissue, lymphatic invasion or the development of a large pleural effusion.
- Pleural fluid is an ominous feature and the presence of blood in a pleural effusion suggests that the pleura has been directly invaded.
- Clubbing and hypertrophic pulmonary osteoarthropathy occasionally accompany some lung cancers and may resolve with excision of the primary lesion.
- Invasion of the mediastinum may result in hoarseness (because of recurrent laryngeal nerve involvement), dysphagia (because of the involvement of, or extrinsic pressure on, the oesophagus) and superior vena caval obstruction.
- Small cell carcinoma is associated with the development of myopathies, including the Eaton–Lambert syndrome, which is similar to myasthenia gravis.

Treatment of lung cancer

Careful investigation is required to determine which tumours are operable and will benefit from a major thoracic resection. The internationally agreed tumour–node–metastasis (TNM) staging system gives prognostic information on the natural history of the disease. Tumours graded up to T3, N1, M0 can be encompassed within an anatomical surgical resection and have a much improved prognosis when treated surgically so the tumour must be staged accurately before resection. Increasingly, for higher stage tumours a multi- or trimodality approach is being offered where patients have chemotherapy, with or followed by radiotherapy followed by surgery. A number of non-tumour-related factors, including the general fitness of the patient and the results of lung function tests, help to determine the appropriate treatment. In patients with incurable disease, treatment is palliative to maximise quality of life.

Survival

Carcinoma of the bronchus generally has a low survival rate after diagnosis. Important factors in determining prognosis are the size of the tumour (T status), the spread or stage of the cancer as determined by the TNM classification, the histological type of the tumour and the general condition of the patient. Early detection and surgical resection offer the best hope for cure.

Henry Khunrath Pancoast, 1875–1939, Professor of Radiology, University of Pennsylvania, Philadelphia, PA, USA, described this condition in 1932.
Lee M Eaton, 1905–1958, neurologist who was a professor at the Mayo Clinic, Rochester, MN, USA.
Edward H Lambert, 1915–2003, Professor of Physiology, University of Minnesota, MN, USA. Eaton and Lambert described this condition in a joint paper in 1956.

Diagnosis and staging

Increasing emphasis in recent years has been on the early detection of lung cancer, with guidance on symptoms and signs of potential lung cancer that require urgent chest radiograph and referral to a lung cancer team.

Non-invasive investigations

Chest radiography

A chest radiograph will detect most lung cancers but some, particularly early curable tumours, are hidden by other structures. Secondary effects such as pleural effusion, distal collapse and raised hemidiaphragm may be evident (*Figure 60.12*).

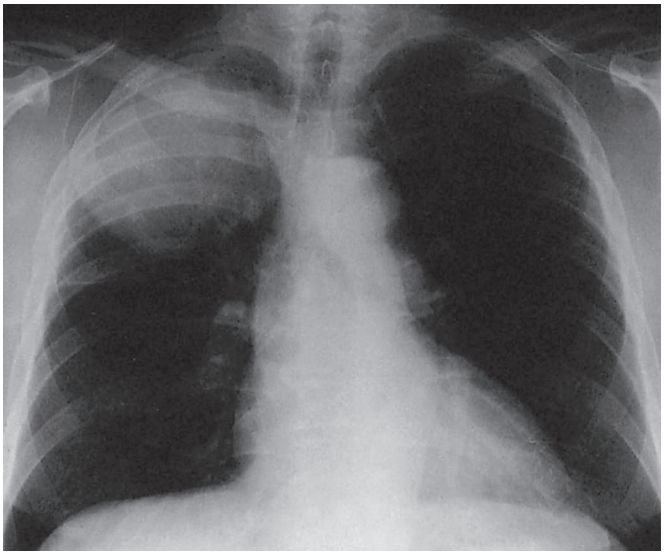

Figure 60.12 Chest radiograph of carcinoma of the lung. This patient has a large mass in the right upper lobe, causing Horner's syndrome, a Pancoast tumour.

Computed tomography

CT is the first investigation in suspected lung cancer. The surgeon needs to know whether the primary is resectable (T stage) and which, if any, lymph nodes are involved (N stage). Lymph nodes more than 2 cm in diameter are likely to be involved in the disease (70%) (*Figure 60.13*) and those less than 10 mm in the shorter axis are unlikely to be involved. Remote metastases to the liver, adrenal glands or elsewhere may be detected.

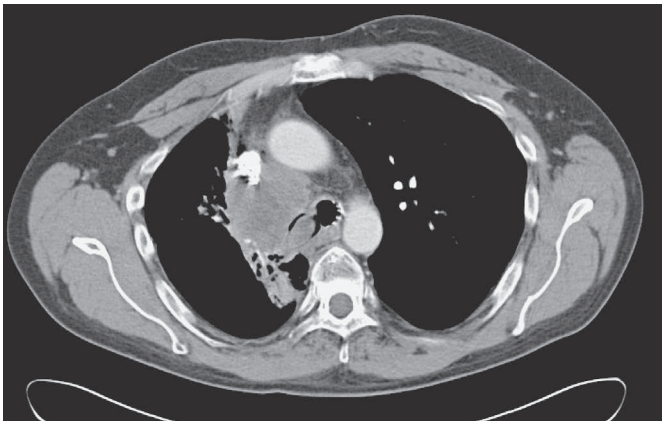

Figure 60.13 Paratracheal lymphadenopathy shown on a computed tomography scan.

Positron emission tomography

The patient is given radiolabelled fluorodeoxyglucose (FDG), which is taken up by all metabolising cells but more avidly by cancer cells. The FDG enters the Krebs cycle but cannot complete it and accumulates in proportion to the glucose avidity of the cells. High accumulation is associated with lung cancers and secondaries. Infection or other inflammation, and lymphadenopathy secondary to it, are also FDG avid.

Sputum cytology

Sputum cytology may reveal malignant cells but the false-negative rate is high.

Invasive investigations

Once lung cancer is suspected, diagnosis and further staging are sought. The choice of investigation depends on the position of the primary tumour in the lung (peripheral or central) and the clinical stage of the cancer (presence of enlarged lymph nodes or metastasis).

Bronchoscopy

Flexible bronchoscopy is usually performed under sedation, particularly in patients with more centrally placed lung cancers. It allows assessment of the segmental airway, cytological testing through brushing and washing of the concerned segmental bronchi and transbronchial needle aspiration (TBNA).

Endobronchial ultrasound

EBUS allows bronchoscopic assessment of suspicious mediastinal lymph nodes with an ultrasound probe incorporated into the tip of the bronchoscope to aid TBNA (*Figure 60.14*).

Endoscopic ultrasound (EUS) is a similar technique that, by passing the probe down the oesophagus, allows fine-needle aspiration (FNA) of less approachable mediastinal lymph nodes.

Navigational bronchoscopy

Navigational bronchoscopy provides a virtual three-dimensional map of the lung using radiological guidance during a flexible bronchoscopy, which can guide the physician to target, locate and perform an anatomically precise lung biopsy, place markers for radiation therapy and/or facilitate surgical removal of a small peripheral lung lesion or use thermal ablative techniques for peripheral lung lesions.

Johann Friedrich Horner, 1831–1886, Professor of Ophthalmology, Zurich, Switzerland, described this syndrome in 1869.
Sir Hans Adolf Krebs, 1900–1981, Professor of Biochemistry, University of Oxford, Oxford, UK.

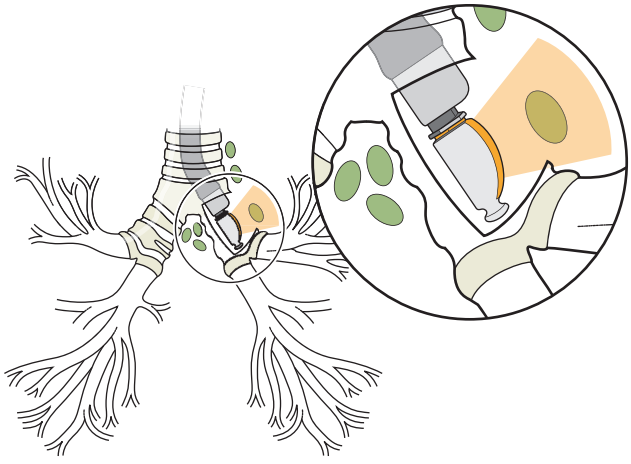

Figure 60.14 Endobronchial ultrasound allows accurate detection of enlarged mediastinal lymph nodes for diagnosis and staging of lung cancer.

Computed tomography-guided biopsy

Percutaneous CT-guided FNA may give a good yield of cells for cytological examination. Alternatively, a core of tissue can be obtained for formal histology. These techniques are best for larger and more peripheral lesions. Pneumothorax is common (10%) but rarely requires intercostal tube drainage. The contraindications include poor respiratory reserve, when even a small pneumothorax would be hazardous.

Surgical diagnosis and staging

Mediastinoscopy, mediastinotomy, VATS or thoracotomy lymph node/lung biopsy are aimed at establishing a tissue diagnosis and assessing the degree of spread (staging), which determines resectability. Histological proof of the status of mediastinal nodes may be important to avoid unnecessary thoracotomy for incurable cancers and, conversely, to avoid denying surgery to patients whose lymph nodes are enlarged but benign.

Mediastinoscopy

Following an incision in the neck and careful blunt dissection in front of the trachea, access to the paratracheal and subcarinal nodes via mediastinoscopy is achieved and biopsies taken (***Figure 60.15***).

These techniques may also be used in the diagnosis of other mediastinal conditions, including:

- lymphoma;
- anterior mediastinal tumours;
- thymoma;
- sarcoid, tuberculosis or any other cause of lymphadenopathy.

VATS mediastinal lymph node and lung biopsy

For inaccessible mediastinal lymph nodes, or when diagnosis of the lung tumour has not been possible through radiological or bronchoscopic techniques, VATS allows diagnosis of the tumour and staging of the mediastinum and gives the opportunity to assess the likely operability of the lung cancer.

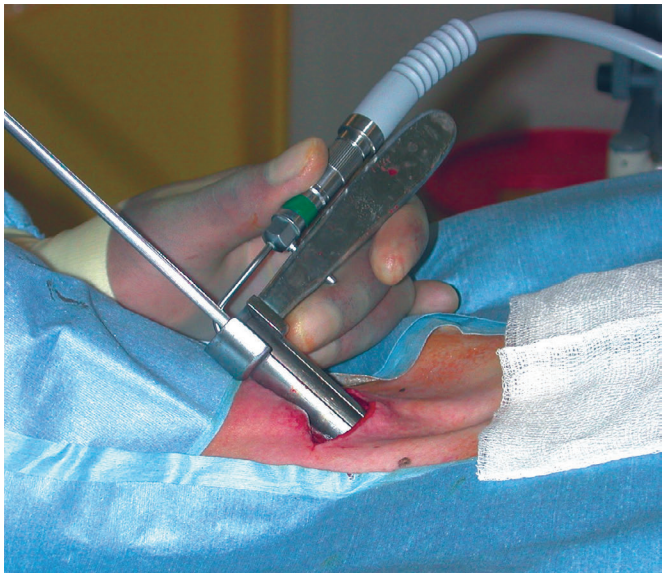

Figure 60.15 Mediastinoscopy. The mediastinoscope slides down immediately in front of the trachea, behind the aortic arch, and behind and between the great vessels of the head and neck.

Surgical approach to lung cancer resection

Thoracotomy

Although the most frequent indication for thoracotomy is lung cancer, all surgeons dealing with trauma should be able to perform a thoracotomy if required. The standard route into the thoracic cavity is through a posterolateral thoracotomy. The incision is used for access to the:

- lung and major bronchi;
- pleura;
- thoracic aorta;
- oesophagus;
- posterior mediastinum.

A double-lumen endotracheal tube is used to allow ventilation of one lung while the other is collapsed, to facilitate surgery and to protect the non-operated lung and retain control of ventilation (***Figure 60.16***). The patient is turned to the

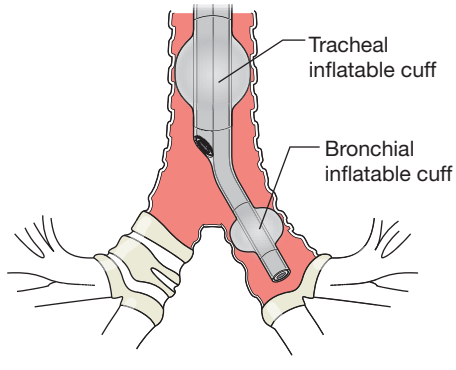

Figure 60.16 The double-lumen tube permits separate ventilation of the right and left lungs.

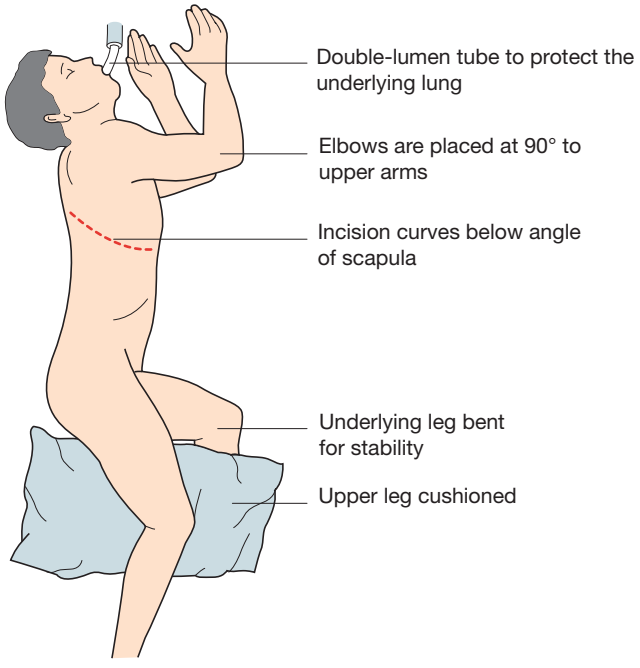

Figure 60.17 Correct positioning for thoracotomy.

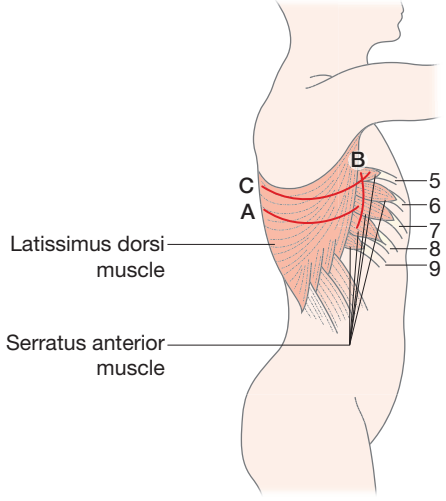

Figure 60.18 Incision and layers encountered during posterolateral thoracotomy. A, The latissimus dorsi is divided in line with the skin incision. B, If the serratus anterior is divided, it should be close to its attachment to ribs 6, 7 and 8. It can be left intact and mobilised along its inferior border. C, The intercostal muscles are stripped off the upper border of the rib.

lateral position with the affected side up (***Figure 60.17***). The incision passes 1–2 cm below the tip of the scapula and extends posteriorly and superiorly between the medial border of the scapula and the spine.

- The incision is deepened through the subcutaneous tissues to the latissimus dorsi. This muscle is divided with coagulating diathermy, taking care over haemostasis.
- A plane of dissection is developed manually, deep to the scapula and serratus anterior. The ribs can be counted down from the highest palpable rib (which is usually the second) and the sixth rib periosteum is scored with the diathermy near its upper border. A periosteal elevator is used to lift the periosteum off the superior border of the rib or, alternatively, the intercostal muscle is cut with diathermy just above the rib (***Figure 60.18***).
- This reveals the pleura, which may be entered by blunt dissection. A rib spreader is inserted between the ribs and opened gently to prevent fracture.

In an emergency thoracotomy for penetrating wounds of the heart, a more anterior approach is used and no specialised supporting equipment is required (***Figure 60.19***). The incision is taken down to the fourth or fifth rib with a scalpel, and the pleural cavity is opened using scissors. This gives rapid access to the left pleural cavity in cases of massive left haemothorax and the pericardium if cardiac tamponade is suspected. A left anterior thoracotomy can be quickly converted to a clamshell or bilateral thoracotomy if necessary.

Analgesia is an important aspect of postoperative care, and the process may be started prior to thoracotomy with an epidural catheter placed by the anaesthetist or intraoperatively by infiltrating the intercostal nerves in the region of the incision with a long-acting local anaesthetic or increasingly via a surgically sited paravertebral catheter. Various strategies have been developed to deliver analgesics postoperatively to facilitate a normal breathing pattern.

Video-assisted thoracoscopic surgery (VATS)

Various approaches utilising thoracoscopic techniques can be used to gain access to the chest cavity and facilitate lung

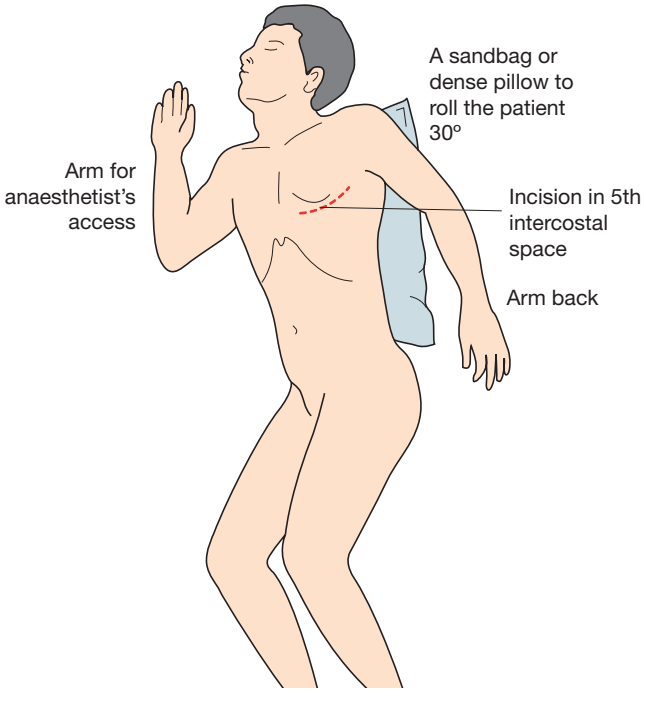

Figure 60.19 Emergency left anterior thoracotomy for access to the heart. This requires no special supports or devices.

resection. VATS is now the approach of choice in early stage lung resections with dissection of the hilar structures and full lymph node staging commonly performed through one- (uniportal), two- or three-port VATS incisions. The technique avoids rib-spreading and appears to reduce postoperative pain and length of stay and aids a speedier recovery, particularly in frail patients.

Robotically assisted thoracic surgery (RATS)

In this approach, the thoracoscopy is done using a robotic system with three-dimensional vision. The surgeon sits at a control panel in the operating room and moves robotic arms to operate through several small incisions in the patient's chest. RATS is similar to VATS in terms of less pain, less blood loss and a shorter recovery time (***Figure 60.20***).

For the surgeon, the robotic system may provide more manoeuvrability and more precision when moving the instruments than standard VATS. It may have advantages when performing more complex lung resections such as segmentectomies or mediastinal tumours (thymectomy).

Surgical management of lung cancer

The principle of surgery is to remove all cancer (the primary and the regional lymph nodes) but to conserve as much lung as possible. The selection of patients in terms of the stage of the lung cancer and fitness to undergo such surgery is paramount. Surgery with curative intent is offered to patients with early stage lung cancer (T1–3, N0–1) (***Table 60.6***). Assessment of a patient's fitness to undergo lung cancer resection involves considering premorbid conditions, which can be aided using risk scores such as Thoracoscore, cardiovascular function and lung function; see BTS guidelines in ***Assessment of fitness for major thoracic surgery*** and UK National Institute for Health and Care Excellence (NICE) guidelines in ***Table 60.7***. Lung function, in particular, will aid the surgeon in selecting the type of procedure offered and the likelihood of breathlessness or dyspnoea following lung resection.

TABLE 60.6 UK National Institute for Health and Care Excellence (NICE) recommendations for surgery for non-small cell lung cancer (NSCLC).

Surgery with curative intent for NSCLC
Offer patients with NSCLC who are fit for surgery open or thoracoscopic lobectomy as the treatment of first choice. If complete resection is possible, consider segmentectomy or wedge resection for patients with smaller tumours (T1a–b, N0, M0) and borderline fitness
Offer more extensive surgery (bronchoangioplastic surgery, bilobectomy, pneumonectomy) only when needed to obtain clear margins
Perform hilar and mediastinal lymph node sampling or *en bloc* resection for all patients undergoing surgery with curative intent
For T3 NSCLC with chest wall involvement, aim for complete resection by extrapleural or *en bloc* chest wall resection
For people with operable stage IIIA–N2 NSCLC who can have surgery and are well enough for multimodality therapy, consider chemoradiotherapy with surgery

Figure 60.20 A thoracic surgeon performing robotically assisted thoracic (RATS) lung resection remotely from an operating console.

Choice of lung resection

Segmentectomy and wedge resection

Segmentectomy and wedge resections are performed in patients with small tumours (1–2 cm) that are predominantly ground glass, not solid (lepidic) and with borderline fitness, through thoracotomy or increasingly by VATS or RATS. Each lobe of the lung has segments, which allows anatomical dissection and ligation of the segmental pulmonary artery, vein and bronchus (segmentectomy) (***Figure 60.2***) or non-anatomical excision can be performed (wedge resection) combined with removal of regional lymph nodes.

Lobectomy

Lobectomy remains the treatment of choice for patients with early-stage lung cancer. The surgery can be performed via thoracotomy or VATS. Following dissection of the fissure and hilar structures, the branches of the pulmonary artery and veins to the lobe are isolated and ligated. The bronchus is usually stapled but can be sewn.

The patient does not routinely need intensive care and postoperative ventilation is best avoided. The 30-day mortality rate is 1–2%, with morbidity such as chest infection or cardiac arrhythmia at around 10%. The average length of stay is around 5–7 days.

Pneumonectomy

Pneumonectomy is removal of a whole lung and has a higher mortality rate (5–8%). As such the number of pneumonectomies performed in the UK has fallen and now makes up less than 5% of lung cancer surgery. The surgeon must be satisfied that the patient is fit to tolerate this procedure from the preoperative work-up. This procedure is reserved for either centrally placed tumours involving the main bronchus or those that straddle the fissure.

Bronchoplastic lung resections

Increasingly, owing to the associated complications and higher mortality of a pneumonectomy, preservation of lung tissue is being considered but without compromise of the surgical resection margins. Sleeve lung resections involve removing a central tumour that is invading a major bronchus, such as the LMB or RMB, together with the lobe of the lung involved,

TABLE 60.7 UK National Institute for Health and Care Excellence (NICE) recommendations for assessing fitness for treatment with curative intent (including surgery).

Perioperative mortality	Consider global risk score, such as Thoracoscore	Ensure patient is aware of risk before consenting
Cardiovascular function	Assess risk factors and cardiac functional capacity	Avoid surgery within 30 days of MI
		Optimise primary cardiac treatment and begin secondary cardiac prophylaxis as soon as possible
		Offer surgery if two or fewer risk factors and good cardiac functional capacity
		Seek cardiology review if active cardiac condition, three or more risk factors or poor cardiac functional capacity
		Consider revascularisation before surgery in stable angina
		Continue anti-ischaemic treatment in perioperative period. Discuss perioperative platelet treatment if patient has a coronary stent
Lung function	Perform spirometry, measure TLCO if disproportionate breathlessness or other lung pathology, perform segment count and assess exercise tolerance	Offer surgery if normal FEV_1 and good exercise tolerance or FEV_1 or TLCO below 30% and patient accepts the risks of dyspnoea
	Consider shuttle walk testing (cut-off 400 m) and cardiopulmonary exercise testing (cut-off 15 mL/kg/minute) if moderate to high risk of postoperative dyspnoea	Offer radiotherapy with curative intent if lung function poor but patient is otherwise suitable for radiotherapy with curative intent and volume of irradiated lung is small

FEV_1, forced expiratory volume in 1 s; MI, myocardial infarction; TLCO, transfer factor for carbon monoxide.
From NICE Clinical Guideline 122, available from: www.nice.org.uk/guidance/ng122.

with reanastomosis of the cut major bronchus to the remaining lobar bronchus.

Complications of lung resection

- **Bleeding**. Bleeding should be avoidable by the use of a careful surgical technique but may be severe in the presence of dense adhesions.
- **Respiratory infection**. Many of these patients are ex-smokers and therefore basal collapse and hypoxaemia are common postoperatively.
- **Persistent air leak**. Chest drains are placed at the time of surgery to deal with the air leak. Rarely, the air leak persists and the remaining lung does not expand. Re-thoracotomy may then be necessary to seal the leak.
- **Bronchopleural fistula**. This is a serious complication. Following pneumonectomy, the space left behind is initially filled with air. This is slowly reabsorbed and the space fills with tissue fluid. The fluid level rises until the air is finally reabsorbed (*Figure 60.21*). Dehiscence of the bronchial stump leads to the development of a bronchopleural fistula and the fluid in the space (which is almost inevitably infected) is expectorated in large quantities. This complication has a high morbidity and mortality rate. The patient is nursed sitting up and turned so that the affected space is dependent; this is to prevent infected fluid from entering the remaining lung while arrangements are made to site a pleural drain. This should be connected to an underwater seal but not suction. Bronchopleural fistulae are unlikely to resolve spontaneously and management is highly specialised.

Postoperative care

Enhanced recovery after surgery (ERAS) is a strategy that seeks to reduce patients' perioperative stress response, thereby reducing potential complications, decreasing hospital length of stay and enabling patients to return more quickly to their baseline functional status. These principles have been applied to patients having lung cancer surgery. Postoperatively, patients have limited respiratory reserve following lung resection, so infection and fluid overload are to be avoided. Once air leaks have settled, the drains are removed. Mobilisation, breathing exercises and regular physiotherapy are begun as soon as the patient's condition permits.

Postoperative pain

It is important to deal with postsurgical pain effectively so that a normal breathing pattern and gas exchange are achieved in the early postoperative period. Four strategies are routinely used in combination:

1. paravertebral/extrapleural or epidural catheter-delivered local anaesthetic;
2. intercostal nerve blocks;
3. PCA with intravenous boluses of opiates;
4. background oral analgesia with paracetamol and/or non-steroidal anti-inflammatory drugs.

Long-term postsurgical pain can be reduced by careful attention to detail during the operation. Sources of avoidable chronic pain include rib fracture and the entrapment of intercostal nerves during wound closure.

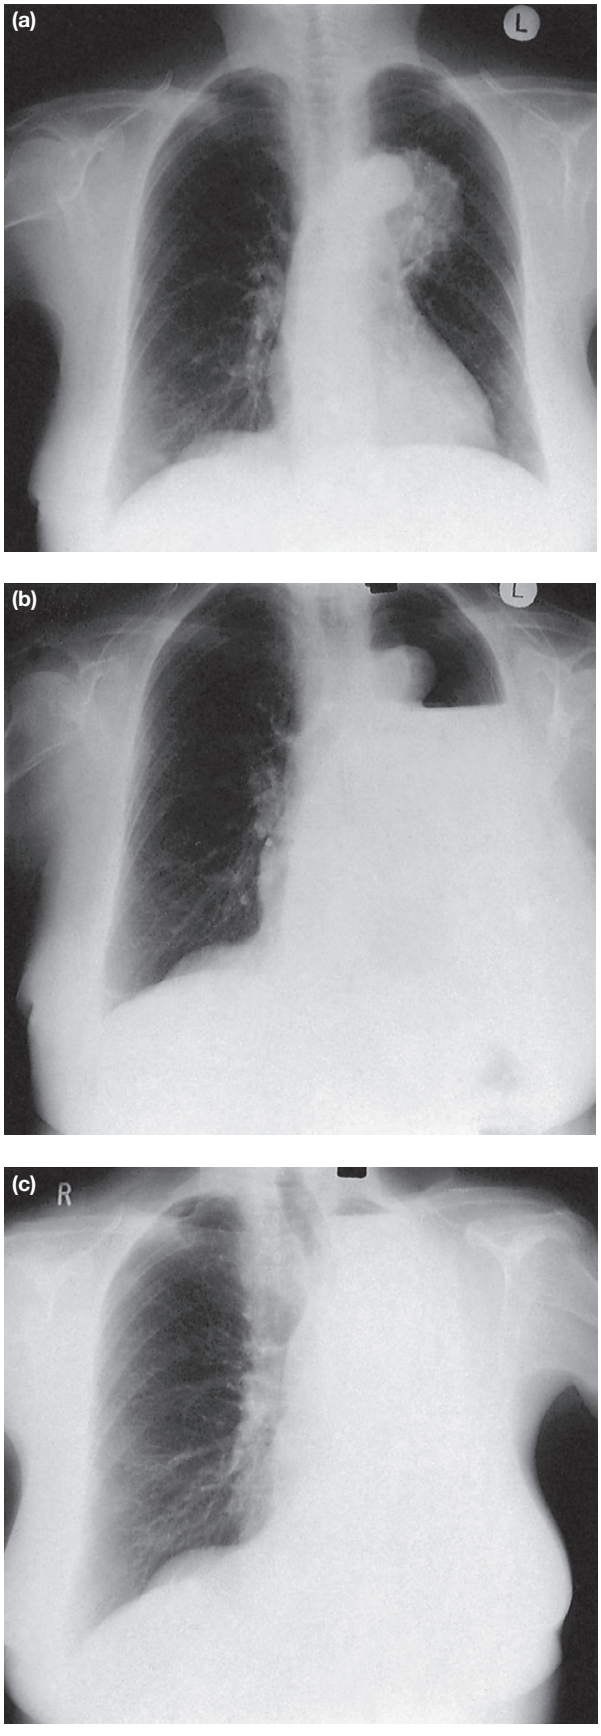

Figure 60.21 Chest radiographs (a) pre- and (b) post-pneumonectomy, with rising fluid level (c) in the left haemothorax.

LUNG METASTASES

For all malignancies, the lung is the most common site of metastases that often develop through haematogenous spread. The presence of metastases is regarded as a sign of advanced disease and few curative treatment options exist; however, surgical resection of lung metastases may result in a survival advantage, particularly with metastases from solid tumours such as colorectal cancer, though the evidence still remains uncertain. The selection criteria often used when considering lung metastasectomy include control of primary tumour; no evidence of metastases outside the lung; possibility of complete resection utilising lung-sparing techniques; and acceptable operative risks with adequate pulmonary function.

Various approaches can be considered, though VATS is increasingly favoured over thoracotomy owing to reduced postoperative pain and length of stay, and therefore speedier recovery. The disadvantage of VATS is the inability to palpate and evaluate the lung in its entirety to locate other nodules deeper within the lung parenchyma, particularly those not identified on prior CT imaging. The main principle when resecting lung metastases is to utilise lung-sparing techniques as much as possible, e.g. wedge resections rather than lobectomy, because it is likely that later reoperations to resect new metastases may be necessary.

Long-term outcome depends on the primary tumour type, with germ cell tumours having the best outcome. Patients with epithelial tumours (carcinomas) generally have a 30–40% 5-year survival, as reported in several retrospective series.

BENIGN LUNG TUMOURS

Benign tumours of the lung are uncommon and account for fewer than 15% of solitary lesions seen on chest radiographs. A peripheral tumour usually causes no symptoms until it is large; a central tumour may present with haemoptysis and signs of bronchial obstruction while still small. A tumour is likely to be benign if it has not increased in size on chest radiographs for more than 2 years or it has some degree of calcification; however, a tissue diagnosis is usually pursued.

Most benign nodules are granulomas (tuberculosis or histoplasmosis). The most common benign tumour is a hamartoma, a developmental abnormality containing mesothelial and endothelial elements. Diagnosis (and definitive treatment) is achieved by excision of the lesion. Any of the mesodermal elements of the lung may form a mesodermal tumour (chondroma, lipoma, leiomyoma). Deposits of amyloid may have a similar radiographic appearance to a nodule (pseudotumour).

THE MEDIASTINUM
